THE ANALYS

THE ORGAN OF THE

Society of Public Analysts and
Analytical Chemists

21. NOV. 19

A MONTHLY JOURNAL DEVOTED TO THE ADVANCEME
OF ANALYTICAL CHEMISTRY

Publication Committee:

E. W. VOELCKER, F.I.C. (PRESIDENT).

EDWARD J. BEVAN, F.I.C.
BERTRAM BLOUNT, F.I.C.
A. CHASTON CHAPMAN, F.I.C.
CECIL H. CRIBB, B.Sc., F.I.C.
BERNARD DYER, D.Sc., F.I.C.
THOMAS FAIRLEY, F.I.C.

OTTO HEHNER, F.I.C.
J. T. HEWITT, D.Sc., PH.D., M
F. G. HOPKINS, M.A., M.B., D.S
ARTHUR R. LING, F.I.C.
P. A. ELLIS RICHARDS, F.I.C.
H. DROOP RICHMOND, F.I.C.

J. AUGUSTUS VOELCKER, PH.D., F.I.C.

Editor: JULIAN L. BAKER, F.I.C.

Abstractors:

J. F. BRIGGS, A.C.G.I.
F. E. HULTON, A.I.C.
C. JONES, A.C.G.I., F.I.C.

C. A. MITCHELL, M.A., F.I.C.
O. E. MOTT, PH.D.
W. P. SKERTCHLY, F.I.C.

A. R. TANKARD, F.I.C.

VOL. XXXVI.

1911.

TRADE AGENTS:
SIMPKIN, MARSHALL, HAMILTON, KENT & CO., LTD.,
2, 4, 6, 8, ORANGE STREET, LONDON, S.W.
1912

INDEX TO VOLUME XXXVI.

INDEX OF NAMES.

ABDERHALDEN, E., *and* Meyer, C., Detection of Active Pepsin in the Intestines by Means of Elastin, 551

————————, *and* Schmidt, H., Use of Triketohydrindene Hydrate for the Detection of Proteins and their Derivatives, 514

Abelin, J., New Method for the Detection of Salvarsan, 452

Achalme, P., *and* Bresson, M., Method for Ascertaining whether a Liquid Contains One or More Enzymes, 110

————————————, Influence of the Viscosity on the Action of Invertase According to the Concentration of Saccharose, 416

Adams, A. B., Detection of the Substitution of Spirit for Aged Whisky, 546

———, L. H., *and* Johnston, J., Phenomenon of Occlusion in Precipitates of Barium Sulphate, and its Relation to the Exact Determination of Sulphates, 426

Adan, R., Researches on the Quantitative Analysis of Pentoses and Pentosans, and its Practical Applications, 293

Ageno, F., *and* Guicciardini, N., Estimation of Arsenic and Iron Salts in Mineral Waters, 466

Agulhon, H., Colorimetric Test for Alcohol in the Presence of Acetone, 592

Albrecht, A., *and* Müller, F., Estimation of Napthalene in Crude Coal-Gas, 510

Alexander, P., Caoutchouc Nitrosite and its Analytical Application, 287

Allen, I. C., Specifications and Sampling of Fuel Oil and Natural Gas, 555

Allesandri, P. E., Là Chimica delle Sostanze Alimentari, *Review*, 40

Amberger, C., Detection of Adulteration of Butter by Ewer's Method, 404

American Chemical Society, Analysis of Fats and Oils, 164

Andouard, —, *and* Bussard, L., Adulteration of Pepper Corns, 349

Andrews, A. E., The Determination of Codeine in Opium, 489

Andriska, V., *and* Liebermann, L. von, Method of Estimating the Quality of Wheaten Flour, 543

Anelli, G., Estimation of Sulphur by the Method of Carius, 296

Angerhausen, J., *and* Nottbohm, F. E., Wendler's Method for the Estimation of Fat in Milk, 14

Archbutt, L., Characteristics of Neutralised Olive-Residuum Oil, 116

Arnold, V., Colour Reaction of Proteins with Sodium Nitroprusside, 235

Arragon, C., New Constant in the Analysis of Pepper, 147

Ashley, H. E., *and* Emley, W. E., Errors in Determining Sizes of Mineral Grains and the Use of Surface Factors, 182

Atack, F. W., *and* Knecht, E., A New Method for the Volumetric Estimation of Molybdenum, 98

Atkinson, F. C., *and* McCandless, J. M., Bacteriological Method of Estimating Available Organic Nitrogen, 219

————, H. M., Modified Separatory Funnel and Washer for Heavy Liquids, 89

Auger, V., *and* Gabillon, M., New Method of Estimating Sulphuric Acid and Sulphates, 178

Autenrieth, W., *and* Funk, A., Colorimetric Estimation of Lactose in Urine and in Milk, 592
——, *and* Müller, G., Colorimetric Estimation of Sugar, Creatine, and Creatinine, in Urine, 591
Auzies, J. A. A., Analysis of a Substance Containing Carbon, Hydrogen, Oxygen, Nitrogen, and Sulphur, 553
——, Analysis of a Substance Containing Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, Chlorine, Bromine, and Iodine, 553
——, New Method of Elementary Analysis of Organic Substances Containing Carbon, Hydrogen, Oxygen, and Nitrogen, 553

Bach, W., Oil from Seeds of the Ash-Tree, 357
Bäcke, A. (*with* A. Wiborg *and* E. Röer), Analysis of Sweetened Condensed Milk, 138
Bacon, R. F., Detection and Estimation of Methyl and Ethyl Alcohols and Formic Acid, 507
——, Philippine Terpenes and Essential Oils, IV., 15
——, W., Note on the Gravimetric Estimation of Phosphorus in Milk, 583
Bailey, H. S., Electrically-Heated Vacuum Fractionation Apparatus, 253
Baker. J. L., *and* Day, F. E., The Chemical Behaviour and Preservative Action of Sulphites in Beer, 495
Bang, I., Estimation of Phosphoric Acid by Neumann's Method, 525
——, Preparation of Menthylglycuronic Acid, 505
——, Preparation of the Copper Solution used in Bang's Sugar Titration Method, 501
Barbier, P., Separation of Alumina from Ferric Oxide, 82
Bardach, B., An Inner Anhydride Reaction of Proteins, 514
——, Reaction of Aromatic Inner Anhydrides Depending on their Influence on the Crystalline Form of Iodoform, 458
——, *and* Silberstein, S., Polarimetric Estimation of Sugar by the Method of Jolles, 361
Barker, B. T. P., *and* Gimingham, C. T., Fungicidal Action of Bordeaux Mixtures, 351
Barrett, W. H., *and* Hartley, H., Determination of the Density of Liquids, 439
Barthel, C., Comparison of the Reductase Test with Other Hygienic Tests for Mi 346
Baskerville, C., *and* Hamor, W. A., Examination of Ether for Anæsthetic and Analytical Purposes, 407
——, *and* Stevenson, R., Analytical Examination of Commercial Oxygen, 469
——, Chemistry of Anæsthetics. III. Nitrous Oxide, 503
——, Oxidation of Ferrous Salts, 467
Batey, J. P., Notes on the Formation of Hypoiodites and their Action on Sodium Thiosulphate—A Source of Error in Certain Iodine Titrations, 132

INDEX OF SUBJECTS.

ABSINTHE and its Imitations, Examination of, 272
————, Commercial, Analysis of, 12
————, Thujone in, Detection of, 495
ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS, 12, 64, 103, 142, 214, 272, 342, 404, 450, 495, 541, 584
Accuracy with which Proteins can be Estimated in Milk by Aldehyde Titration, the Degree of, 9
Acetaldehyde, Quantitative Estimation of, by Means of Pyrrol, 157
Acetic Anhydride, Small Quantities of, in Acetic Acid, Detection and Estimation of, 417
Acetin Process for Glycerol Determination, Report on, 316
Acetone, Alcohol in the Presence of, Colorimetric Test for, 592
————, in Animal Fluids, the Estimation of, Method for, 548
Acetyl Chloride and Acetone, the Action of, on the Mixed Chlorides, Separation and Estimation of Barium in Presence of Calcium and Magnesium by, 426
Acid, Acetic, Small Quantities of Acetic Anhydride in, Detection and Estimation of, 417
——, and Saponification Values in Wax, Estimation of, Simplified Process for, 355
——, Arsenic, in Presence of Arsenious Acid, Detection and Estimation of, by Means of Magnesia Mixture, 30
——, Benzoic, Estimation of, 584
——, ————, in Flesh and Fats, Detection of, 12
——, ————, in Foods, etc., Detection of, 584
——, Boric, Decomposition of Silicates by Fusion with, as Applied to Qualitative Analysis, 371
—— Citrate in Certain Organic Liquids, the Estimation of Quinine as the, 396
——, Citric, in Milk, Estimation of, 105
——, Dihydroxystearic, in Good and Poor Soils, 504
——, Diphenylamine-Sulphuric, Test, Estimation of Nitrates in Milk by Means of the, 587
——, Dimethylaminobenzene-azo-benzene Sulphonic, Use of, as a Reagent, in Microchemistry 232
——, Formic, and Methyl and Ethyl Alcohols, Detection and Estimation of, 507
——, ————, Chemical Differentiation between Fermentation Vinegars and "Vinegar Essence," Particularly with Respect to the Amount of, 455
——, ————, Estimation of, 355
——, ————, in Foods, Estimation of, 103, 496
——, Free, and Basic Alumina, in Aluminium Salts, Estimation of, 236
——, Glycuronic, Small Quantities of, Detection of, 596
——, Hippuric, as a Cause of the Failure of the Spectroscopic Test for Hæmoglobin in Urine, 417
——, Hydrated Silicic, in Clay, Determination of, 85
——, Hydrochloric, Chlorine in, Electrolytic Determination of, with the Use of a Silver Anode and Mercury Cathode, 33
——, Hydrofluoric, Preservation of Fruit Juices with, 218
——, Hypophosphorous, Estimation of Copper by Means of, 302
——, Iodic, Detection and Estimation of Thorium by Means of. (Separation of Thorium from Scandium), 436
——, Lactic, Analysis of, 556
——, ————, the Anhydride of, 235
——, Malic, the Determination of, Polarimetric Method for, and its Application in Cane and Maple Products, 498

Acid, Menthylglycuronic, Preparation of, 505
——, Nitric, and Nitrous Acid, in Water, Detection and Estimation of, 433
——, ——, Decomposition of the Bromide by, Estimation of Rubber as Tetrabromide, 361
——, ——, in Nitrocellulose, Nitroglycerol, and Other Compounds, Volumetric Determination of, 34
——, ——, in Vegetable Products, Quantitative Estimation of, 163
——, Nitrous, and Nitric Acid, in Water, Detection and Estimation of, 433
——, Oleic, Separation of, from Stearic and Palmitic Acids, 23
——, Pertitanic, the Influence of, on the Estimation of Iron in Minerals, 304
——, Phosphoric, as Magnesium-Ammonium Phosphate, Estimation of, 434
——, ————, Colorimetric Estimation of, 525
——, ————, Colorimetric Method of Estimating, 307
——, ————, Estimation of, by Neumann's Method, 525
——, ————, in Milk, Distribution of, 345
——, ————, Loss of, on Incineration in Presence of Organic Matter, Causes of, 360
——, ————, Magnesia Method for Estimation of, Criticism of, 176
——, ————, Reverted, the Estimation of, Improved, Hollemann's Method for, 605
——, ————, Soluble in 2 per Cent. Citric Acid Solution, Volumetric Estimation of, 308
——, ————, Volumetric Estimation of, 472
——, Phosphotungstic, Precipitation of Proteins, 461
——, Racemic, as a Reagent (Precipitant of Calcium and Strontium), 365
——, Salicylic, a Test for, Kobert's Reagent as, 540
——, ————, Action of, on Metallic Acids, 567
——, ————, and Phenol, Sensitive Test for, 295
——, ————, Detection of, 463
——, ————, in Fruit Juices, Estimation of, 411
——, Silicotungstic, Estimation of Aconitine by, 142
——, Sulphuric, and Sulphates, New Method of Estimating, 178
——, ————, and Zinc, Separation of, 607
——, Sulphurous, Complex Compounds of, Sulphurous Acid, and Sulphites, the Antiseptic Properties of, Experiments on, 285
——, ————, in Glucose Syrup, Estimation of, 543
——, ————, in White Wines, 351
——, Tartaric, Estimation of, 148
——, ————, in Apples, Pears, Cider, and Perry, Estimation of, 545
——, ————, Total, Estimation of, 148
——, ————, ——, ————, by Goldenberg's Method, 81
——, Telluric, Alkalimetric Estimation of, and Gravimetric Estimation of Tellurium, 248
——, Vanadic, Precipitation of, as Silver Vanadate, and Estimation of Phosphoric and Vanadic Acids in Presence of Each Other, 35
Acidity in Hydrogen Peroxide Solutions, Estimation of, 82
——— of Fats and Oils, Particularly Lubricating Oils, Estimation of, 290
——— of Tan Liquors, the Estimation of, Electrometric Method for, 121; Part II., 515
Acids, Amino-, and Peptones or Peptides, Differentiation between, 593
——, Fatty, Free, Estimation of, in the Presence of Soaps of the Alkalis and Alkaline Earths, 595
——, ——, in Soaps, Estimation of, 355
——, ——, Liquid, Separation of Solid from, 22, 114
——, ——, Soluble and Volatile, Loss of, during the Ageing of Butter, 64
——, ——, Total, in Fat, Oils, and Soaps, Estimation of, 115
——, ——, ——, in Soap, 20
——, Free Fatty, in Fats, Estimation of, 355

Acids, in Sugar-Cane Juice, Determination of, 594
——, Metallic, Action of Salicylic Acid on, 567
——, Nitric and Nitrous, the Diphenylamine Test for, Modification of, 370
——, Palmitic and Stearic, Separation of Oleic Acid from, 23
——, Phosphoric and Vanadic, in Presence of Each Other, Estimation of, and Precipitation of Vanadic Acid as Silver Vanadate, 35
—— Suitable for Use as Standards in Acidimetry, 25
 the Fatty, Effect of the Glycerol Method of Saponification upon, 425
 Total Fatty, in Soap, Estimation of, 20
 Volatile Fatty, in Fæces, Quantitative Estimation of, 505
 ———, in Wine, Estimation of, 502
 ———, of Honey, 277
Aconite, Assay of, 450
Aconitine, Estimation of, by Silicotungstic Acid, 142
Adrenaline and Allied Bases, Colour Reactions of, 18
Adulterant of African Sandal-Wood Oil, 146
Adulteration of Butter, Detection of, by Ewer's Method, 404
———— of Linseed Cakes and Linseed Meals in Belgium, 218
———— of Pepper Corns, 349
————, Turpentine, Detection of, 413
Affinity Values, Indicators for Determining, Use of, 569
Africa, German East, and Togo, Leguminous Plants Grown in, Composition of the Seeds of, 345
African Sandal-Wood Oil, Adulterant of, 146
Age of Blood-Stains, Estimation of, 455
Aged Whisky, the Substitution of Spirit for, Detection of, 546
Ageing of Butter, Loss of Soluble and Volatile Fatty Acids during, 64
Agitation, Rapid Electro-Analysis with, by Means of a Current of Gas, 600
Air, Oxygen in, Volumetric Estimation of, 569
—, Ozonised, a Constant Current of, Laboratory Apparatus for the Production of, 479
Albumin, in Urine, etc., Heller's Ring Test for the Detection of, Modification of, 152
——————, the Estimation of, Rapid Gravimetric Method for, 551
Albumins, Egg Serum, and Milk, Coagulating-Points of, and of Serum Globulin, in Ammonium Sulphate Solutions, 416
Alcohol, Ether and Benzene in, Estimation of, 19
——— -Ether, in Mineral Lubricating Oils, Proportion of Asphalt Insoluble in, 418
———, Ethyl, in the Presence of Methyl-Alcohol, Detection of, 18
———, in the Presence of Acetone, Colorimetric Test for, 592
———, Methyl, Detection of Ethyl Alcohol in the Presence of, 18
———, Propyl, Use of. Estimation of the Saponification Value of Oils, Fats, and Waxes, 290
——— -Soluble Constituents of Litmus, 25
Alcoholic Solutions, Iodine in, Estimation of, 235
Alcohols, Ethyl and Methyl, and Formic Acid, Detection and Estimation of, 507
———, Higher, Occurring in Jamaica Rum, 411
Aldehyde, *d*- Perilla, and Myrtenal, the Occurrence of, in Nature: Essential Oil of "False Camphor-Wood," 289
———— Titration, the Degree of Accuracy with which Proteins can be Estimated in Milk by, 9
Aldehydes, Aromatic, Colour Reactions of, and their Applicability in the Analysis of Spirits, 273
Algæ, Marine, and Products Derived from them, Relative Proportions of Arsenic in, 218
Aliphatic Amino Groups, Quantitative Estimation of, and its Application in the Chemistry of the Proteins, Urine, and Enzymes, 17

Alkali Carbonates, in Presence of Alkali Hydroxides or Bicarbonates, Titration of, 362
——— ———, the Use of, in Cheese Manufacture, Detection of, 218
———, Iodine, and Silver, Volumetric Solutions of, Use of Sulphur Dioxide in Checking Strengths of, 248
——— -Metal Cyanides, Sulphides in, Estimation of, 436
——— Metals, Estimation of, Elimination of Ammonium Salts Prior to, 30
———, "Titratable," in Blood, the Estimation of, New Indicator for, 415
Alkalimetric Estimation of Telluric Acid, and Gravimetric Estimation of Tellurium, 248
Alkalimetry, Standard in, Sodium Thiosulphate as, 435
Alkaline Earths and Alkalis, Soaps of the, Estimation of Free Fatty Acids in the Presence of, 595
——— Potassium Iodide Solution, Estimation of Ozone by Means of, 525
Alkaloids in Belladonna Extracts, Titration of. Estimation of Atropine, 142
Allelotropic Mixtures, the Quantitative Estimation of Enols in, Colorimetric Method for, 554
Alloys, Aluminium and Aluminium, Analysis of, 425
———, Antimony in, Volumetric Method for, 299
——— Containing Antimony and Tin, Lead in, Estimation of, 367
———, Ferrotitanium, Containing Much Silicon, Analysis of, 373
———, Iron, Estimation of Silicon in Vanadium and Molybdenum, and in their, 311
———, Other, and German Silver, the Separation of Nickel and Zinc in, Method for, 524
———, Silicon, Dissolving, 178
Almond and Apricot Kernel Oils, Note on, 263
Alumina, Basic, and Free Acid in Aluminium Salts, Estimation of, 236
———, Separation of, from Ferric Oxide, 82
Aluminium Alloys, and Aluminium, Analysis of, 425
———, Amalgamated, in Chemical Analysis, Some Uses of, 516
——— and Chromium in Ferro-Vanadium, Estimation of, 123
———, Chromium, and Iron, Precipitation of, by Ammonium Nitrite, 559
——— Hydroxide in Granular Form, Precipitation of, 299
———, Microchemical Test for, by Means of Caesium Chloride, 362
——— Salts, Free Acid and Basic Alumina in, Estimation of, 236
———, Separation of, from Beryllium, 426
———, the Separation of Iron from, and New Test for Ferrous Oxide, 373
("Amang"), Rare Earth-Containing Sands, from Malay States, 523
Amino-Acids and Peptones or Peptides, Differentiation between, 593
——— Compounds and Urine, Amino Groups in, Estimation of, and a Method for the Analysis of Proteins, 457
——— Groups, Aliphatic, Quantitative Estimation of, and its Application in the Chemistry of the Proteins, Urine, and Enzymes, 17
Ammonia and Pyridine, Separation and Estimation of, 508
——— Method, Estimation of Formaldehyde by the, 421
Ammoniacal Solution of its Oxalate, Estimation of Silver by Electrolysis of an, 308
——— Solutions, Precipitation of Zinc, Manganese, Cobalt, Nickel, Copper, and Cadmium from, by Means of Sodium Carbonate and Trimethylphenylammonium Carbonate, 599
Ammonium Nitrite, Precipitation of Aluminium, Chromium, and Iron by, 559
——— Salts, Elimination of, Prior to Estimation of Alkali Metals, 30
——— Sulphate, Estimation of Sulphur in Coal-Gas and of, 309
——— ——— Solutions, Coagulating-Points of Egg Serum and Milk Albumins, and of Serum Globulin, in, 416
Amylolytic Enzymes in Fæces, Detection of, 74

Anasthesia, Chloroform, Composition of the Gases of the Blood in, 154
Anæsthetic and Analytical Purposes, Examination of Ether for, 407
Anæsthetics, Certain Other, and Cocaine, Tests for, 2
————, Chemistry of. III. Nitrous Oxide, 503
Analysis, Capillary, 251
———, Chemical, New Method of, 376
———, Electro, 565
———, Elementary, 516
———, Qualitative, without the Use of Hydrogen Sulphide, 517
———, Toxicological, Method of Destroying Organic Matter by Means of Bromine, Particularly Applicable to, 592
Analytical Constants of Shellac, Lac Resin, and Lac-Wax, 119
———— Methods for the Estimation of Caoutchouc, Critical Investigation of, 158
Anhydride, Acetic, in Acetic Acid, Small Quantities of, Detection and Estimation of, 417
————, the, of Lactic Acid, 235
————, Reaction, an Inner, of Proteins, 514
Anhydrides, Aromatic Inner, Reaction of, Depending on their Influence on the Crystalline Form of Iodoform, 458
Anhydrous Chlorides, the Preparation of, General Method for, and its Application in Chemical Analysis, 31
Animal and Vegetable Substances, Ash in, Estimation of, 237
——— Fluids, Acetone in, Method for the Estimation of, 548
——— Organs or Plants, the Ash of, Estimation of Small Quantities of Manganese, Especially in, 369
——— Organs, Oxidising Substances in, Colorimetric Detection of, 152
——— Sizing in Paper, Detection of, Differentiation of Gelatin and Casein, 290
——— Tissues, Indophenol Oxydase of, Estimation of, 550
——— ———, Inorganic Phosphorus in, Estimation of, 284
Annual Address of the President, 43
Anode, Silver, and Mercury Cathode, Electrolytic Determination of Chlorine in Hydrochloric Acid with the Use of, 33
——, Stationary and Gauze Cathode, Rapid Determination of Nickel and Cobalt by Means of, 307
——, ————————, ———————— Silver and Cadmium by Means of, 473
——, ————, —— Mercury Cathode, Rapid Determinations and Separations by Means of, 83
Anthracite, Calorific Value of, Accurate Technical Estimation of, 518
————, Practical Value of Calorimetry in Testing, 562
Antimony, a Solid Hydride of, Attempts to Prepare, 300
———— and Arsenic Compounds, Germicidal Action of, on *Bacillus Typhosus*, 282
in Copper, Estimation of, 171
– and Tin, Alloys Containing, Estimation of Lead in, 367
– in Alloys, Volumetric Method for, 299
–, Small Quantities of, the Detection and Estimation of, Note on, 101
Antiseptic Properties of Hops, Valuation of, 65
———————— Sulphurous Acid, Sulphites, and Complex Compounds of Sulphurous Acid, Experiments on, 285
Apparatus, a New Extraction, 529
APPARATUS, ABSTRACTS, 36, 86, 126, 180, 249, 312, 376, 437, 477, 528, 568, 607
Apparatus and Methods for Sampling and Analysis of Furnace Gases, 530
————, Extraction, 609

Apparatus, Extraction, and Condenser, 378
——— for Electrolytic Estimations with Mercury Cathode, 529
———— Exact Gas Analysis, 379
———— Filtering Hygroscopic Substances or those Affected by Air, 87
———— Flue Gas Analysis, 440
———— Measuring Radioactivity, 380
———— Precipitating, Filtering, and Drying in an Inert Gas, 313
———— Rapid Electro-Analytical Determination of Metals, 181
———— Storing and Measuring Poisonous, Hygroscopic, or Volatile Liquids, 88
———— the Estimation of the Hexabromide Value of Oils, 607
—————— Melting-Point of Fats, 569
———— the Maintenance of Constant Pressures Above and Below the Atmospheric Pressure, Application to Fractional Distillation, 441
———, Laboratory, for the Production of a Constant Current of Ozonised Air, 479
———, Microdistillation, 37
———, Sand's, Electrolytic Estimation of Copper and Zinc, Using, 182
———, Vacuum Fractionation, Electrically-Heated, 253
Apples, Pears, Cider, and Perry, Tartaric Acid in, Estimation of, 545
Apricot Kernel and Almond Oils, Note on, 263
—— Kernels, Sweet, Composition of, 450
Aqueous Liquids, Automatic Extraction of, by Means of Specifically Lighter Solvents, 87
Aromatic Inner Anhydrides, Reaction of, Depending on their Influence on the Crystalline Form of Iodoform, 458
Arsacetin and Atoxyl, the Estimation of Arsenic in, Simplified Method for, 273
Arsenate, Lead, in the Products of Vines Treated with Arsenical Washes, Proportion of, 301
Arsenic, Absorption of, by Sugar Beets, 549
—— Acid, in Presence of Arsenious Acid, Detection and Estimation of, by Means of Magnesia Mixture, 30
—— and Antimony Compounds, Germicidal Action of, on *Bacillus Typhosus*, 282
———— in Copper, Estimation of, 171
—— and Iron Salts in Mineral Waters, Estimation of, 466
—— in Insecticides, Estimation of, 237
—— in Marine Algæ, and Products Derived from them, Relative Proportions of, 218
——, in Pyrites, Estimation of, 362
——, in Schweinfurt Green, Estimation of, 363
——, the Solid Hydride of, Detection of, 300
——, Vanadium in Presence of, Estimation of, and Analysis of Ferro-Vanadium, 437
Arsenical Washes, Vines Treated with, Proportion of Lead Arsenate in the Products of, 301
Arsenious Acid, Arsenic Acid in Presence of Detection and Estimation of, by Means of Magnesia Mixture, 30
Ash, in Sugar and Syrups, Estimation of, by the Determination of Electrical Conductivity, Estimation of, 298
——, in Vegetable and Animal Substances, Estimation of, 237
—— of Plants or of Animal Organs, Estimation of Small Quantities of Manganese, Especially in, 369
—— Tree, Oil from Seeds of the, 357
Asphalt Insoluble in Alcohol-Ether in Mineral Lubricating Oils, Proportion of, 418
——, Petroleum, Technical Analysis of, 294
Asphaltum, Examination of, 225

Asphaltum from Mexican Petroleum, 353
Association of Official Agricultural Chemists, the Proceedings of, Extracts from, 186
Atmosphere, the Degree of Vitiation of, Method of Measuring, 363
Atmospheric Pressure, the Maintenance of Constant Pressures Above and Below, Apparatus for, Application to Fractional Distillation, 441
Atomic Weights, International, 1911, 1
Atoxyl and Arsacetin, the Estimation of Arsenic in, Simplified Method for, 273
Atropine, Estimation of. Titration of the Alkaloids in Belladonna Extracts, 142
Automatic Extraction of Aqueous Liquids by Means of Specifically Lighter Solvents, 87
——— Inflammable Gas and Vapour Detector, New Type of, 528

Bacilli, Typhoid, in River Water, Vitality of, with Special Reference to the Question of Storage, 185
Bacillus, the Bulgarian, Note on, 221
——— *Typhosus*, Germicidal Action of Arsenic and Antimony Compounds on, 282
"Backa-Margarine," the Manufacture of, the Poisonous "Cardamon" (Maratti) Fat Employed in, Nature of, 542
Bacteriological Examination of Honey, 505
——— Investigation of Soil, 219
——— Method of Estimating Available Organic Nitrogen, 219
——— Study of Honey, 353
BACTERIOLOGICAL, PHYSIOLOGICAL, ETC., ABSTRACTS, 16, 69, 109, 152, 218, 282, 351, 415, 455, 503 548, 590
Bacteriology of Water: Its Present Position, 285
Baking-Powder and Self-Raising Flour, the Presence of Calcium Sulphate in, Report on, 255
Balsams and Essential Oils, the Examination of, Use of Miscibility Curves in, 556
Bananas, Ripe and Unripe, Composition of, 274, 541
Bang's Sugar Titration Method, the Copper Solution Used in, Preparation of, 501
Barium, in Presence of Calcium and Magnesium, Separation and Estimation of, by the Action of Acetyl Chloride and Acetone on the Mixed Chlorides, 426
———, Strontium, and Calcium, Quantitative Separation of, 364
——— Sulphate, Precipitates of, Phenomenon of Occlusion in, and its Relation to the Exact Determination of Sulphate, 426
Bark, Seychelles Cinnamon, 217
Barley, Germinating, Hordenine in, Estimation of, 162
Baroda, India, Lac Resin from, 171
Bases, Pyridine, Nicotine in the Presence of, Estimation of, 452
Basic Alumina and Free Acid in Aluminium Salts, Estimation of, 236
——— Constituents, Soluble, of the Mushroom 347
——— Slag, Phosphoric Oxide in, Citrate-Solubility of, 32
Bath, Constant-Temperature, for Use at Temperatures both Above and Below that of the Room, 249
Baths, Creosote (Dips), and Creosote Oil, the Dimethyl Sulphate Test for, 585
Bean Oil, Soya, 358
Beef and Yeast Extracts of Known Origin, Comparison of, 64
———, Australian, on a Parasite Condition (Onchocerciasis) Met with in, 129
Beer, Carbon Dioxide in, Solubility of, 404
———, Sulphites in, the Chemical Behaviour and Preservative Action of, 495
Beeswax, Analysis of, with Special Reference to East Indian and the So-Called China Beeswax, 554
———, Paraffin, Spermaceti, etc., Fat in, Detection of, 496

Beet Sugar Factory Products, Determination of Sucrose in, by Clerget's Process, Using Invertase as Hydrolyst, 120
Beets, Sugar, Absorption of Arsenic by, 549
Belgium, Linseed Cakes and Linseed Meals in, Adulteration of, 218
Belladonna Extracts, the Alkaloids in, Titration of, Estimation of Atropine, 142
Benzene and Ether, in Alcohol, Estimation of, 19
——— Derivatives, the Estimation of Halogens in, Use of Metallic Potassium in, 287
Benzidine, the Quinonoid Imonium Salts of, Estimation of the Activity of Oxidising Agents by Means of, 233
Benzoic Acid, Estimation of, 584
————, in Flesh and Fats, Detection of, 12
———— Foods, etc., 584
Berries, Coffee, the Fatty Oil and Wax Obtained from, 106
Beryllium, Separation of Aluminium from, 426
Bicarbonates, or Alkali Hydroxides, Alkali Carbonates in Presence of, Titration of, 362
Bichromate Process for Glycerol Determination, Report on, 319
Biological Examination of Honey (Enzymes), 220
——— Method for Identifying Various Fleshes, 455
——— Reactions with Serum-Precipitin and the So-Called Erythro-Precipitin for the Detection of Blood, Comparative Values of, 590
Bismuth, Estimation of. Use of Logwood in Qualitative Analysis, 603
——— Method, Estimation of Manganese by the, 430
——— Ochres from California, 174
Salicylate, Examination of, 342
Bismuthate Method, Estimation of Manganese by, 305
Blast Furnace Gas, Dust in, Determination of, 601
Blasting in Mines, the Gases Caused by, Composition of, Report on, 321
Blaud's Pill, the Composition of, Note on, 387
Bleached Flour, Digestibility of, 64
Bleaching of Flour, and the Addition of So-Called "Improvers" to Flour, Report on, 254
———, the Chemical Changes Produced in Flour by, Report on, 254
Blood, Chlorine in, Estimation of, 72
——, Detection of, 549
——, ————, by Means of Leuco-Malachite Green, 284
——, in Chloroform Anæsthesia, Condition of the Gases of, 154
——, Reagents, Influence of Metals in Presence of Hydrogen Peroxide on, 352
—— -Stains, the Age of, Estimation of, 455
——, Sugar in, Estimation of, 73
——, the Detection of, Comparative Values of the Biological Reactions with Serum Precipitin and the So-Called Erythro-Precipitin, 590
——, the Estimation of "Titratable" Alkali in, New Indicator for, 415
——, the Quantity of Calcium Contained in, Small Variations in, Method for the Estimation of, 220
Bog-Iron Ores, Analysis of, 123
Boltwood Vacuum Pump, Modified, 128
Bomb, Calorimetric, Estimation of Carbon in Steel by Means of, 562
Bombax Malabricum, Gum from, 356
Books, New, 42, 93, 326, 612
Books, Reviews of:
A Course of Practical Work in Agricultural Chemistry for Senior Students, 324

BOOKS, REVIEWS OF—*continued.*
  A Primer on Explosives for Coal-Miners, 380
  A Systematic Handbook of Volumetric Analysis, 484
  A Textbook of Botany and Pharmacognosy, 130
  Allen's Commercial Organic Analysis, Fourth Edition, Vol. III., 187, 257; Vol. IV., 380
  An Introduction to the Chemistry of Colloids, 485
  Analytical Chemistry, 611
  Arsenical Gas-Poisoning, 321
  Bacteriological and Enzyme Chemistry, 260
  Collective Index of the Journal of the Institute of Brewing, 1887-1910, 576
  Edible Fats and Oils: Their Composition, Manufacture, and Analysis, 487
  Fibres Used in Textile and Allied Industries, 322
  Huiles Minérales (Pétroles, Benzols, Brais, Paraffines, Vaselines, Ozokérite), 575
  Identification of the Commercial Dyestuffs, 385
  Laboratory Text-Book for Brewers, 441
  Là Chimica delle Sostanze Alimentari, 40
  Modern Industrial Chemistry, 325
  ——— Methods of Water Purification, 261
  National Physical Laboratory, 1910-1911, 443
  Organic Analysis Chart, 40
  Physico-Chemical Tables, Vol. II., 192
  Qualitative Chemical Analysis from the Standpoint of Solubilities, Ionisation, and Mass Action, 259
  Rubber, 443, 532
  Technical Mycology, 92
  The Chemistry and Testing of Cement, 258
  ————— of Enzymes (Allgemeine Chemie der Enzyme), 534
  The Extra Pharmacopœia, 38
  The Microscopical Examination of Food and Drugs, 384
  The Principal Starches Used as Food, 488
  The Sale of Food and Drugs Acts, 325
  The Soil Solution: The Nutrient Medium for Plant Growth, 574
  The Spark Spectra of the Metals, 41
Borax Bead Tests for Nickel and Cobalt in Admixture, Efficiency of, 173
Bordeaux Mixtures, Fungicidal Action of, 351
Boric Acid, Decomposition of Silicates by Fusion with, as Applied to Qualitative Analysis, 371
Bougies, Earthenware Filtering, Testing the Porosity of, 16
Bran, Rye and Wheat, Customs Examination of, 350
Brandy, Fusel Oil in, Detection of, 216
Bread Made from Different Varieties of Flour, the Nutritive Value of, Report to the Local Government Board on, 479
Brewers' Grains, Starch in, Estimation of, 500
British Wines, the Composition of, Note on, 60
Bromide, Decomposition of, by Nitric Acid. Estimation of Rubber as Tetrabromide, 361
Bromination Methods for the Estimation of Caoutchouc in Vulcanised Products, the Application of, 558
Bromine, Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, Chlorine, and Iodine, Analysis of a Substance Containing, 553
——— in Presence of Chlorides and Iodides, Estimation of, 241
———, ———————————, Very Small Quantities of, Estimation of, 365

Bromine, Method of Destroying Organic Matter by Means of, Particularly Applicable to Toxicological Analysis, 592
———, New Reaction of, 427
——— Value of Fats and Oils, Estimation of. Primary and Secondary Bromine Values, 19
Buchner Funnel, Addition to the, 438
Bulb, Potash, 86
Bulgarian Bacillus, Note on the, 221
Bumping, Prevention of, 608
Burette, Device for Accurately Reading a, 312
Burned Pyrites and Pyrites, Copper in, Estimation of, 366
Butter, Adulteration of, Detection of, by Ewer's Method, 404
——— and Cocoanut Oil in Butter and Margarine, Some Methods of Estimating, Observations on, 333
———, Cocoanut Oil in, Detection of, by Means of Ewer's Method, 451
———, —————, —————, ————— Fendler's Method, 451
Butter-Fat, the Composition of, the Effect of Feeding with Cocoanut Cake and Linseed Cake on, 445
———, the Ageing of, Loss of Soluble and Volatile Fatty Acids during, 64
Butters and Fats, Vegetable, Toxic Substances in, 65

Cadmium and Silver, Rapid Determination of, by Means of the Gauze Cathode and Stationary Anode, 473
———, Zinc, Manganese, Cobalt, Nickel, and Copper, Precipitation of, from Ammoniacal Solutions, by Means of Sodium Carbonate and Trimethyphenylammonium Carbonate, 599
Caesium Chloride, Microchemical Test for Aluminium by Means of, 362
Caffeine and Theobromine, Estimation of, 501
——————————, in the Presence of Each Other, Estimation of, 297
Cake, Cocoanut, and Linseed Cake, the Effect of Feeding with, on the Composition of Butter-Fat, 445
Cakes, Linseed, and Linseed Meals, in Belgium, Adulteration of, 218
——, Rapeseed, Green Colour of, 411
Calcium and Magnesium, Separation and Estimation of Barium in Presence of, by the Action of Acetyl Chloride and Acetone on the Mixed Chlorides, 426
(————— Strontium, Precipitant of), Racemic Acid as a Reagent, 365
——————————-, Sulphite Method for Separating and Identifying, 301
———, Barium, and Strontium, Quantitative Separation of, 364
——— Carbide, Use of, for Determining Moisture, 112
——— Contained in Blood, Small Variations in the Quantity of, Method for the Estimation of, 220
——— Cyanamide, Analysis of, 429, 560
——————————-, and of Norwegian Nitre, 561
——————————, Commercial, Analysis of, 76
——————————, in the Presence of Other Fertilisers, Detection and Estimation of, 466
——— Hypophosphite, Analysis of, 605
——— Nitrate and Nitrite, Commercial, Nitrate and Nitrite Nitrogen in, Estimation of, 524
———, Separation of Strontium from, 247
——— Sulphate in Baking-Powder and Self-Raising Flour, the Presence of, Report on, 258
——— Tartrate and Potassium Bitartrate, Separate Estimation of, 234
——— Very Small Amounts of, Estimation of, by Means of Permanganate, 174

California, Bismuth Ochres from, 174
Calorific Value of Anthracite, Accurate Technical Estimation of, 518
Calorimeter, Recording Thermo-Electric, 312
———, Still Water Gas, 251
Calorimetric Bomb, Estimation of Carbon in Steel by Means of, 562
Calorimetry, Practical Value of, in Testing Anthracite, 562
Camphor, Estimation of, 593
———, in Smokeless Powder, Estimation of, 420
———, Testing of, 343
"Camphor-Wood, False," Essential Oil of: The Occurrence of Myrtenal and *d*-Perilla Aldehyde in Nature, 289
Candelilla Wax, 598
Candle Turbidimeter, Jackson's, Determination of Sulphur in Coal by Means of, 519
Cane and Maple Products, Polarimetric Method for the Determination of Malic Acid, and its Application in, 498
Canned Foods, Tin in, Estimation of, 149
Cantharides and Tinctures, Quantitative Estimation of Cantharidine in, 343
———, Tincture and Oil of, Estimation of Cantharidine in, 404
Caoutchouc as Tetrabromide, Direct Estimation of, 224
———, ———, Estimation of, 159, 509
———, Crude, Analysis of, 159
———, in Vulcanised Products, the Estimation of, the Application of Bromination Methods for, 558
———, in Vulcanised Rubber Articles, Direct Estimation of, 113
———, in Vulcanised Rubber Goods, Direct Estimation of, 75
———, Nitrosite and its Analytical Application, 287
———, Tetrabromide, Hubener's, Notes on, 235
———, the Analytical Methods for the Estimation of, Critical Investigation of, 158
Cap-Compositions, Fulminate, Analysis of, 595
Capillary Analysis, 251
Caramel and Prune Juice in Vanilla Flavouring Extracts, Detection of, 281
———, Preparation and Constitution of, and its Estimation in Sugar Juices and Syrups, 273
Carbalkyloxy Derivatives, Use of, for the Quantitative Estimation of Hydroxyl Groups, 227
Carbinol, Phenyl-ethyl, Estimation of Morphine by Extraction with, 587
Carbon and Nitrogen in Organic Compounds, Estimation of, 593
——— Sulphur in High-Grade Alloys of Tungsten, Molybdenum, and Vanadium, with Iron, Estimation of, 31
——— Dioxide in Beer, Solubility of, 404
——— Dioxide in Carbonates and Nitrogen Pentoxide in Nitrates, the Estimation of, by Loss on Ignition, Application of Sodium Paratungstate in, 526
——— Dioxide Recorder, Multiple, 252
———, Hydrogen, Oxygen, and Nitrogen, Organic Substances Containing, New Method of Elementary Analysis of, 553
———, Hydrogen, Oxygen, Nitrogen, and Sulphur, Analysis of a Substance Containing, 553
———, Hydrogen, Oxygen, Nitrogen, Sulphur, Chlorine, Bromine, and Iodine, Analysis of a Substance Containing, 553
———, in Organic Substances, the Estimation of, Wet Method for, 354
———, in Steel, Estimation of, by Means of a Calorimetric Bomb, 562
———, Microscopical Examination and Identification of, 428
——— Monoxide Detector, 608

Carbon Monoxide Hæmoglobin, and Oxyhæmoglobin, the Spectroscopic Differentiation between, and Hæmochromogen, 550

———, Oxygen, Hydrogen, and Nitrogen, Organic Substances Containing, New Method of Elementary Analysis of, 553

Carbonates, Alkali, in Presence of Alkali Hydroxides or Bicarbonates, Titration of, 362

————, ———, the Use of, in Cheese Manufacture, Detection of, 218

————, Carbon Dioxide in, and Nitrogen Pentoxide in Nitrates, the Estimation of, by Loss on Ignition, Application of Sodium Paratungstate in, 526

Carbonylferrocyanides: Their Extraction and Analysis, 157

Carborundum, in Coke Crucible Scrap, Estimation of, 31

"Cardamon" (Maratti) Fat, Poisonous, Employed in the Manufacture of "Backa Margarine," Nature of, 542

Carius, the Method of, Estimation of Sulphur by, 296

Casein and Gelatin, Differentiation of. Detection of Animal Sizing in Paper, 290

——— Product, 406

———, Quantitative Estimation of Tannin by Means of, 123

Cassia Fistula, the Pulp of, Composition of, 213

Catalase in Milk, Estimation of, 284

Cathode, Gauze, and Stationary Anode, Rapid Determination of Nickel and Cobalt by Means of, 307

———, ———, ——————, Rapid Determination of Silver and Cadmium by Means of, 473

———, Mercury, and Silver Anode, Electrolytic Determination of Chlorine in Hydrochloric Acid with the Use of, 33

———, ————, and Stationary Anode, Rapid Determinations and Separations by Means of, 83

———, ————, Electrolytic Estimations with, Apparatus for, 529

Caulophyllin, a Reaction for, 270

Ceara Rubber, 424

Cellulose, Estimation of, by Simon and Lohrisch's Method, 77

Cement, Ferric Oxide in, Rapid Estimation of, 563

———, Portland, Uniform Methods of Analysis for, 247

Cereals and Wood-Fungi, Pentosans and Methylpentosans in, Estimation of, 460

Cerium, Separation of, by Potassium Permanganate, 429

———, —————, New Method for, 518

Changes which Mercury Compounds undergo when in Contact with Organic Matters, 154

Cheese, Gorgonzola, Note on, 61

——— Manufacture, the Use of Alkali Carbonates in, Detection of, 218

———, Roquefort, Composition of, 542

Chemical Analysis, Some Uses of Amalgamated Aluminium in, 516

———— Changes Produced in Flour by Bleaching, Report on, 254

———— Disinfectants, Study of, Contribution to, 69

——————, ———, —————, Second Paper, 283

Chicken and Turkey Fats, Constants of, 213

China, the So-Called, and East Indian Beeswax, Analysis of Beeswax, with Special Reference to, 554

Chlorate, Potassium, Estimation of Potassium Perchlorate in, 248

Chlorates, Chlorides, and Perchlorates, in the Presence of Each Other, Estimation of, 365

Chloride, Acetyl, and Acetone, the Action of, on the Mixed Chlorides, Separation and Estimation of Barium in Presence of Calcium and Magnesium by, 426

————, Caesium, Microchemical Test of Aluminium by Means of, 362

Chloride, Mercuric, Volumetric Estimation of, 34
———, Stannous Estimation of Tungsten by Means of, 310
Chlorides and Iodides, Bromine in Presence of, Estimation of, 241
——————, Very Small Quantities of Bromine in Presence of, Estimation of, 365
————, Anhydrous, the Preparation of, General Method for, and its Application in Chemical Analysis, 31
————, Chlorates, and Perchlorates, in the Presence of Each Other, Estimation of, 365
————, Mixed, the Action of Acetyl Chloride and Acetone on, Separation and Estimation of Barium in Presence of Calcium and Magnesium by, 426
Chlorine, Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, Bromine, and Iodine, Analysis of a Substance Containing, 553
———— in Blood, Estimation of, 72
———— in Hydrochloric Acid, Electrolytic Determination of, with the Use of a Silver Anode and Mercury Cathode, 33
Chloriplatinate, Potassium, Reduction of, 526
Chloroform Anæsthesia, Composition of the Gases of the Blood in, 154
Chocolate, Cocoanut Oil in, the Detection of, Note on, 275
Chromate, Lead as, Volumetric Determination of, 602
Chrome Ironstone, Chromium in, Estimation of, 428
———— Tungsten Steel, Chromium in, Estimation of, 83
Chrome-Vanadium and Vanadium Steels, Manganese in, Estimation of, 604
————————————————, Vanadium in, Determination of, 475
Chromium, Aluminium, and Iron, Precipitation of, by Ammonium Nitrite, 559
-- and Aluminium in Ferro-Vanadium, Estimation of, 123
————, in Chrome Ironstone, Estimation of, 428
————, ———— Tungsten Steel, Estimation of, 83
———— in Steel, Detection of, 428
——, Minute Quantities of, Colorimetric Estimation of, 238
Cider, Apples, Pears, and Perry, Tartaric Acid in, Estimation of, 545
—— Vinegar, 589
Cinnamon Bark, Seychelles, 217
Citrate-Solubility of Phosphoric Oxide in Basic Slag, 32
Citric Acid in Milk, Estimation of, 105
———— Solution, 2 per Cent., Phosphoric Acid Soluble in, Volumetric Estimation of, 308
Classen Dish, Holder for, 180
Clay, Hydrated Silicic Acid in, Determination of, 85
Clerget's Process, Determination of Sucrose in Beet Sugar Factory Products by, Using Invertase as Hydrolyst, 120
Coagulating-Points of Egg, Serum, and Milk Albumins, and of Serum Globulin, in Ammonium Sulphate Solutions, 416
Coal-Gas, Crude, Naphthalene in, Estimation of, 510
————, Sulphur in, Estimation of, and of Ammonium Sulphate, 309
————, Total Sulphur in, the Estimation of, "Perhydrol" for, 309
Coal, Purchase of, under Specifications, 229
——, Sampling of, in the Mine, 527
——, Sulphur in, Determination of, by Means of Jackson's Candle Turbidimeter, 519
—— -Tar Creosote, Testing of, 419
—— Tar, the Residues from the Distillation of, Estimation of Rosin in, 463
—— Tars, and Refined Tars, Oils, and Pitches Derived Therefrom, Methods for Testing, 298

Cobalt and Nickel, Gravimetric Estimation of, 598
——————— in Admixture, Borax Bead Tests for, Efficiency of, 173
———————, Rapid Determination of, by Means of the Gauze Cathode and Stationary Anode, 307
———————, the Differentiation of, New Reaction for, 238
Cobalt Reaction, Modified, for the Detection of Very Small Quantities of Hydrogen Peroxide, 598
———, Zinc, Manganese, Nickel, Copper, and Cadmium, Precipitation of, from Ammoniacal Solutions, by Means of Sodium Carbonate, and Trimethylphenylammonium Carbonate, 599
Cobalti-Nitrite, Small Quantities of Potassium as, Detection of, 606
Coca Leaves, Analysis of, 274
Cocaine and Certain Other Anæsthetics, Tests for, 2
————- Substitutes, Identification of, 405
——— Solutions, Precipitation of, with Platinum Chloride, 354
Cocoa Powder, Husk in, Estimation of, 275
—— Products, Husk and Germ in, Quantity of, 214
Cocoanut Cake and Linseed Cake, the Effect of Feeding with, on the Composition of Butter-Fat, 445
——— Oil and Butter in Butter and Margarine, Some Methods of Estimating, Observations on, 333
—————- in Butter, Detection of, by Means of Ewer's Method, 451
——————, ————-, ———— Fendler's Method, 451
————— in Chocolate, the Detection of, Note on, 275
—————- in Lard, Estimation of, by Means of the "Ethyl Ester Value," 106
—————-, Shrewsbury and Knapp's Process for the Estimation of, Examination of, 195
Codeine, in Opium, the Determination of, 489
Cod-Liver Oil, Analysis of, by Means of its Miscibility Curve, 275
Coffee Berries, the Fatty Oil, and Wax obtained from, 106
——, Glazed, Resin in, Detection of, 275
Coke Crucible Scrap, Carborundum in, Estimation of, 31
—— Furnaces, the Gases from, Cyanogen Compounds in, Estimation of, 77
Colchicine, in Toxicology, Detection of, 73
Colophony, Colour Reactions of Certain Resins with Halphen's Reagent for, 170
Colorimeter, New, 478
Colorimetric Detection of Oxidising Substances in Animal Organs, 152
—————- Estimation of Lactose in Urine and in Milk, 592
—————————— of Minute Quantities of Chromium, 238
—————————— of Phosphoric Acid, 525
—————————— of Strychnine, 144
—————————— of Sugar, Creatine, and Creatinine in Urine, 591
—————————— of Titanium, Sensitiveness of, 310
——————————————, Use of Methyl Orange in, 310
—————- Method of Estimating Phosphoric Acid, 307
———————— for Estimating Urochrome and Urochromogen, and Relation of the Normal Yellow Pigmentary Substances of Urine to the Diazo-Reaction, 223
———————— for the Estimation of the Molecular Weight of Polysaccharides, 360
———————— for Vanadium in Iron and Steel, 473
—————- Test for Alcohol, in the Presence of Acetone, 592
Colostrum, Behaviour of Schardinger's Reagent towards, 221
Colour Reaction, Characteristic, of Ovolecithin, 460

Colour Reaction of Proteins with Sodium Nitroprusside, 235
——— Reactions, Differentiation of Minerals by Means of, 242
—— of Adrenaline and Allied Bases, 18
—— of Aromatic Aldehydes and their Applicability in the Analysis of Spirits, 273
—— of Certain Resins with Halphen's Reagent for Colophony, 170
—— of Edible Fats and Oils, 406
—— of Strychnine, Influence of Certain Compounds upon the, 296
——— Scale Used with Schaeffer's Curd Tester, Control Tests of, 378
Colouring Matters, Certain, Used in Foods, Report on the Solubility, Extraction, and Reactions of, 186
Columbium and Tantalum, Indirect Method for Determining, 239
———, ——— for the Estimation of, 310
———, Separation of, 239
Combustible Gases and Vapour, Safety Lamps or Other Apparatus for the Detection of, Methods of Testing, 528
Commercial Absinthe, Analysis of, 12
——— Calcium Cyanamide, Analysis of, 76
——— Nitrate and Nitrite, Nitrate and Nitrite Nitrogen in, Estimation of, 524
——— Dextrins, Analysis of, 276
——— Gelatins, Sulphur Dioxide in, 271
——— Oxygen, Analytical Examination of, 469
——— Peptones, Certain, Physical Constants and Analyses of, 111
——— Starch Syrup, the So-Called Gallisin (Glucosin) Occurring in, Composition of, 543
Concentrate, Wolfram, the Assay of, 398
Condensed Milk, Sweetened, Analysis of, 138
——— Milks, an Inquiry as to, Report to the Local Government Board on; with Special Reference to their Use as Infants' Foods, 572
Condenser and Extraction Apparatus, 378
———, Improved Soxhlet, 528
Conductivity, Electrical, and Osmotic Pressure, Application of, in the Examination of Soils, 184
———, ———, of Soils, Determination of, 183
———, ———, the Determination of, Estimation of Ash in Sugar and Syrups by, 298
Conference, International, on Food Analysis, 536
Congress of Applied Chemistry, Eighth International, 386
Conifer Fatty Oils, Characteristics of, 511
Constant, New, in the Analysis of Pepper, 147
Constant Pressures Above and Below the Atmospheric Pressure, the Maintenance of, Apparatus for, Application to Fractional Distillation, 441
———-Temperature Bath for Use at Temperatures both Above and Below that of the Room, 249
——— Temperature Drying-Oven, New Form of, 126
Convallamarin and Convallarin: Glucoside Reactions, 289
Copper and Zinc, Electrolytic Estimation of, Using Sand's Apparatus, 181
Copper, Arsenic and Antimony in, Estimation of, 171
———, Estimation of, by Means of Hypophosphorous Acid, 302
——— in Pyrites and in Burned Pyrites, Estimation of, 366
———, Ores Containing Much, Pot Assay of Gold and Silver in, 240
———, Refined, Exact Electrolytic Assay of. I. Standard Method, 172
——— Solution Used in Bang's Sugar Titration Method, Preparation of, 501

Copper, Zinc, Manganese, Cobalt, Nickel, and Cadmium, Precipitation of, from Ammoniacal Solutions, by Means of Sodium Carbonate and Trimethyphenylammonium Carbonate, 599
Coprah, Examination of, 512
Cows' Milk, Oxydase and Reductase Occurring in, 16
———, on the Peroxydase of, and its Detection by Means of the *p*-Phenylenediamine Test, 222
Cows' Milk, the Detection of Goats' Milk in, and Composition of Goats' Milk, 218
Creatine in Pathological Urine, Direct Estimation of, 504
——— Sugar, and Creatinine, in Urine, Colorimetric Estimation of, 591
Creatinine, the Folin Method of Estimating, Sources of Error in, 288
Creosote and Tar Oils Available for Wood Preservation, Characters of, 228
——— Baths (Dips) and Creosote Oil, the Dimethyl Sulphate Test for, 585
———, Coal-Tar, Testing of, 419
——— Oil and Creosote Baths (Dips), the Dimethyl Sulphate Test for, 585
p-Cresol and Phenol in the Presence of Each Other, Estimation of, 79
Crucible, Gooch, for Micro-Analysis, 180
Crude Caoutchouc, Analysis of, 159
——— Coal-Gas, Naphthalene in, Estimation of, 510
——— Glycerol, Analysis of, Report on, 314
Cryoscopic Examination of Milk, 345
"Cupferron," in Quantitative Analysis, Application of, 175
———, Quantitative Separation by Means of, 520
Cupreïne, New Test for, 113
Curd-Tester, Schaeffer's, the Colour Scale Used with, Control Tests of, 378
Customs Examination of Rye and Wheat Bran, 350
Cyanamide, Calcium, Analysis of, 429, 560
———, ———, ———, and of Norwegian Nitre, 561
———, ———, Commercial, Analysis of, 76
———, ———, in the Presence of Other Fertilisers, Detection and Estimation of, 466
Cyanide, Hydrogen, Traces of, The Detection of, 266
———, Potassium, in Presence of Potassium Ferrocyanide, Titration of, 460
Cyanides, Alkali-Metal, Sulphides in, Estimation of, 436
Cyanogen Compounds in the Gases from Coke Furnaces, Estimation of, 77
Cylinder Oils, Dark Mineral, Estimation of Tarry Substances in, 298

Dammar Resin, Different Varieties of, Characteristics of, 422
Dangers Connected with the Storage and Transport of Ferrosilicon, 302
("Death Camas"), *Zygadenus Intermedius*, Analysis of, 156
Denitrifying Organisms, the Gases Produced by, Occurrence, Detection, and Estimation of Nitrous Oxide in, 591
Density of Liquids, Determination of, 439
Deposits Resulting from the Lubrication of Engines, 230
Detector, Automatic Inflammable Gas and Vapour, New Type of, 528
———, Carbon Monoxide, 608
Detonation, the Velocity of, Study of, 288
Device for Accurately Reading a Burette, 312
Dextrin in Foods, the Detection of, Estimation of Sucrose and, 588
Dextrins, Commercial, Analysis of, 276
Dextrose, Normal Weight of, 78
Diazo-Reaction, Relation of the Normal Yellow Pigmentary Substances of Urine to, and a Colorimetric Method for Estimating Urochrome and Urochromogen, 223
Digestibility of Bleached Flour, 64

Dihydroxystearic Acid in Good and Poor Soils, 504
Dimethyl Sulphate Test for Creosote Oil and Creosote Baths (Dips), 585
Dimethylaminobenzene-azo-benzene Sulphonic Acid, Use of, as a Reagent in Microchemistry, 232
Dinner, Anniversary, 96
Diphenylamine-Sulphuric Acid Test, Detection and Estimation of Nitrates in Milk by Means of the, 67
——————————————, Estimation of Nitrates in Milk by Means of the, 587
Diphenylamine Test for Nitrous and Nitric Acids, Modification of, 370
(Dips) Creosote Baths and Creosote Oil, the Dimethyl Sulphate Test for, 585
Disaccharides, Small Quantities of, Detection of, 594
Dish, Classen, Holder for, 180
Disinfectants, Chemical, Study of, Contribution to, 69
—————, ————, ———, ——————, Second Paper, 283
Dissolved Oxygen, Estimation of, 245
Distillation, Fractional, Application to, Apparatus for the Maintenance of Constant Pressures Above and Below the Atmospheric Pressure, 441
————— of Tar, Flask for, 529
————— of Tars Containing Water, 171
Doughing Value of Flour, Estimation of, 216
Dried Milk Powders, Composition of, 279
Drinking Water, Sterilisation of, by Means of Ultra-Violet Rays, 457
(Drop Hammer), the Impact Machine, Sensitiveness Tests by, 314
Drugs, etc., Quinine in, Volumetric Estimation of, 143
Drying-Oven, Constant Temperature, New Form of, 126
———, Precipitating, and Filtering, in an Inert Gas, Apparatus for, 313
Dust in Blast-Furnace Gas, Determination of, 601

Earth-Containing Sands, Rare, ("Amang"), from Malay States, 523
——— Minerals, Rare, the Determination and Analysis of, Use of Sulphur Monochloride in, 567
Earths, Alkaline, and Alkalis, Soaps of the, Estimation of Free Fatty Acids in the Presence of, 595
East Indian and the So-Called China Beeswax, Analysis of Beeswax, with Special Reference to, 554
Edible Fats and Oils, Colour Reactions of, 406
Effluents, Sewage, Containing Nitrites, the Amount of Dissolved Oxygen Absorbed by the Determination of, and of the Amount of Nitrite in Sewage Effluents and Water, 393
Egg, Serum, and Milk Albumins, Coagulating-Points of, and of Serum Globulin, in Ammonium Sulphate Solutions, 416
Egypt, Survey Department, 1910, the Work of the Laboratories, Report on, 532
Elastin, Detection of Active Pepsin in the Intestines by Means of, 551
———— in the Detection of Proteolytic Enzymes, Use of, 590
Electrical Conductivity and Osmotic Pressure in the Examination of Soils, Examination of, 184
—————————— of Soils, Determination of, 183
——————————, the Determination of, Estimation of Ash in Sugar and Syrups by, 298
Electrically-Heated Vacuum Fractionation Apparatus, 253
Electro Analysis, 565
———————, Rapid, under Reduced Pressure, 601
———————, ———, with Agitation by Means of a Current of Gas, 600

Electro Analysis, Rapid, with Stationary Electrodes, Adaptation of the Tap-Funnel to, 313
——— -Analytical Determination of Metals, Rapid, Apparatus for, 181
Electrolytic Assay, Exact, of Refined Copper. I. Standard Method, 172
——— Determination of Chlorine in Hydrochloric Acid with the Use of a Silver Anode and Mercury Cathode, 33
——— Estimation of Copper and Zinc, Using Sand's Apparatus, 182
——— ——— of Manganese, 177
——— ——— of Metals, Exact Method for, 370
——— Estimations with Mercury Cathode, Apparatus for, 529
——— Separations, 32
Electrometric Method for the Estimation of the Acidity of Tan Liquors, 121; Part II., 515
Elements, the Sulphides of which are Precipitated by Hydrogen Sulphides in Acid Solution, Rapid Qualitative Detection of, 568
Enamel, Analysis of, 33
Engines, the Lubrication of, Deposits Resulting from, 230
Enols in Allelotropic Mixtures, the Quantitative Estimation of, Colorimetric Method for, 554
Enzymatic Activity of Nuclease, Estimation of, 109
Enzymes, Amylolytic, in Fæces, Detection of, 74
———, Honey, Biological Examination of, 220
———, One or More, Method for Ascertaining whether a Liquid Contains, 110
———, Proteins, and Urine, the Chemistry of, Quantitative Estimation of Aliphatic Amino Groups, and its Application in, 17
-, Proteolytic, the Detection of, Use of Elastin in, 590
Errata, 141, 610
Error, Some Sources of, in Gasometric Estimation of Nitrate by Schloesing's Method, and of Nitrite by Piccini's Method, 525
———, ———, in the Folin Method of Estimating Creatinine, 288
Erythro-Precipitin, the So-Called, and Serum-Precipitin, the Biological Reactions with, for the Detection of Blood, Comparative Values of, 590
Essence, Rosin, Turpentine Oil, and Wood Turpentine Oil, Reaction of, 107
Essential Oil of "False Camphor Wood": The Occurrence of Myrtenal and *d*-Perilla Aldehyde in Nature, 289
——— of Orange Flowers, 67
——— of *Santolina Chamæcyparissus*, 589
——— of *Schinus Molle* (L.), 68
——— of Spanish Marjoram (*Thymus Mastichina*, L.), 69
——— Oils and Balsams, the Examination of, Use of Miscibility Curves in, 556
——— and Philippine Terpenes, 15
———, Estimation of, 288
, Ketones in, Estimation of, 514
Ether and Benzene in Alcohol, Estimation of, 19
——— in the Analysis of Metals, Use of, 431
———, Quantitative Analysis of Gold with the Use of, 303
———, Separation of Iron and Vanadium by Means of, 522
———, The Examination of, for Anæsthetic and Analytical Purposes, 407
———, Traces of Water in, the Accurate Estimation of, Method for, 420
Ethyl Alcohol in the Presence of Methyl Alcohol, Detection of, 18
——— and Methyl Alcohols and Formic Acid, Detection and Estimation of, 507
"Ethyl Ester Value," Estimation of Cocoanut Oil in Lard by Means of the, 106
Evaporated Milk and Milk Products, Analysis of, 278
Ewer's Method, Detection of Adulteration of Butter by, 404

Ewer's Method, Detection of Cocoanut Oil in Butter by Means of, 451
Experiments on the Precipitation of Proteins, 295
Explosives in Various Countries, the (General) Stability of, Methods of Testing, 79
Extinguishing the Flame of Petroleum Spirit, 252
Extraction Apparatus, 609
—————— and Condenser, 378
——————, New, 529
————, Automatic, of Aqueous Liquids by Means of Specifically Lighter Solvents, 87
Extracts and Powder, Liquorice, Glycyrrhizin and Sugars in, Estimation of, 409
———, Belladonna, Titration of the Alkaloids in. Estimation of Atropine, 142
——— of Known Origin, Beef and Yeast, Comparison of, 64
——————————, Meat and Yeast, Comparison of, 104
———, Tobacco, and Nicotine Solutions, Nicotine in, Estimation of, 544
———, ———, and their Value, 411
———, ———, Nicotine in, Estimation of, 348
———, ———, ————, Polarimetric Estimation of, 279
———, Vanilla Flavouring, Prune Juice and Caramel in, Detection of, 281

Factors, Surface, The Use of, and Errors in Determining Sizes of Mineral Grains, 182
Fæces, Amylolytic Enzymes in, Detection of, 74
——, Preservation of, 74
——, Volatile Fatty Acids in, Quantitative Estimation of, 505
Fat from the Seeds of *Lophira Alata* (Banks), Composition of, 493
— in Beeswax, Paraffin, Spermaceti, etc., Detection of, 496
— in Feeding Stuffs, Estimation of, by Means of Trichlorethylene, 542
— in Milk, the Estimation of, Wendler's Method for, 14
— in Pathological Urine, Estimation of, 417
— in (Maratti), Cardamon, Poisonous, Employed in the Manufacture of "Backa-Margarine," Nature of, 542
—, Oils, and Soaps, the Total Fatty Acids in, Estimation of, 115
— Pitch, Petroleum Pitch in, Detection of, 462
Fats and Butters, Vegetable, Toxic Substances in, 65
—— and Flesh, Benzoic Acid in, Detection of, 12
—— and Oils, Analysis of, 164
—————, Edible, Colour Reactions of, 406
—————, Particularly Lubricating Oils, the Acidity of, Estimation of, 290
—————, Some Indian, 108
—————, the Bromine Value of, Estimation of. Primary and Secondary Bromine Values, 19
—————, Vegetable, Some Little-Known Characteristics of, 21
Fats, Chicken and Turkey, Constants of, 213
——, Estimation of the Reichert-Meissl Value of, by Means of Glycerol-Potassium Hydroxide, 542
——, Free Fatty Acids in, Estimation of, 355
——, Melting-Point of, Apparatus for the Estimation of, 569
——, Oils, and Soaps, Train Oil in, Detection of, 359
——, Oils, and Waxes, the Saponification Value of, Estimation of. Use of Propyl Alcohol, 290
Fatty Acids, Effect of the Glycerol Method of Saponification upon the, 425
————, Free, in Fats, Estimation of, 355
————, ——, Estimation of, in the Presence of Soaps of the Alkalis and Alkaline Earths, Estimation of, 595
———— in Soaps, Estimation of, 355
————, Liquid, Separation of Solid from, 22, 114

Fatty Acids, Soluble and Volatile, Loss of, during the Ageing of Butter, 64
————, Total, in Soap, Estimation of, 20
————, ——, in Soaps, Fat, and Oils, Estimation of, 115
————, Volatile, in Fæces, Quantitative Estimation of, 505
—— Oil and Wax Obtained from Coffee Berries, 106
—— Oils, Conifer, Characteristics of, 511
————, Rosin in, Estimation of, 557
Feeding Stuffs, Fat in, Estimation of, by Means of Trichlorethylene, 542
————, Sugars in, Estimation of, 453
Fehling's Solution, Estimation of Pentosans with the Aid of, 161
Fendler's Method, Detection of Cocoanut Oil in Butter by Means of, 451
Fermentation Experiments, Quantitative, Flask for, 568
Fermentation Vinegars and "Vinegar Essence," Chemical Differentiation between, Particularly with Respect to the Amount of Formic Acid, 455
Ferric Iron, Volumetric Estimation of, by Permanganate, after Reduction with Zinc, 521
—— Oxide in Cement, Rapid Estimation of, 563
————, Separation of Alumina from, 82
—— Sulphate as Standard for Permanganate Solutions, 520
Ferrocyanide, Potassium, Potassium Cyanide in Presence of, Titration of, 460
————, Pure Potassium, Preparation of, and its Analytical Control, 564
Ferrocyanides and Thiocyanates, Simultaneous Estimation of, 563
Ferrosilicon, the Storage and Transport of, Dangers Connected with, 302
Ferrotitanium Alloys Containing Much Silicon, Analysis of, 373
Ferro-Uranium, Analysis of, 125
Ferro-Vanadium, Aluminium and Chromium in, Estimation of, 123
————, Analysis of, and Estimation of Vanadium in Presence of Arsenic, 437
Ferro-Zircon, Analysis of, 124
Ferrous Iron, in Silicate Rocks, Determination of, 602
—— Oxide in Silicates, Titration of, by the Pebal-Dölter Method, Note on, 372
————, New Test for, and the Separation of Iron from Aluminium, 373
—— Salts, Oxidation of, 467
Fertilisers, Other, Calcium Cyanamide in the Presence of, Detection and Estimation of, 466
Fiehe's Reaction, Examination of Honey by, 451
Fillers (Mineral Matter) in Rubber Mixtures, Estimation of, 558
Filtering Funnel, Rapid, 609
Filtering Hygroscopic Substances or those Affected by Air, Apparatus for, 87
————, Precipitating, and Drying in an Inert Gas, Apparatus for, 313
Filters, Earthenware (Bougies), Testing the Porosity of, 16
Finnish Turpentine, the Examination of, Note on, 577
Flame of Petroleum Spirit, Extinguishing the, 252
Flask for Distillation of Tar, 529
Flask for Quantitative Fermentation Experiments, 568
——, Measuring, for Use in Determining Iodine Values of Oils, 379
Flesh and Fats, Benzoic Acid in, Detection of, 12
Fleshes, Various, Biological Method for Identifying, 455
Flour, Bleached, Digestibility of, 64
——, Bread Made from Different Varieties of, the Nutritive Value of, Report to the Local Government Board on, 479
——, Self-Raising, and Baking-Powder, the Presence of Calcium Sulphate in, Report on, 255
——, the Bleaching of, and the Addition of So-Called "Improvers" to Flour, Report on, 254

Flour, the Chemical Changes Produced in, by Bleaching, Report on, 254
——, the Doughing Value of, Estimation of, 216
——, Wheaten, the Quality of, Method of Estimating, 543
Flowers, Orange, Essential Oil of, 67
Flue Gas Analysis, Apparatus for, 440
Fluids, Animal, Acetone in, the Estimation of, Method for, 548
Fluorine, Estimation of, 303
—— in the Human Body, Distribution of, 75
Fodder-Stuffs, Poisonous Ricinus Constituents in, Detection of, 506
Folin Method of Estimating Creatinine, Sources of Error in, 288
Food Analysis, International Conference on, 536
FOODS AND DRUGS ANALYSIS, ABSTRACTS, 12, 64, 103, 142, 214, 272, 342, 404, 450, 495, 541, 584
Foods, Canned, Tin in, Estimation of, 149
——, Certain Colouring Matters Used in, Report on the Solubility, Extraction, and Reactions of, 186
——, etc., Benzoic Acid in, Detection of, 584
——, Formic Acid in, Estimation of, 103, 496
——, Inspectors of, on the Work of, 128
——, the Detection of Dextrin in, and Estimation of Sucrose, 588
Formaldehyde, Estimation of, 114, 595
——, ——, by the Ammonia Method, 421
Formic Acid and Methyl and Ethyl Alcohols, Detection and Estimation of, 507
——, Chemical Differentiation between Fermentation Vinegars and "Vinegar Essence," Particularly with Respect to the Amount of, 455
——, Estimation of, 355
in Foods, Estimation of, 103, 496
Fractional Distillation, Application to, Apparatus for the Maintenance of Constant Pressures above and below the Atmospheric Pressure, 441
Fractionation Apparatus, Vacuum, Electrically-Heated, 233
Free Acid and Basic Alumina in Aluminium Salts, Estimation of, 236
Freezing Mixtures, 127
French Wool-Grease Oleines, Rosin Oils in, Detection of, 30
Frey's, Henry C., Method of Estimating Petroleum in Turpentine, Note on, 137
Fruit Juices. Preservation of with Hydrofluoric Acid, 218
——, Salicylic Acid in, Estimation of, 411
Fuel Oil and Natural Gas, Specifications and Sampling of, 555
Fulminate Cap-Compositions, Analysis of, 595
Fungi, Wood, and Cereals, Pentosans and Methylpentosans in, Estimation of, 460
——, Certain, Pentosans of, 162
Fungicidal Action of Bordeaux Mixtures, 351
Funnel, Filtering, Rapid, 609
——, Separatory, Modified, and Washer for Heavy Liquids, 89
——, the Buchner, Addition to, 438
Furfural Method for the Estimation of Pentosans, Modification of, 161
Furnace, Blast, Gas, Dust in, Determination of, 601
—— Gases, Sampling and Analysis of, Apparatus and Methods for, 530
Furnaces, Coke, the Gases frnm, Estimation of Cyanogen Compounds in, 77
Fusel Oil in Brandy, Detection of, 216

Gallisin (Glucosin), the So-called, Occurring in Commercial Starch Syrup, Composition of, 543
Galvanised Iron, Method for Testing, to Replace the Preece Test, 304
Gambier, Microscopical Examination of, 344

Gas, An Inert, Precipitating, Filtering, and Drying in, Apparatus for, 313
——, Analysis, Exact, Apparatus for, 379
——, ————, Flue, Apparatus for, 440
——, Blast Furnace, Dust in, Determination of, 601
——, Calorimeter, Still Water, 250
—— -Engines and Motor-Cars, Lubricating Oils for, 291
—— in Sealed Tube Reactions, Detection of, 531
—— Mixtures, Hydrogen in, Estimation of, 84
——, Natural, and Fuel Oil, Specifications and Sampling of, 555
—— -Pressure Regulators, Simple Forms of, 477
——, Rapid Electro-Analysis with Agitations by Means of a Current of, 600
—— Regulator for Thermostats, 127
——, Tar and Tar Constituents in, New Method of Estimating, 299
Gases Caused by Blasting in Mines, Composition of, Report on, 321
———, Combustible, and Vapour, Safety Lamps or Other Apparatus for the Detection of, Methods of Testing, 528
——— from Coke Furnaces, Cyanogen Compounds in, Estimation of, 77
———, Furnace, Sampling and Analysis of, Apparatus and Methods for, 530
——— of the Blood in Chloroform Anæsthesia, Composition of, 154
——— Produced by Denitrifying Organisms, Nitrous Oxide in, Occurrence, Detection, and Estimation of, 591
Gelatin and Casein, Differentiation of. Detection of Animal Sizing in Paper, 290
————, Estimation of, 585
Gelatine, Analysis of, 289
Gelatins, Analysis of, 116
————, Commercial, Sulphur Dioxide in, 271
Germ and Husk in Cocoa Products, Quantity of, 214
German Margarine, the Poisonous Properties of Certain Brands of, Cause of, 216
———— Silver and Other Alloys, the Separation of Nickel and Zinc in, Method for, 524
Germicidal Action of Arsenic and Antimony Compounds on *Bacillus Typhosus*, 282
—————- and Insecticidal Values of Different Soaps, with or without Associated Active Agents, 505
Germinating Barley, Hordenine in, Estimation of, 162
Ghee, Further Analyses of, 392
Glance, Molybdenum, Analysis of, 243
Glass Manometer, Some Forms of, 437
Glazed Coffee, Resin in, Detection of, 275
Globulin, Serum, in Ammonium Sulphate Solutions, Coagulating-Points of Egg, Serum, and Milk Albumins, and of, 416
"Glow Reaction," Application of, to the Detection of the Platinum Metals, 434
Glucose Syrup, Sulphurous Acid in Estimation of, 543
Glucoside Reactions: Convallarin and Convallamarin, 289
(Glucosin) Gallisin, the So-Called, Occuring in Commercial Starch Syrup, Composition of, 543
Gluten, Wheat, Influence of Certain Vegetable Proteins on, 407
Glycerol, Crude, Analysis of, Report on, 314
————- Determination, Acetin Process for, Report on, 316
————————————-, Bichromate Process for, Report on, 319
—————, Estimation of, 289
————, Method of Saponification, Effect of, upon the Fatty Acids, 425
————- -Potassium Hydroxide, Estimation of the Reichert-Meissl Value of Fats by Means of, 542
Glycogen and Starch, the Separation of, Method for, 501

Glycuronic Acid, Small Quantities of, Detection of,.596
Glycyrrhizin and Sugars in Liquorice Powder and Extracts, Estimation of, 409
Goats' Milk; Composition of, and the Detection of Goats' Milk in Cows' Milk, 218
Gold and Silver, in Ores Containing Much Copper, Pot Assay of, 240
——, Estimation of, by Means of Hydrogen Peroxide, 34
——, Quantitative Analysis of, with the Use of Ether, 303
Goldenberg's Method, Estimation of Total Tartaric Acid by, 131
Gooch Crucible for Micro-Analysis, 180
Gorgonzola Cheese, Note on, 61
Government Laboratory, the Work of, for the Year Ending March 31, 1911, Report of the Principal Chemist upon, with Appendices, 571
———— Reports, 128, 479, 571
Grains, Brewers', Starch in, Estimation of, 500
Granular Form, Aluminium Hydroxide in, Precipitation of, 299
Graphite, Analysis of, 562
————, in Lubricants, Detection of, 356
Gravimetric Estimation of Tellurium, and Alkalimetric Estimation of Telluric Acid, 248
Grease, Heavy, Soap in, Estimation of' 559
———, Resistance to, Testing of Imitation Parchment Papers for, 597
Green Colour of Rapeseed Cakes, 411
Gum Arabic Pastilles, Analysis of, 344
—— from *Bombax Malabricum,* 356
—— Kino, Some Reactions of, 544
Gums from Northern Nigeria, 162
Gun-Cotton, Nitrates, etc., Nitrogen in, Estimation of, 243
————, Nitroglycerine, and the Like, Nitric Nitrogen in, Estimation of, 513

Hæmochromogen and the Spectroscopic Differentiation between Oxyhæmoglobin and Carbon Monoxide Hæmoglobin, 550
Hæmoglobin in Urine, the Failure of the Spectroscopic Test for, Hippuric Acid as a Cause of, 417
———— Preparations, 222
Halogens in Benzene Derivatives, the Estimation of, Use of Metallic Potassium in, 287
———— in Organic Compounds, Estimation of, 509
————, Other, Estimation of Iodine in Organic Compounds and its Separation from, 118
Halphen's Reagent for Colophony, Colour Reactions of Certain Resins with, 170
Hardness of Water, Estimation of: The Wartha-Pfeiffer Method and its Modification, 311
Heavy Grease, Soap in, Estimation of, 559
——— Liquids, Modified Separatory Funnel and Washer for, 89
Heller's Ring Test for the Detection of Albumin in Urine, etc., Modification of, 152
Hevea Latex, Some Analyses of, 6
Hexabromide Value of Oils, the Estimation of, Apparatus for, 607
Hexamethylenetetramine (Urotropine) in Urine, Estimation of, 285
Hippuric Acid as a Cause of the Failure of Spectroscopic Test for Hæmoglobin in Urine, 417
Histological Chemical Detection of Peroxydase, 75
Holder for Classen Dish, 180
Hollemann's Method, Improved, for the Estimation of Reverted Phosphoric Acid, 605
Honey, Analysis of, 276

Honey, Analysis of, with Special Reference to the Nitrogenous Constituents, 277
——, ——, Use of the Quantitative "Precipitin" Reaction in, 456
——, Bacteriological Estimation of, 505
——, —— Study of, 353
——, (Enzymes), Biological Examination of, 220
——, Examination of, by Fiehe's Reaction, 451
——, Formation, Chemistry of, 223
——, Invert Sugar in, Detection of, 586
——, Volatile Acids of, 277
——, Water in, Estimation of, 586
Hops, the Antiseptic Properties of, Valuation of, 65
——, Valuation of, by Analysis, 587
Hordenine, in Germinating Barley, Estimation of, 162
Hubener's Caoutchouc Tetrabromide, Notes on, 235
"Hughes' Reaction" of Potassium Iodide on Paper, and its Bearing on the Question of Acidity, 292
Human Body, Fluorine in, Distribution of, 75
Humus, in Soils, Estimating, 597
Husk and Germ in Cocoa Products, Quantity of, 214
——, in Cocoa Powder, Estimation of, 275
Hydrargyrometric Analyses, 357
Hypoiodites, the Formation of, and their Action on Sodium Thiosulphate, Notes on —A Source of Error in Certain Iodine Titrations, 132
Hypophosphite, Calcium, Analysis of, 605
Hypophosphorous Acid, Estimation of Copper by Means of, 302
Hydrated Silicic Acid in Clay, Determination of, 85
Hydrazine Hydrate, the Precipitation of Iron with, 521
—— Sulphate, Action of, on Nitrites, and a Method for the Estimation of Nitrite Nitrogen, 468
Hydride, Solid, of Antimony, Attempts to Prepare, 300
——, ——, — Arsenic, Detection of, 300
Hydrocarbon and Resin Oils in Other Oils, Detection of, 513
Hydrochloric Acid, Chlorine in, Electrolytic Determination of, with the Use of a Silver Anode and Mercury Cathode, 33
Hydrofluoric Acid, Preservation of Fruit Juices with, 218
Hydrogen, Active, in Organic Compounds, Quantitative Estimation of, by Means of Magnesium-Methyl Iodide, 117
——, ——, in Organic Molecules, Estimation of, 459
——, Carbon, Oxygen, and Nitrogen, Organic Substances Containing, New Method of Elementary Analysis of, 553
——, ——, ——, Nitrogen, and Sulphur, Analysis of a Substance Containing, 553
——, ——, ——, ——, Sulphur, Chlorine, Bromine, and Iodine, Analysis of a Substance Containing, 553
—— Cyanide, Traces of, the Detection of, 266
——, Delicate Test for, 34
——, in Gas Mixtures, Estimation of, 84
—— Peroxide, Estimation of Gold by Means of, 34
—— ——, Metals in Presence of, Influence of, on Blood Reagents, 352
—— —— Solutions, Acidity in, Estimation of, 82
—— ——, the Detection of Very Small Quantities of, Modified Cobalt Reaction for, 598
—— Sulphide, in Acid Solution, Rapid Qualitative Detection of Elements, the Sulphides of which are Precipitated by, 568

Hydrogen Sulphide, Qualitative Analysis without the Use of, 517
Hydrolyst, Determination of Sucrose in Beet Sugar Factory Products by Clerget's Process, Using Invertase as, 120
Hydroquinone, Estimation of, 163
Hydroxide, Aluminium, in Granular Form, Precipitation of, 299
———, Nickel, in Tannin Estimation, Use of, 516
Hydroxides, Alkali, or Bicarbonates, Alkali Carbonates in Presence of, Titration of, 362
Hydroxyl Groups, the Quantitative Estimation of, Use of Carbalkyloxy Derivatives for, 227
Hygienic Tests, Other, for Milk, Comparison of the Reductase Test with, 346
Hygroscopic, Poisonous, or Volatile Liquids, Apparatus for Storing and Measuring, 88
——— Substances or those Affected by Air, Apparatus for Filtering, 87

Ignition, Effect of, on Solubility of Soil Phosphates, 371
———, the Estimation of Carbon Dioxide in Carbonates and Nitrogen Pentoxide in Nitrates by loss on, Application of Sodium Paratungstate in, 526
Imitation Parchment Papers, Testing of, for Resistance of Grease, 597
Impact Machine (Drop Hammer), Sensitiveness Tests by the, 314
"Improvers," So-Called, the Addition of, to Flour, and the Bleaching of Flour, Report on, 254
Inactive Substances, Influence of, on the Rotation of Lævulose, 228
Incandescent Mantles, Testing of, 125
India, Travancore, Monazite Sand from, 523
———, Turpentine Oil from, 415
Indian Oils and Fats, Some, 108
Indicator, Methyl Red, as, Compared with Methyl Orange, 118
———, New, for the Estimation of "Titratable" Alkali in Blood, 415
———, Sensitive, 26
Indicators, Behaviour of Uranium Phosphates towards, 375
———, for Determining Affinity Values, Use of, 569
———, Phenolphthaleïn Derivatives and their Properties as, 169
Indigotin in the Presence of Starch, Estimation of, 290
Indophenol Oxydase of Animal Tissues, Estimation of, 550
Inert Gas, Precipitating, Filtering, and Drying in, Apparatus for, 313
Inflammable Gas and Vapour Detector, Automatic, New Type of, 528
INORGANIC ANALYSIS, ABSTRACTS, 30, 82, 123, 171, 236, 299, 362, 425, 466, 516, 559, 598
——— Phosphorus in Animal Tissue, Estimation of, 284
Insecticidal and Germicidal Values of Different Soaps, with or without Associated Active Agents, 505
Insecticides, Arsenic in, Estimation of, 237
INSTITUTE OF CHEMISTRY, 94, 193, 262, 444
Interpolation Method of Oil Analysis, 166
Intestines, Active Pepsin in, Detection of, by Means of Elastin, 551
Invert Sugar in Honey, Detection of, 586
Invertase as Hydrolyst, Determination of Sucrose in Beet Sugar Factory Products by Clerget's Process, Using, 120
———, in Wine, Detection of, 350
———, the Action of, Influence of the Viscosity on, According to the Concentration of Saccharose, 416
Iodic Acid, Detection and Estimation of Thorium by Means of. (Separation of Thorium from Scandium), 436
Iodide, Magnesium-Methyl, Quantitative Estimation of Active Hydrogen in Organic Compounds by Means of, 117

Iodides and Chlorides, Bromine in Presence of, Estimation of, 241
——————, Very Small Quantities of Bromine in Presence of, Estimation of, 365
———, Small Quantities of, in the Presence of Other Compounds, Estimation of, 241
Iodine, Action of, on Phenols, and their Volumetric Determination. Part I., 294
———, Alkali, and Silver, Volumetric Solutions of, Use of Sulphur Dioxide in Checking Strengths of, 248
———, Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, Chlorine, and Bromine, Analysis of a Substance Containing, 553
——— in Alcoholic Solutions, Estimation of, 235
——— in Organic Compounds, Estimation of, and its Separation from Other Halogens, 118
——— Solution, Titration of "Salvarsan" with, 350
——— Titrations, Certain, a Source of Error in—Notes on the Formation of Hypoiodites and their Action on Sodium Thiosulphate, 132
——— Values of Linoxyn, 24
——— ——— Oils, Measuring Flask for Use in Determining, 379
Iodoform, the Crystalline Form of, Reaction of Aromatic Inner Anhydrides Depending on their Influence on, 458
Iron Alloys, Estimation of Silicon in Vanadium and Molybdenum, and in their, 311
——, Aluminium, and Chromium, Precipitation of, by Ammonium Nitrite, 559
—— and Steel, Sulphur in, Volumetric Estimation of, 374
—————, Vanadium in, Colorimetric Method for, 473
—— and Vanadium, Separation of, by Means of Ether, 522
——————, Simultaneous Volumetric Estimation of, 475
——, Ferric, Volumetric Estimation of, by Permanganate after Reduction with Zinc, 521
——, Ferrous, in Silicate Rocks, Determination of, 602
——, Galvanised, Method for Testing, to Replace the Preece Test, 304
—— in Minerals, the Estimation of, the Influence of Pertitanic Acid on, 304
——, New Method of Separating, from Manganese, 604
—— Salts and Arsenic in Mineral Waters, Estimation of, 466
——, Separation of, from Aluminium, and New Test for Ferrous Oxide, 373
——, the Precipitation of, with Hydrazine Hydrate, 521
——, Tungsten, Molybdenum, and Vanadium, with High-Grade Alloys of, Estimation of Carbon and Sulphur in, 31
Ironstone, Chrome, Estimation of Chromium in, 428

Jackson's Candle Turbidimeter, Determination of Sulphur in Coal by Means of, 519
Jamaica Rum, Higher Alcohols Occurring in, 411
Jams, Analysis and Composition of, 144
——, etc., Starch Syrup in, Estimation of, 280
Jolles, the Method of, Polarimetric Estimation of Sugar by, 361
Juice, Liquorice, Analysis of, 410, 497
——, Prune, and Caramel in Vanilla Flavouring Extracts, Detection of, 281
——, Sugar-Cane, Acids in, Determination of, 594
——, Tobacco, and Extracts, Analysis of, and of Nicotine Salts, by the Method of Ulex, 545
—————, Concentrated, Estimation of Nicotine in, 106
Juices and Syrups, Sugar, Preparation and Constitution of Caramel and its Estimation in, 278
——, Fruit, Preservation of, with Hydrofluoric Acid, 218
——, ———, Salicylic Acid in, Estimation of, 411
——, Tobacco, Concentrated, Estimation of Nicotine in, 143

Kernels, Sweet Apricot, Composition of, 450
Ketones in Essential Oils, Estimation of, 514
Kino, Gum, Some Reactions of, 544
Knapp and Shrewsbury's Process for the Estimation of Cocoanut Oil, Examination of, 195
Kobert's Reagent as a Test for Salicylic Acid, 540

Laboratory Apparatus for the Production of a Constant Current of Ozonised Air, 479
———— Suction Pump, Simple, 532
Lac-Resin from Baroda, India, 171
————, Shellac, and Lac-Wax, Analytical Constants of, 119
Lactic Acid, Analysis of, 556
————, the Anhydride of, 235
Lactose in Urine and in Milk, Colorimetric Estimation of, 592
Lævulose, the Rotation of, Influence of Inactive Substances on, 228
Lamps, Safety, or Other Apparatus, for the Detection of Combustible Gases and Vapour, Methods of Testing, 528
Lard, Cocoanut Oil in, Estimation of, by Means of the "Ethyl Ester Value," 106
——, Small Quantities of Water in, Estimation of, 497
Latex, *Hevea*, Some Analyses of, 6
Lead Arsenate in the Products of Vines Treated with Arsenical Washes, Proportion of, 301
—— as Chromate, Volumetric Determination of, 602
——, Higher Oxides of, Valuation of, 366
—— in Alloys Containing Antimony and Tin, Estimation of, 367
—— Peroxide, Volumetric Estimation of, 467
Leaves, Coca, Analysis of, 274
Lecithin, 510
————, Estimation of, 510
————, in Oil, Estimation of, 166
Leguminous Plants Grown in Togo and German East Africa, Composition of the Seeds of, 345
Leuco-Malachite Green, Detection of Blood by Means of, 284
Lime, Separation of, from Large Quantities of Magnesia, 242
Linoxyn, Iodine Values of, 24
Linseed and Other Oils, Notes on, 278
———— Cake and Cocoanut Cake, the Effect of Feeding with, on the Composition of Butter-Fat, 445
———— Cakes and Linseed Meals, in Belgium, Adulteration of, 218
———— Oil, Analytical Examination of, 407
Liquid Fatty Acids, Separation of Solid from, 22, 114
————, Small Volumes of, Volumetric Analysis with, 185
Liquids and Solids, Vapour Pressures of, Static Method for Determining, 36
————, Aqueous, Automatic Extraction of, by Means of Specifically Lighter Solvents, 87
————, Heavy, Modified Separatory Funnel and Washer for, 89
————, Hygroscopic, Poisonous or Volatile, Apparatus for Storing and Measuring, 88
————, Mixed, Detection of Definite Compounds in, by its Means, and Direct Measurement of Changes of Vapour Pressure, 379
————, Organic, Purifying and Drying by Wiping, Method for, 26
————, Poisonous, Hygroscopic, or Volatile, Apparatus for Storing and Measuring, 88
————, the Density of, Determination of, 439
Liquorice Juice, Analysis of, 410, 497
———— Powder and Extracts, Glycyrrhizin and Sugars in, Estimation of, 409

Liquorice Powder, Compound, the Analytical and Microscopical Examination of, 198
Liquors, Tan, the Acidity of, Electrometric Method for the Estimation of, 121; Part II., 515
Lithium, Quantitative Estimation of, 175
Litmus, the Alcohol-Soluble Constituents of, 25
Logwood, Use of, in Qualitative Analysis, Estimation of Bismuth, 603
————, Valuation of, 26
Lophira alata (Banks), the Seeds of, Composition of the Fat from, 493
Lubricants, Graphite in, Detection of, 356
Lubricating Oils, Estimation of the Acidity of Fats and Oils, Particularly, 290
———— for Motor-Cars and Gas-Engines, 291
————, Mineral, Alcohol-Ether in, Proportion of Asphalt Insoluble in, 418
————, ————, of High Boiling-Point, Composition of, 461
Lubrication of Engines, Deposits Resulting from, 230

Machine, Impact (Drop Hammer), Sensitiveness Tests by, 314
Madeira, Preparation of, and its Composition, 410
Magnesia, Large Quantities of, Separation of Lime from, 242
———— Method for Estimation of Phosphoric Acid, Criticism of, 176
———— Mixture, Detection and Estimation of Arsenic Acid in Presence of Arsenious Acid by Means of, 30
Magnesium-Ammonium Phosphate, Estimation of Phosphoric Acid as, 434
———— and Calcium, Separation and Estimation of Barium in Presence of, by the Action of Acetyl Chloride and Acetone on the Mixed Chlorides, 426
———— as Oxide, Estimation of, 604
———— -Methyl Iodide, Quantitative Estimation of Active Hydrogen in Organic Compounds by Means of, 117
Malay States, Rare Earth-Containing Sands ("Amang"), from, 523
Malic Acid, the Determination of, Polarimetric Method for, and its Application in Cane and Maple Products, 498
Malt Analysis, the Method of, Improvement in, 146
Manganese, Electrolytic Estimation of, 177
————, Estimation of, as Oxide, 566
————, ————, by the Bismuth Method, 430
————, ————, by the Bismuthate Method, 305
————, ————, Rapid and Accurate Method for, 368
————, in Vanadium and Chrome-Vanadium Steels, Estimation of, 604
————, New Method of Separating Iron from, 604
————, Small Quantities of, Especially in the Ash of Plants or of Animal Organs, Estimation of, 369
————, the Volumetric Estimation of, Volhard's Method for, Waldemar Fischer's Modification of, and its Comparison with Other Well-known Methods, 52
————, Zinc, Cobalt, Nickel, Copper, and Cadmium, Precipitation of, from Ammoniacal Solutions by Means of Sodium Carbonate and Trimethylphenylammonium Carbonate, 599
Manometer, Glass, Some Forms of, 437
Mantles, Incandescent, Testing of, 125
Maple and Cane Products, Polarimetric Method for the Determination of Malic Acid, and its Application in, 498
Margarine, and Butter, Cocoanut Oil and Butter in, Some Methods of Estimating, Observations on, 333
————, German, the Poisonous Properties of Certain Brands of, Cause of, 216
————, the Analysis of, Notes on, 327
Marine Algæ, and Products Derived from Them, Relative Proportions of Arsenic in, 218

Marjoram, Spanish (*Thymus mastichina*, L.), Essential Oil of, 69
Mascarenhasia elastica, Rubber of, 159
Meals, Linseed, and Linseed Cakes, in Belgium, Adulteration of, 218
Measuring Flask for Use in Determining Iodine Values of Oils, 379
———— Radioactivity, Apparatus for, 380
———— the Degree of Vitiation of the Atmosphere, Method of, 363
Measurement, Direct, of Changes of Vapour Pressure and Detection of Definite Compounds in Mixed Liquids by its Means, 379
Meat and Yeast Extracts of Known Origin, Comparison of, 104
—— -Juices, Analysis of, 13
——, Potassium Nitrate in, Estimation of, 217
Melting-Point Determinations, 438
———— of Fats, Apparatus for the Estimation of, 569
Menthylglycuronic Acid, Preparation of, 505
Mercuric Chloride, Volumetric Estimation of, 34
Mercury Cathode and Silver Anode, Electrolytic Determination of Chlorine in Hydrochloric Acid with the Use of, 33
———— and Stationary Anode, Rapid Determinations and Separations by Means of, 83
————, Electrolytic Estimations with, Apparatus for, 529
—— in Urine, Detection of, 552
—— Pump for Rapidly Obtaining a High Vacuum, 89
—— Salts, Soluble, at Great Dilutions, Estimation of, 305
——, the Estimation of, Volumetric Method for, Depending on Reduction to Metal, 431
Metallic Acids, Action of Salicylic Action on, 567
Metals, Alkali, Estimation of, Elimination of Ammonium Salts Prior to, 30
——, in Presence of Hydrogen Peroxide, Influence of, on Blood Reagents, 352
——, Rapid Electro-Analytical Determination of, Apparatus for, 181
——, the Analysis of, Use of Ether in, 431
——, the Electrolytic Estimation of, Exact Method for, 370
——, the Platinum, Application of the "Glow Reaction" to the Detection of, 434
——, White, the Analysis of, Rapid and Accurate Method for, 606
Methyl Alcohol, Ethyl Alcohol in the Presence of, Detection of, 18
—— and Ethyl Alcohols and Formic Acid, Detection and Estimation of, 507
—— Orange, Methyl Red as an Indicator Compared with, 118
————, Use of, in the Colorimetric Estimation of Titanium, 310
—— Red as an Indicator Compared with Methyl Orange, 118
Methylpentosans and Pentosans in Cereals and Wood-Fungi, Estimation of, 460
Mexican Petroleum, Asphaltum from, 353
Micro-Analysis, Gooch Crucible for, 180
Microchemical Detection of Protein, 111
———— Test for Aluminium by Means of Caesium Chloride, 362
———————— Sodium, 372
Microchemistry, Use of Dimethylaminobenzene-azo-benzene Sulphonic Acid as a Reagent in, 232
Microdistillation Apparatus, 37
Microscopical and Analytical Examination of Compound Liquorice Powder, 198
———— Examination of Gambier, 344
———— ———— and Identification of Carbon, 428
———— Preparations, Combined Fixing and Staining Processes for, 569
Microtome Sections, Incineration of, 74
Milk, and Urine, Lactose in, Colorimetric Estimation of, 592
——, Catalase in, Estimation of, 284

Milk, Citric Acid in, Estimation of, 105
——, Condensed, Sweetened, Analysis of, 138
——, Cow's, on the Peroxydase of, and its Detection by Means of the *p*-Phenylenediamine Test, 222
——, ——, Goats' Milk in, the Detection of, and Composition of Goats' Milk, 218
——, ——, Oxydase and Reductase Occurring in, 16
——, Cryoscopic Examination of, 345
——, Egg, and Serum Albumins, Coagulating-Points of, and of Serum Globulin, in Ammonium Sulphate Solutions, 416
——, Evaporated, and Milk Products, Analyses of, 278
——, Fat in, the Estimation of, Wendler's Method for, 14
——, Goats', Composition of, and the Detection of Goats' Milk in Cows' Milk, 218
——, Nitrates in, Detection and Estimation of, by Means of the Diphenylamine-Sulphuric Acid Test, 67
——, ——— in, Estimation of, by Means of the Diphenylamine-Sulphuric Acid Test, 587
——, Other Hygienic Tests for, Comparison of the Reductase Test with, 346
——, Phosphorus in, the Gravimetric Estimation of, Note on, 579
—— Powders, Dried, Composition of, 279
—— Products, and Evaporated Milk, Analyses of, 278
—— Test, the "Neusal," 203
——, the Composition of, 390
——, the Degree of Accuracy with which Proteins can be Estimated in, by Aldehyde Titration, 9
——, the Examination of, Applicability of Recent Methods for, 347
——, the Phosphoric Acid in, Distribution of, 345
——, Very Small Quantities of, the Specific Gravity of, Determination of, 500
Milks, Condensed, an Inquiry as to, Report to the Local Government Board on; with Special Reference to their Use of Infants' Foods, 572
Mine, Coal in the, Sampling of, 527
Mineral Cylinder Oils, Dark, Tarry Substances in, Estimation of, 298
——— Grains, Errors in Determining Sizes of, and the Use of Surface Factors, 182
——— Lubricating Oils, Alcohol-Ether in, Proportion of Asphalt Insoluble in, 418
——— ————— —— of High Boiling-Point, Composition of, 461
(——— Matter) Fillers, in Rubber Mixtures, Estimation of, 558
——— Oil, in Wool-Grease Oleine, Detection of, 29
——— Oils and their Products, Origin of, Determination of, 167
——— Poisons, Method of Destroying Organic Matters in Testing for, 110
"——— Rubber" and Similar Products in Rubber Articles, Estimation of, 235
——— Waters, Arsenic and Iron Salts in, Estimation of, 466
Minerals, Differentiation of, by Means of Colour Reactions, 242
———, Iron in, the Estimation of, the Influence of Pertitanic Acid on, 304
———, Rare Earth, the Determination and Analysis of, Use of Sulphur Monochloride in, 567
Mines, the Gases Caused by Blasting in, Composition of, Report on, 321
Minute Quantities of Chromium, Colorimetric Estimation of, 238
——— ———— of Nitroglycerin, Estimation of, 556
Miscibility Curve, Analysis of Cod-Liver Oil by Means of its, 275
———— Curves, in the Examination of Essential Oils and Balsams, Use of, 556
Mixtures, Freezing, 127
———, Quantitative Analysis of, by Differences in the Specific Gravities of their Components, 306
Moisture, Use of Calcium Carbide for Determining, 112
Molecular Weight of Polysaccharides, the Estimation of, Colorimetric Method for, 360

Molecules, Organic, Active Hydrogen in, Estimation of, 459
Molybdenum and Vanadium, Estimation of Silicon in, and in their Iron Alloys, 311
——— Glance, Analysis of, 243
———, the Volumetric Estimation of, a New Method for, 98
———, Tungsten, and Vanadium, with Iron, High-Grade Alloys of, Carbon and Sulphur in, Estimation of, 31
Monazite Sand from Travancore, India, 523
——— Sands, Analysis of, 522
Monochloride, Sulphur, Use of, in the Determination and Analysis of Rare Earth Minerals, 567
Moroccan Olive Oil, 107
Morphine, Estimation of, by Extraction with Phenyl-ethyl Carbinol, 587
———, New Reaction of, 66
———, Quantitative Estimation of, 142
Mushroom, Soluble Basic Constituents of the, 347
Mutton-Bird Oil, Some Constants of, 290
Myrtenal and *d*-Perilla Aldehyde, the Occurrence of, in Nature: Essential Oil of "False Camphor-Wood," 289

Naphthalene in Crude Coal Gas, Estimation of, 510
Natural Gas and Fuel Oil, Specifications and Sampling of, 555
——— Vichy Salts, Characteristic Constituent of, 85
Neats-Foot Oil, 512
Neumann's Method, Estimation of Phosphoric Acid by, 525
"Neusal" Milk Test, 203
Neutralised Olive-Residuum Oil, Characteristics of, 116
Nickel and Cobalt, Gravimetric Estimation of, 598
——— in Admixture, Borax Bead Tests for, Efficiency of, 173
———, Rapid Determination of, by Means of the Gauze Cathode and Stationary Anode, 307
———, the Differentiation of, New Reaction for, 238
——— and Zinc in German Silver and Other Alloys, the Separation of, Method for, 524
——— Compounds, the Precipitation of, and Preparation of Spongy Nickel, 539
——— Hydroxide in Tannin Estimation, Use of, 516
——— in Steel, Determination of, Comparison of Methods for, 524
——— ——, Rapid Estimation of, 373
———, Spongy, Preparation of, and the Precipitation of Nickel Compounds, 539
———, Zinc, Manganese, Cobalt, Copper, and Cadmium, Precipitation of, from Ammoniacal Solutions by Means of Sodium Carbonate and Trimethylphenyl-ammonium Carbonate, 599
Nicotiana tabacum, Green Plants of, and Tobacco, Nicotine in, Accurate Estimation of, 348
Nicotine, Estimation of, in the Presence of Pyridine Bases, 452
——— in Concentrated Tobacco Juice, Estimation of, 106, 143
——— in Nicotine Solutions and Tobacco Extracts, Estimation of, 544
———, in Tobacco and in Green Plants of *Nicotiana tabacum*, Accurate Estimation of, 348
———, ——— Extracts, Estimation of, 348
——— ——— Polarimetric Estimation of, 279
——— ——, the Estimation of, New Method for, 280
——— Salts, Analysis of, and of Tobacco Juice and Extracts, by the Method of Ulex, 545
Niger-Seed Oil, 358
Nigeria, Northern, Gums from, 162

Nitrate and Nitrite Nitrogen in Commercial Calcium Nitrate and Nitrite, 524
———, Estimation of, 467
———, Gasometric Estimation of, by Schloesing's Method, and of Nitrite by Piccini's Method, Some Sources of Error in, 525
Nitrates and Nitrites, in Water, Detection of, 432
———, Estimation of, by the Phenol Sulphonic Acid Method, 84
———, Gun-Cotton, etc., Nitrogen in, Estimation of, 243
——— in Milk, Detection and Estimation of, by Means of the Diphenylamine-Sulphuric Acid Test, 67
——————, Estimation of, by Means of the Diphenylamine-Sulphuric Acid Test, 587
——— in Water, Estimation of, by a Sulpho-Salicylic Reagent, 85
———, ———, the Estimation of, Study of the Phenolsulphonic Acid Method for. III. Chief Sources of Error, 244
———, Nitrogen Pentoxide in, and Carbon Dioxide in Carbonates, the Estimation of, by Loss on Ignition, Application of Sodium Paratungstate in, 526
———, the Estimation of, Rapid Method for, 468
Nitre, Norwegian, Analysis of, and of Calcium Cyanamide, 561
Nitric Acid, and Nitrous Acid in Water, Detection and Estimation of, 433
—————, Decomposition of the Bromide by, Estimation of Rubber as Tetrabromide, 361
—————, in Nitrocellulose, Nitroglycerol, and Other Compounds, Volumetric Determination of, 34
————— in Vegetable Products, Quantatitive Estimation of, 163
——— and Nitrous Acids, the Diphenylamine Test for, Modification of, 370
——— Nitrogen in Gun-Cotton, Nitroglycerine, and the Like, Estimation of, 513
——— Oxide, Estimation of, and its Behaviour towards Water, 433
Nitrite, Ammonium, Precipitation of Aluminium, Chromium, and Iron by, 559
——— and Nitrate, Commercial Calcium, Estimation of Nitrate and Nitrite Nitrogen in, 524
———, Gasometric Estimation of, by Piccini's Method, and of Nitrate by Schloesing's Method, Some Sources of Error in, 525
——— in Sewage Effluents and Water, the Amount of, the Determination of, and of the Amount of Dissolved Oxygen Absorbed by Sewage Effluents Containing Nitrites, 393
Nitrites, Action of Hydrazine Sulphate on, and a Method for the Estimation of Nitrite Nitrogen, 468
——— and Nitrates in Water, Detection of, 432
———, in Water, Detection of, 370
———, New Method of Estimating, 307
Nitrocellulose, Nitroglycerol, and Other Compounds, Nitric Acid in, Volumetric Determination of, 34
Nitrogen and Carbon in Organic Compounds, Estimation of, 593
———, Carbon, Hydrogen, and Oxygen, Organic Substances Containing, New Method of Elementary Analysis of, 553
——————, Oxygen, and Sulphur, a Substance Containing, Analysis of, 553
—————————, Sulphur, Chlorine, Bromine, and Iodine, a Substance Containing, Analysis of, 553
——— in Liquids, Estimation of, 421
———, in Nitrates, Gun-Cotton, etc., Estimation of, 243
———, Nitric, Gun-Cotton, Nitroglycerine, and the Like, Estimation of, 513
Nitrate and Nitrite in Commercial Calcium Nitrate and Nitrite, Estimation of, 524

Nitrogen, Nitrite, a Method for the Estimation of, and Action of Hydrazine Sulphate on Nitrites, 468
———, Organic, Available, Bacteriological Method of Estimating, 219
Nitrogenous Constituents, Analysis of Honey, with Special Reference to the, 276
Nitroglycerine, Gun-Cotton, and the Like, Nitric Nitrogen in, Estimation of, 513
Nitroglycerin, Minute Quantities of, Estimation of, 556
Nitroglycerol, Nitrocellulose, and Other Compounds, Nitric Acid in, Volumetric Determination of, 34
Nitrosite, Caoutchouc, and its Analytical Application, 287
Nitrous Acid, and Nitric Acid, in Water, Detection and Estimation of, 433
——— and Nitric Acids, the Diphenylamine Test for, Modification of, 370
——— Oxide, in the Gases Produced by Denitrifying Organisms, Occurrence, Detection, and Estimation of, 591
—————. Chemistry of Anæsthetics, III., 503
Normal Weight of Dextrose, 78
——— Yellow Pigmentary Substances of Urine, Relation of, to the Diazo-Reaction, and a Colorimetric Method for Estimating Urochrome and Urochromogen, 223
Norwegian Nitre, Analysis of, and of Calcium Cyanamide, 561
Nuclease, the Enzymatic Activity of, Estimation of, 109
Nutritive Value of Bread made from Different Varieties of Flour, Report to the Local Government Board on, 479

Occlusion, Phenomenon of, in Precipitates of Barium Sulphate, and its Relation to the Exact Determination of Sulphates, 426
Ochres, Bismuth, from California, 174
Oil, African Sandal-Wood, Adulterant of, 146
—— Analysis, Interpolation Method of, 166
—— and Tincture of Cantharides, Cantharidine in, Estimation of, 404
——, Cocoanut, and Butter, in Butter and Margarine, Some Methods of Estimating, Observations on, 333
——, ————, in Butter, Detection of, by Means of Ewer's Method, 451
——, ————, ————, ————, ———— Fendler's Method, 451
——, ————, in Chocolate, the Detection of, Note on, 275
——, ————, in Lard, Estimation of, by Means of the "Ethyl Ester Value," 106
——, ————, Shrewsbury and Knapp's Process for the Estimation of, Examination of, 195
——, Cod-Liver, Analysis of, by Means of its Misability Curve, 275
——, Creosote, and Creosote Baths (Dips), the Dimethyl Sulphate Test for, 585
——, Essential, of Orange Flowers, 67
——, ————, of *Santolina Chamæcyparissus*, 589
——, ————, of *Schinus molle* (L.), 68
——, ————, of Spanish Marjoram (*Thymus mastichina*, L.), 69
——, Fatty, and Wax, Obtained from Coffee Berries, 106
—— from Seeds of the Ash-Tree, 357
—— from the Seeds of *Xanthophyllum lanceolatum*, 406
——, Fuel, and Natural Gas, Specifications and Sampling of, 555
——, Fusel, in Brandy, Detection of, 216
——, Lecithin in, Estimation of, 166
——, Linseed, Analytical Examination of, 407
——, Mineral, in Wool-Grease Oleine, Detection of, 29
——, Mutton-Bird, Some Constants of, 290
——, Neats-Foot, 512
——, Niger-Seed, 358
——, Olive, Moroccan, 107

Oil, Olive-Residuum, Neutralised, Characteristics of, 116
—, ——, Wines, and Vinegar, Portuguese Standards for. (Extract from the Official Methods of Analysis), 502
—. Para Rubber-Seed, Composition of, 491
—, Rice, 357
—, Soya Bean, 358
—, ————, Composition of, 513

—, Fat, and Soaps, the Total Fatty Acids in, Estimation of, 115
—, Fats, and Soaps, Train Oil in, Detection of, 359
—, Fats, and Waxes, the Saponification Value of, Estimation of, Use of Propyl Alcohol, 290
— from Papilionaceous Plants, Characteristics of, 231
—, Fatty, Rosin in, Examination of, 557
—, Iodine, Values of, Measuring Flask for Use in Determining, 379
—, Linseed, and Other, Notes on, 278
—, Lubricating, Estimation of the Acidity of Fats and Oils, Particularly, 290
—, ————, for Motor-Cars and Gas-Engines, 291
—, ————, Mineral, of High Boiling-Point, Composition of, 461
—, Mineral, and their Products, Origin of, Determination of, 167
—, ———, Lubricating, Alcohol-Ether in, Proportion of Asphalt Insoluble in, 418
— of Turpentine, Analysis of, II., 150
—, Resin, and Hydrocarbon in Other Oils, Detection of, 513
—, Rosin, in French Wool-Grease Oleines, Detection of, 30
—, Tar, and Creosote, Available for Wood Preservation, Characters of, 228
—, the Hexabromide Value of, the Estimation of, Apparatus for, 607
—, the Specific Gravity of, Estimation of, 557
—, Wool, Unsaponifiable Matter in, Estimation of, 168
Oleic Acid, Separation of, from Stearic and Palmitic Acids, 23
Oleine, Wool-Grease, Mineral Oil in, Detection of, 29
Oleines, Wool-Grease, Examination of, 29
———, ————, French, Rosin Oils in, Detection of, 30
Olive Oil, Moroccan, 107

Olive Oil, Wines, and Vinegar, Portuguese Standards for. (Extract from the Official Methods of Analysis), 502
—— -Residuum Oil, Neutralised, Characteristics of, 116
(Onchocerciasis) a Parasitic Condition Met with in Australian Beef, 129
Opium, Codeine in, the Determination of, 489
Opsonin Reaction, 455
Orange Flowers, Essential Oil of, 67
Ores, Bog-Iron, Analysis of, 123
—— Containing Much Copper, Gold, and Silver in, Pot Assay of, 240
——, Refractory Tin, Simple Method of Decomposing, 309
——, Tin in, Estimation of, 527
ORGANIC ANALYSIS, ABSTRACTS, 17, 75, 112, 157, 224, 287, 353, 417, 457, 507, 553, 592
Organic Bodies, Influence of Potassium Permanganate upon, 232
—— Liquids, Purifying and Drying by Wiping, Method for, 26
—— Matter, Incineration in Presence of, Causes of Loss of Phosphoric Acid on, 360
————, Method of Destroying, by Means of Bromine, Particularly Applicable to Toxicological Analysis, 592
—— Matters, Changes which Mercury Compounds Undergo when in Contact with, 154
————, Method of Destroying, in Testing for Mineral Poisons, 110
—— Molecules, Active Hydrogen in, Estimation of, 459
—— Nitrogen, Available, Bacteriological Method of Estimating, 219
—— Substances, Action of Permanganate on, 422
———— in Water, Estimation of, by Means of Permanganate, 502
———— the Estimation of Carbon in, Wet Method for, 354
Organisms, Denitrifying, the Gases Produced by Occurrence, Detection, and Estimation of Nitrous Oxide in, 591
Osmotic Pressure and Electrical Conductivity, Application of, in the Examination of Soils, 184
Oven, Drying, Constant Temperature, New Form of, 126
Ovolecithin, Characteristic Colour Reaction of, 460
Oxidation of Ferrous Salts, 467
Oxide, Estimation of Manganese as, 566
——, Ferric, in Cement, Rapid Estimation of, 563
————, Separation of Alumina from, 82
—— Ferrous, in Silicates, the Titration of, by the Pebal-Dölter Method, Note on, 372
————, New Test for, and the Separation of Iron from Aluminium, 373
—— Magnesium as, Estimation of, 604
—— Nitric, Estimation of, and its Behaviour towards Water, 433
—— Nitrous, Chemistry of Anæsthetics, III., 503
————, in the Gases Produced by Denitrifying Organisms, Occurrence, Detection, and Estimation of, 591
——, Phosphoric, in Basic Slag, Citrate-Solubility of, 32
Oxides, Higher, of Lead, Valuation of, 366
Oxidising Agents, the Activity of, Estimation of, by Means of the Quinonoid Imonium Salts of Benzidine, 233
—— Substances in Animal Organs, Colorimetric Detection of, 152
Oxydase and Reductase Occurring in Cow's Milk, 16
——, Indophenol, of Animal Tissues, Estimation of, 550
Oxygen, Carbon, Hydrogen, and Nitrogen, Organic Substances Containing, New Method of Elementary Analysis of, 553
——, Carbon, Hydrogen, Nitrogen, and Sulphur, Analysis of a Substance Containing, 553

Oxygen, Carbon, Hydrogen, Nitrogen, Sulphur, Chlorine, Bromine, and Iodine, Analysis of a Substance Containing, 553
———, Commercial, Analytical Examination of, 469
———, Dissolved, Absorbed by Sewage Effluents Containing Nitrites, the Determination of the Amount of, and of the Amount of Nitrite in Sewage Effluents and Water, 393
———, ———, Estimation of, 245
——— in Air, Volumetric Estimation of, 569
Oxyhæmoglobin, and Carbon Monoxide Hæmoglobin, the Spectroscopic Differentiation between, and Hæmochromogen, 550
Ozone, Estimation of, by Means of Alkaline Potassium Iodide Solution, 525
Ozonised Air, a Constant Current of, Laboratory Apparatus for the Production of, 479

Paints, Consistency of, by the Stormer Viscosimeter, 609
———, New Accelerated Test for, 608
Palmitic and Stearic Acids, Separation of Oleic Acid from, 23
Paper, Animal Sizing in, Detection of. Differentiation of Gelatin and Casein, 290
———, "Hughes' Reaction" of Potassium Iodide on, and its Bearing on the Question of Acidity, 292
———, Reagent, for the Volumetric Estimation of Zinc, 126
Papers, Imitation Parchment, Testing of, for Resistance to Grease, 597
Papilionaceous Plants, Oils from, Characteristics of, 231
Para Rubber-Seed Oil, Composition of, 491
Paraffin, Beeswax, Spermaceti, etc., Fat in, Detection of, 496
Pastilles, Gum Arabic, Analysis of, 344
Pathological Urine, Creatine in, Direct Estimation of, 504
———————, Fat in, Estimation of, 417
"Pearl Coating" of Pills, Note on, 389
Pears, Apples, Cider, and Perry, Tartaric Acid, Estimation of, 545
Pebal-Dölter Method, the Titration of Ferrous Oxide in Silicates by, Note on, 372
Pentosans and Methylpentosans in Cereals and Wood-Fungi, Estimation of, 460
———— and Pentoses, the Quantitative Analysis of, and its Practical Applications, Researches on, 293
————, Estimation of, with the Aid of Fehling's Solution, 161
———— of Certain Wood-Fungi, 162
————, the Estimation of, the Furfural Method for, Modification of, 161
Peppercorns, Adulteration of, 349
Pepper, the Analysis of, New Constant in, 147
Pepsin, Active, in the Intestines, Detection of, by Means of Elastin, 551
———, the Valuation of, Comparative Studies on, 155
Peptones, Commercial, Certain, Physical Constants and Analyses of, 111
———— or Peptides, and Amino-Acids, Differentiation between, 593
Perborates, and Similar Compounds, Detection of, 470
Perchlorate, Potassium, in Potassium Chlorate, Estimation of, 248
Perchlorates, Chlorides, and Chlorates, in Presence of Each Other, Estimation of, 365
"Perhydrol" for the Estimation of Total Sulphur in Coal Gas, 309
d-Perilla Aldehyde, and Myrtenal, Occurrence of, in Nature: Essential Oil of "False Camphor-Wood," 289
Permanganate, Action of, on Organic Substances, 422
——————, Estimation of Organic Substances in Water by Means of, 502
——————, —————— Very Small Amounts of Calcium by Means of, 174
——————, Potassium, Influence of, upon Organic Bodies, 232
——————, —————, Separation of Cerium by, 429

Permanganate Solutions, Ferric Sulphate as Standard for, 520
—————, Volumetric Estimation of Ferric Iron by, after Reduction with Zinc, 521
Peroxide, Hydrogen, Estimation of Gold by Means of, 34
————, ————, Metals in Presence of, Influence of, on Blood Reagents, 352
————, ————, Solutions, Estimation of Acidity in, 82
————, ————, the Detection of Very Small Quantities of, Modified Cobalt Reaction for, 598
————, Lead, Volumetric Estimation of, 467
Peroxydase, Histological-Chemical Detection of, 75
———— of Cow's Milk, and its Detection by Means of the *p*-Phenylenediamine Test, 222
Perry, Apples, Pears, and Cider, Tartaric Acid in, Estimation of, 545
Pertitanic Acid, the Influence of, on the Estimation of Iron in Minerals, 304
Petroleum Asphalt, Technical Analysis of, 294
———— in Turpentine, Henry C. Frey's Method of Estimating, Note on, 137
————, Mexican, Asphaltum from, 353
———— Pitch, in Fat Pitch, Detection of, 462
———— Spirit, Extinguishing the Flame of, 252
Phenol and *p*-Cresol in the Presence of Each Other, Estimation of, 79
——— and Salicylic Acid, Sensitive Test for, 295
——— Sulphonic Acid Method, Estimation of Nitrates by, 84
Phenolphthaleïn Derivatives and their Properties as Indicators, 169
——————, Volumetric Estimation of, 14
Phenols, Action of Iodine on, and their Volumetric Determination. (Part I.), 294
Phenolsulphonic Acid Method for the Estimation of Nitrates in Water, Study of. III. Chief Sources of Error, 244
Phenolsulphonic Acid Method for the Estimation of Nitrates in Water, Study of. IV. A Modified Method, 244
Phenyl-ethyl Carbinol, Estimation of Morphine by Extraction with, 587
p-Phenylenediamine Test, on the Peroxydase of Cow's Milk, and the Detection by Means of the, 222
Philippine Terpenes and Essential Oils, 15
Phosphate, Magnesium-Ammonium, Estimation of Phosphoric Acid as, 434
Phosphates, Soil, Solubility of, Effect of Ignition on, 371
—————, Titration of, 473
—————, Uranium, Behaviour of, towards Indicators, 375
Phosphoric Acid, as Magnesium-Ammonium Phosphate, Estimation of, 434
——————, Colorimetric Estimation of, 525
——————, ————— Method of Estimating, 307
——————, Estimation of, by Neumann's Method, 525
——————, in Milk, Distribution of, 345
——————, Loss of, on Incineration in Presence of Organic Matter, Causes of, 360
——————, Magnesia Method for Estimation of, Criticism of, 176
——————, Reverted, the Estimation of, Improved Hollemann's Method for, 605
—————— Soluble in 2 per cent. Citric Acid Solution, Volumetric Estimation of, 308
——————, Volumetric Estimation of, 472
—————— and Vanadic Acids, in Presence of Each Other, Estimation of, and Precipitation of Vanadic Acid as Silver Vanadate, 35
—— Oxide, in Basic Slag, Citrate Solubility of, 32
Phosphorus and Sulphur in Organic Substances, Estimation of, 81
———— in Milk, the Gravimetric Estimation of, Note on, 579

Phosphorus, Inorganic, in Animal Tissues, Estimation of, 284
———— in Small Amounts, Titrimetric Estimation of, 246
Phosphotungstic Acid Precipitation of Proteins, 461
Physical Constants and Analyses of Certain Commercial Peptones, 111
Piccini's Method, Gasometric Estimation of Nitrite by, and of Nitrate by Schloesing's Method, Some Sources of Error in, 525
Pigmentary Substances, Normal Yellow, of Urine, Relation of, to the Diazo-Reaction, and a Colorimetric Method for Estimating Urochrome and Urochromogen, 223
Pill, Blaud's, the Composition of, Note on, 387
Pills, the "Pearl Coating" of, Note on, 389
Pitch, Fat, Petroleum Pitch in, Detection of, 462
Plants, Leguminous, Grown in Togo and German East Africa, the Seeds of, Composition of, 345
——— or Animal Organs, the Ash of, Estimation of Small Quantities of Manganese, Especially in, 369
Plaster of Paris, Testing, 246
Platinum and Tin, Separation of, 177
————, Assay of, 605
———— Chloride, Precipitation of Cocaine Solutions with, 354
———— Metals, the Detection of, Application of the "Glow Reaction" to, 434
Poisonous "Cardamon" (Maratti) Fat Employed in the Manufacture of "Backa-Margarine," Nature of, 542
————, Hygroscopic, or Volatile Liquids, Apparatus for Storing and Measuring, 88
———— Properties of Certain Brands of German Margarine, Cause of, 216
———— Ricinus Constituents in Fodder-Stuffs, Detection of, 506
Poisons, Mineral, Method of Destroying Organic Matters in Testing for, 110
Polarimetric Estimation of Sugar by the Method of Jolles, 361
Polysaccharides, the Molecular Weight of, Colorimetric Method for the Estimation of, 360
Porosity of Earthenware Filtering Bougies, Testing the, 16
Portland Cement, Uniform Methods of Analysis for, 247
Portuguese Standards for Wines, Vinegar, and Olive Oil. (Extract from the Official Methods of Analysis), 502
Pot Assay of Gold and Silver in Ores Containing Much Copper, 240
Potable Spirits, Analysis of, and its Bearing on the Definition of Whisky (Report), 441
Potash Bulb, 86
Potassium as Potassium Platini-Chloride, Estimation of, 178
———— Bitartrate, and Calcium Tartrate, Separate Estimation of, 234
———— Chlorate, Potassium Perchlorate in, Estimation of, 248
———— Chloriplatinate, Reduction of, 526
———— Cyanide, in Presence of Potassium Ferrocyanide, Titration of, 460
———— Ferrocyanide, Pure, Preparation of, and its Analytical Control, 564
————————, Titration of Potassium Cyanide in Presence of, 460
———— Iodide, "Hughes' Reaction" of, on Paper, and its Bearing on the Question of Acidity, 292
———————— Solution, Alkaline, Estimation of Ozone by Means of, 525
———— Metallic, in the Estimation of Halogens in Benzene Derivatives, Use of, 287
———— Nitrate in Meat, Estimation of, 217
———— Perchlorate, in Potassium Chlorate, Estimation of, 248
———— Permanganate, Influence of, upon Organic Bodies, 232
————————, Separation of Cerium by, 429
————, Small Quantities of, Detection of, as the Cobalti-Nitrite, 606

Powder and Extracts, Liquorice, Glycyrrhizin and Sugars in, Estimation of, 409
———, Cocoa, Husk in, Estimation of, 275
———, Compound Liquorice, the Analytical and Microscopical Examination of, 198
———, Smokeless, Camphor in, Estimation of, 420
———————, Stability Tests of, 295
Powders, Dried Milk, Composition of, 279
Precipitates of Barium Sulphate, Phenomenon of Occlusion in, and its Relation to the Exact Determination of Sulphate, 426
Precipitating, Filtering, and Drying, in an Inert Gas, Apparatus for, 313
Precipitin Reaction, 456
———————, the Quantitative, Use of, in Honey Analysis, 456
Preece Test, Method for Testing Galvanised Iron to Replace the, 304
Preparations, Hæmoglobin, 222
————, Microscopical, Combined Fixing and Staining Processes for, 569
Pressure, Osmotic, and Electrical Conductivity, Application of, in the Examination of Soils, 184
———, Reduced, Rapid Electro-Analysis under, 601
———, Vapour, Direct Measurement of Changes of, and Detection of Definite Compounds in Mixed Liquids by its Means, 379
Pressures, Vapour, of Solids and Liquids, Static Method for Determining, 36
Propyl Alcohol, Use of. Estimation of the Saponification Value of Oils, Fats, and Waxes, 290
Protein, Microchemical Detection of, 111
Proteins, an Inner Anhydride Reaction of, 514
———, and their Derivatives, the Detection of, Use of Triketohydrindene Hydrate for, 514
———, Certain Vegetable, Influence of, on Wheat Gluten, 447
———, Colour Reaction of, with Sodium Nitroprusside, 235
———, Phosphotungstic Acid Precipitation of, 461
———, the Analysis of, a Method for, and Estimation of Amino Groups in Amino Compounds and in Urine, 457
———, the Precipitation of, Experiments on, 295
———, Urine, and Enzymes, the Chemistry of, Quantitative Estimation of Aliphatic Amino Groups, and its Application in, 17
Proteolytic Enzymes, the Detection of, Use of Elastin in, 590
Prune Juice and Caramel in Vanilla Flavouring Extracts, Detection of, 281
Pulp of *Cassia fistula*, Composition of, 214
Pump, Mercury, for Rapidly Obtaining a High Vacuum, 89
——, Modified Boltwood Vacuum, 128
——, Suction, Simple Laboratory, 532
Pyridine and Ammonia, Separation and Estimation of, 508
——— Bases, Nicotine in the Presence of, Estimation of, 452
——— in Vinegar, Estimation of, 414
Pyrites and Burned Pyrites, Copper in, Estimation of, 366
———, Arsenic in, Estimation of, 362
Pyrrol, Quantitative Estimation of Acetaldehyde by Means of, 157

Qualitative Analysis, Decomposition of Silicates by Fusion with Boric Acid as Applied to, 371
———————, Use of Logwood in. Estimation of Bismuth, 603
——————— without the Use of Hydrogen Sulphide, 517
Quantitative Fermentation Experiments, Flask for, 568
———— Separation by Means of "Cupferron," 520
Quinine, in Durgs, etc., Volumetric Estimation of, 143

Quinine, the Estimation of, as the Acid Citrate in Certain Organic Liquids, 396
Quinones, Volumetric Estimation of, by Means of Titanium Trichloride, 80
Quinonoid Imonium Salts of Benzidine, Estimation of the Activity of Oxidising Agents by Means of, 233

Racemic Acid as a Reagent (Precipitant of Calcium and Strontium), 365
Radioactivity, Apparatus for Measuring, 380
——— of Radium, the Measurement of, International Standard Units for, 35
Rapeseed Cakes, Green Colour of, 411
Raw Rubber, the Analytical Methods for, Critical Investigations on, 27
———, the Valuation of, Comparative Tests for, Proposed Uniform Method of Carrying out, 423
Raw Sugars and Other Products, the Polarisation of, upon Quartz Wedge Saccharimeters, Use of Temperature Corrections in, 297
Rays, Ultra-Violet, Sterilisation of Drinking Water by Means of, 457
Reagent Paper for the Volumetric Estimation of Zinc, 126
———, Schardinger's, Behaviour of, towards Colostrum, 221
———, Sulpho-Salicylic, Estimation of Nitrates in Water by, 85
Reagents, Blood, Influence of Metals in Presence of Hydrogen Peroxide on, 352
Recorder, Multiple Carbon Dioxide, 252
Recording Thermo-Electric Calorimeter, 312
Reducing Sugars, Estimation of, 298
Reductase and Oxydase Occurring in Cow's Milk, 16
——— Test, Comparison of, with Other Hygienic Tests for Milk, 346
Reduced Pressure, Rapid Electro-Analysis under, 601
Refined Copper, Exact Electrolytic Assay of. I. Standard Method, 172
Refractometer, Estimation of the Salinity of Sea Water by Means of the, 311
Refractometric Examinations, Thermostat for, 89
Refractory Tin Ores, Simple Method of Decomposing, 309
Regulator, Gas, for Thermostats, 127
Regulators, Gas-Pressure, Simple Forms of, 477
Reichert-Meissl Value of Fats, Estimation of, by Means of Glycerol-Potassium Hydroxide, 542
Report, Annual, of the Dominion Laboratory, Wellington, New Zealand (1909), 91
———, Composition of the Gases Caused by Blasting in Mines, 321
——— (Government Paper, Western Australia, 1911). Analysis of Potable Spirits, and its Bearing on the Definition of Whisky, 441
———, Metropolitan Water Board, 185
——— of the Malt Analysis Committee (Coloured Malts and Caramel), 1910, to the Council of the Institute of Brewing, 90
——— of the Principal Chemist upon the Work of the Government Laboratory for the Year ending March 31, 1911, with Appendices, 571
——— on a Parasite Condition (Onchocerciasis) Met with in Australian Beef, 129
——— on the Bleaching of Flour and the Addition of So-called "Improvers" to Flour, 254
——— on the Chemical Changes Produced in Flour by Bleaching, 254
——— on the Presence of Calcium Sulphate in Baking-Powder and Self-Raising Flour, 255
——— on the Solubility, Extraction, and Reactions of Certain Colouring Matters Used in Foods, 186
——— on the Work of Inspectors of Foods, 128
——— on the Work of the Laboratories, Survey Department, Egypt (1910), 532
——— to the Government of Western Australia, 1911, 321

Report to the Local Government Board on the Nutritive Value of Bread Made from Different Varieties of Flour, 479
———, United States Department of Agriculture, Bureau of Chemistry, Circular, 186
Residues from the Distillation of Coal Tar, Rosin in, Estimation of, 463
Resin, Dammar, Different Varieties of, Characteristics of, 422
—— in Glazed Coffee, Detection of, 275
——, Lac, from Baroda, India, 171
—— Oils and Hydrocarbon in Other Oils, Detection of, 513
Resins, Certain, Colour Reactions of, with Halphen's Reagent for Colophony, 170
Rice Oil, 357
Ricinus Constituents, Poisonous, in Fodder-Stuffs, Detection of, 506
Ripe and Unripe Bananas, Composition of, 274, 541
Rocks, Silicate, Ferrous Iron in, Determination of, 602
Roquefort Cheese, Composition of, 542
Rosin Essence, Turpentine Oil and Wood Turpentine Oil, Reaction of, 107
—— in Fatty Oils, Estimation of, 557
—— in the Residues from the Distillation of Coal Tar, Estimation of, 463
—— Oils in French Wool-Grease Oleines, Detection of, 30
Rubber Articles, "Mineral Rubber," and Similar Products in, Estimation of, 235
——————, Vulcanised, Caoutchouc in, Direct Estimation of, 113
———, Cearà, 424
———, Estimation of, as Tetrabromide. Decomposition of the Bromide by Nitric Acid, 361
——— Goods, Vulcanised, Caoutchouc in, Direct Estimation of, 75
——— Mixtures, Fillers (Mineral Matter) in, Estimation of, 558
——— of *Mascarenhasia elastica*, 160
———, Raw, the Analytical Methods for, Critical Investigations on, 27
the Valuation of, Proposed Uniform Method of Carrying Out Comparative Tests for, 423
--Seed Oil, Para, Composition of, 491
Stoppers, Substitute for, 610
Rum, Jamaica, Higher Alcohols Occurring in, 411
Rye and Wheat Bran, Customs Examination of, 350

Saccharimeters, Quartz Wedge, the Polarisation of Raw Sugars and Other Products upon, Use of Temperature Corrections in, 297
Saccharose, the Concentration of, Influence of the Viscosity on the Action of Invertase According to, 416
Safety Lamps, or Other Apparatus, for the Detection of Combustible Gases and Vapour, Methods of Testing, 528
Salicylate, Bismuth, Examination of, 342
Salicylic Acid, a Test for, Kobert's Reagent as, 540
—————, Action of, on Metallic Acids, 567
————— and Phenol, Sensitive Test for, 295
Detection of, 463
– in Fruit Juices, Estimation of, 411
Salinity of Sea Water, Estimation of, by Means of the Refractometer, 311
Salts, Aluminium, Free Acid and Basic Alumina in, Estimation of, 236
——, Ammonium, Elimination of, Prior to Estimation of Alkali Metals, 30
——, Iron, and Arsenic, in Mineral Waters, Estimation of, 466
——, Mercuric, Soluble, at Great Dilutions, Estimation of, 305
——, Natural Vichy, Characteristic Constituent of, 85
——, Nicotine, Analysis of, and of Tobacco Juice and Extracts, by the Method of Ulex, 545

Salts, Quinonoid Imonium, of Benzidine, Estimation of the Activity of Oxidising Agents by Means of, 233
——, Uranium, Reaction of, 180
Salvarsan, Detection of, 153
————, the Detection of, New Method for, 452
" Salvarsan," Titration of, with Iodine Solution, 350
Sampling of Coal in the Mine, 527
Sand, Monazite, from Travancore, India, 523
Sandal-Wood Oil, African, Adulterant of, 146
Sand's Apparatus, Electrolytic Estimating of Copper and Zinc, Using, 182
Sands, Monazite, Analysis of, 522
——, Rare Earth-Containing (" Amang ") from Malay States, 523
Santolina chamæcyparissus, Essential Oil of, 589
Saponification and Acid Values in Wax, Estimation of, Simplified Process for, 355
——————, the Glycerol Method of, Effect of, upon the Fatty Acids, 425
—————— Value of Oils, Fats, and Waxes, Estimation of. Use of Propyl Alcohol, 290
Sauerkraut, Composition of, 548
(Scandium, Separation of Thorium from). Detection and Estimation of Thorium by Means of Iodic Acid, 436
Schaeffer's Curd Tester, Control Tests of the Colour Tests Used with, 378
Schardinger's Reagent, Behaviour of, towards Colostrum, 221
Schinus molle (L.), Essential Oil of, 68
Schloesing's Method, Gasometric Estimation of Nitrate by, and of Nitrite by Piccini's Method, Some Sources of Error in, 525
Schweinfurt Green, Arsenic in, Estimation of, 363
Scrap, Coke Crucible, Estimation of Carborundum in, 31
Sealed Tube Reactions, Gas in, Detection of, 531
Seeds of Leguminous Plants Grown in Togo and German East Africa, Composition of, 345
—— of *Lophira alata* (Banks), the Fat from, Composition of, 493
—— of the Ash-Tree, Oil from, 357
—— of *Xanthophyllum lanceolatum*, Oil from, 406
Sensitive Indicator, 26
———— Test for Phenol and Salicylic Acid, 295
Sensitiveness of the Colorimetric Estimation of Titanium, 310
—————— Tests by the Impact Machine (Drop Hammer), 314
Separating Funnel, Modified, and Washer, for Heavy Liquids, 89
Serum, Egg, and Milk Albumins, Coagulating-Points of, and of Serum Globulin, in Ammonium Sulphate Solutions, 416
———-Precipitin and the So-called Erythro-Precipitin, the Biological Reactions with, for the Detection of Blood, Comparative Values of, 590
Sewage Effluents and Water, the Amount of Nitrite in, the Determination of, and of the Amount of Dissolved Oxygen Absorbed by Sewage Effluents Containing Nitrites, 393
Seychelles Cinnamon Bark, 217
Shellac and Shellac Varnish, Analysis of, 464
Shrewsbury and Knapp's Process for the Estimation of Cocoanut Oil, Examination of, 195
Silicate Rocks, Ferrous Iron in, Determination of, 602
Silicates, Decomposition of, by Fusion with Boric Acid as Applied to Qualitative Analysis, 371
——, Ferrous Oxide in, the Titration of, by the Pebal-Dölter Method, Note on, 372
[illegible] Acid, Hydrated, in Clay, Determination of, 85

Silicon Alloys, Dissolving, 178
———, Ferrotitanium Alloys Containing Much, Analysis of, 373
———, in Vanadium and Molybdenum, and in their Iron Alloys, Estimation of, 311
Silicotungstic Acid, Estimation of Aconitine by, 142
Silver and Cadmium, Rapid Determination of, by Means of the Gauze Cathode and Stationary Anode, 473
—— and Gold, in Ores Containing Much Copper, Pot Assay of, 240
—— Anode and Mercury Cathode, Electrolytic Determination of Chlorine in Hydrochloric Acid with the Use of, 33
——, Assay of, by Means of the Touchstone, 372
——, Estimation of, by Electrolysis of an Ammoniacal Solution of its Oxalate, 308
——, German, and Other Alloys, the Separation of Nickel and Zinc in, Method for, 524
——, Iodine, and Alkali, Volumetric Solutions of, Use of Sulphur Dioxide in Checking Strengths of, 248
—— Vanadate, Precipitation of Vanadic Acid as, and Estimation of Phosphoric and Vanadic Acids in Presence of Each Other, 35
Simon and Lohrisch's Method, Estimation of Cellulose by, 77
Sizing, Animal, in Paper, Detection of. Differentiation of Gelatin and Casein, 290
Slag, Basic, Phosphoric Oxide in, Citrate-Solubility of, 32
Smokeless Powder, Camphor in, Estimation of, 420
————————, Stability Tests of, 295
Soap, in Heavy Grease, Estimation of, 559
——, Total Fatty Acids in, Estimation of, 20
Soaps, Different, Germicidal and Insecticidal Values of, with or without Associated Active Agents, 505
——, Fat, and Oils, the Total Fatty Acids in, Estimation of, 115
——, Fats, and Oils, Train Oil in, Detection of, 359
——, Fatty Acids in, Estimation of, 355
—— of the Alkalis and Alkaline Earths, Estimation of Free Fatty Acids in the Presence of, 595
SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS, PROCEEDINGS OF, 2, 43, 95, 132, 195, 263, 327, 387, 445, 489, 535, 577
Soda-Water, 16
Sodium Carbonate and Trimethylphenylammonium Carbonate, Precipitation of Zinc, Manganese, Cobalt, Nickel, Copper, and Cadmium, from Ammoniacal Solutions by Means of, 599
———, Micro-Chemical Test for, 372
——— Nitroprusside, Colour Reaction of Proteins with, 235
——— Paratungstate, in the Estimation of Carbon Dioxide in Carbonates and Nitrogen Pentoxide in Nitrates by Loss on Ignition, Application of, 526
——— Thiosulphate as Standard in Alkalimetry, 435

Soil, Bacteriological Investigation of, 219
—— Phosphates, Solubility of, Effect of Ignition on, 371
Soils, Good and Poor, Dihydroxystearic Acid in, 504
——, Humus in, Estimation of, 597
——, the Electrical Conductivity of, Determination of, 183
——, the Examination of, Application of the Osmotic Pressure and Electrical Conductivity in, 184
Solid Hydride of Antimony, Attempts to Prepare, 300
—————— of Arsenic, Detection of, 300
Solids and Liquids, Vapour Pressures of, Static Method for Determining, 36

Soluble and Volatile Fatty Acids, Loss of, during the Ageing of Butter, 64
Solvents, Specifically Lighter, Automatic Extraction of Aqueous Liquids by Means of, 87
Soot, the Composition of, Note on, 120
Soxhlet Condenser, Improved, 528
Soya Bean Oil, 358
————, Composition of, 513
Spanish Marjoram (*Thymus mastichina*, L.), Essential Oil of, 69
——— Oil of Turpentine, 589
Sparteine, Reaction of, 559
Specific Gravities of their Components, Differences in, Quantitative Analysis of Mixtures by, 306
——— Gravity of Oils, Estimation of, 557
————— of Very Small Quantities of Milk, Determination of, 500
Specifications, Purchase of Coal under, 229
Spectroscopic Differentiation between Oxyhæmoglobin and Carbon Monoxide Hæmoglobin, and Hæmochromogen, 550
———— Test for Hæmoglobin in Urine, the Failure of, Hippuric Acid as a Cause of, 417
Spermaceti, Beeswax, Paraffin, etc., Fat in, Detection of, 496
Spirit, the Substitution of, for Aged Whisky, Detection of, 546
Spirits, Potable, the Analysis of, and its Bearing on the Definition of Whisky (Report), 441
———, the Analysis of, Colour Reactions of Aromatic Aldehydes and their Applicability in, 273
Spiritus Ætheris Nitrosi, Simple Volumetric Method for Testing, 454
Spongy Nickel, Preparation of, and the Precipitation of Nickel Compounds, 539
Stability (General) of Explosives in Various Countries, Methods of Testing, 79
——— Tests of Smokeless Powder, 295
Standard for Permanganate Solutions, Ferric Sulphate as, 520
——— in Alkalimetry, Sodium Thiosulphate as, 435
Standards in Acidimetry, Acids Suitable for Use as, 25
————, Portuguese, for Wines, Vinegar, and Olive Oil. (Extract from the Official Methods of Analysis), 502
Stannous Chloride, Estimation of Tungsten by Means of, 310
Starch and Glycogen, the Separation of, Method for, 501
———, Estimation of, 588
——— in Brewers' Grains, Estimation of, 500
———, Indigotin in the Presence of, Estimation of, 290
——— -Iodine Reaction, 28
——— Syrup, Commercial, the So-called Gallisin (Glucosin) Occurring in, Composition of, 543
————— in Jams, etc., Estimation of, 280
Static Method for Determining Vapour Pressures of Solids and Liquids, 36
Stearic and Palmitic Acids, Separation of Oleic Acid from, 23
Steel and Iron, Sulphur in, Volumetric Estimation of, 374
Vanadium in, Colorimetric Method for, 473
-, Carbon in, Estimation of, by Means of a Calorimetric Bomb, 562
-, Chrome Tungsten, Estimation of Chromium in, 83
-, Chromium in, Detection of, 428
-, Determination of Nickel in, Comparison of Methods for, 524
-, Nickel in, Rapid Estimation of, 373
Steels, Vanadium and Chrome-Vanadium, Manganese in, Estimation of, 604
——, ————————, Vanadium in, Determination of, 475

Sterilisation of Drinking Water by Means of Ultra-Violet Rays, 457
Stoppers, Rubber, Substitute for, 610
Stormer Viscosimeter, Consistency of Paints by the, 609
(Strontium and Calcium, Precipitant of), Racemic Acid as a Reagent, 365
————————, Sulphite Method for Separating and Identifying, 301
————, Barium, and Calcium, Quantitative Separation of, 364
————, Separation of, from Calcium, 247
Strychnine, Colorimetric Estimation of, 144
————, the Colour Reactions of, Influence of Certain Compounds upon, 296
Sublimed Sulphur, in a Mixture of Different Kinds of Sulphur, Estimation of, 374
Substitutes, and Cocaine, Identification of, 405
————, Turpentine, the Question of, a Further Contribution to, 207
Sucrose, Estimation of, and the Detection of Dextrin in Foods, 588
———, in Beet Sugar Factory Products, Determination of, by Clerget's Process, Using Invertase as Hydrolyst, 120

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE ordinary monthly meeting of the Society was held on Wednesday evening, December 7, in the Chemical Society's Rooms, Burlington House. In the absence of the President, the chair was occupied by Mr. A. E. Ekins, F.I.C., Vice-President.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. C. L. L. Claremont, B.Sc., A.I.C., and H. D. Elkington, were read for the second time; and certificates in favour of Messrs. Ronald Leslie Collett, B.A. (Cantab.), A.I.C., Little Dawley, Hayes, Middlesex, assistant to Mr. A. Chaston Chapman, F.I.C.; William Beaverley Cowie, 26, Clyde Street, Edinburgh; Frank Evershed, analyst and consulting chemist to Messrs. Clarke, Nicholls and Coombs, Ltd., Victoria Park, London, N.E.; and George Taylor, 6, Vicarage Park, Plumstead, S.E., assistant to Dr. Bernard Dyer, F.I.C., were read for the first time.

Messrs. G. Jörgensen and F. F. Shelley, F.I.C., were elected members of the Society.

The following papers were read: "On Fischer's Modification of Volhard's Method for the Estimation of Manganese, and its Comparison with Other Well-known Methods," by Edward Cahen, A.R.C.Sc., F.I.C., and Harry F. V. Little, A.R.C.Sc., B.Sc.; "A New Volumetric Process for the Estimation of Tungsten," by E. Knecht, Ph.D., F.I.C., and Miss E. Hibbert; "A New Volumetric Process for the Estimation of Molybdenum," by E. Knecht, Ph.D., F.I.C., and F. W. Atack; "Note on the Composition of British Wines," by Edward Russell, B.Sc., F.I.C., and T. R. Hodgson, M.A., F.I.C.; "The Degree of Accuracy with which the Proteins of Milk can be Estimated by the Aldehyde Method," by H. Droop Richmond, F.I.C.; "Note on Gorgonzola Cheese," by Edward Hinks, B.Sc., F.I.C.; "Tests for Cocaine and Certain Cocaine Substitutes," by E. H. Hankin, M.A., Sc.D.; and "Some Analyses of *Hevea* Latex," by Clayton Beadle and Henry P. Stevens, M.A., Ph.D., F.I.C.

* * * * *

TESTS FOR COCAINE AND CERTAIN OTHER ANÆSTHETICS.

BY E. H. HANKIN, M.A., Sc.D.

(*Read at the Meeting, December* 7, 1910.)

COCAINE is a substance the tests for which do not work so well in practice as might be expected from textbook statements. Even the permanganate test, which is stated to be delicate, should, according to Autenreith ("Detection of Poisons," translated by Warren, p. 85), be carried out with a concentrated aqueous solution of a cocaine salt. I have discovered some modifications of this test, by means of which extremely minute quantities of cocaine can be readily detected, and also clearly distinguished from tropacocaine and other allied cocaine substitutes.

If a drop of a solution of cocaine and a drop of a solution of permanganate of potassium are placed together on a glass slide, it frequently happens that on microscopical examination no crystals of cocaine permanganate are seen, but only a dark red viscous mass. If the two drops, however, are rubbed together at the moment of mixing with a glass rod, so that the red coagulum is pressed and squeezed, there is a much greater chance of the characteristic crystals of cocaine permanganate being formed. I noticed also that the formation of the crystals was hindered by any condition that tended to dilute the cocaine. To prevent this effect, I tried precipitating the cocaine by the addition of ammonia before the addition of the permanganate. This I found to be advantageous, especially when dealing with minute quantities. The delicacy of the test was found to be increased by the substitution of bromine-water for ammonia. A trace of cocaine is placed on a glass slide in a minute drop of a one-third or one-quarter saturated solution of bromine in water. A drop of an acid solution of permanganate (4 per cent. potassium permanganate and 3 per cent. sulphuric acid freshly mixed) is added. If the drops are mixed thoroughly, the formation of crystals is generally immediate. If the drops are not thoroughly mixed, the cocaine permanganate crystals are usually formed more slowly, and may take the form of large branched aggregates that give a remarkable play of colour with polarised light.

In a case of cocaine smuggling, I received for examination the ashes of a fire in which cocaine was suspected to have been burnt. Embedded in the ashes was a piece of paper about an inch square that was charred only along one edge. Small pieces of this paper, only a few millimetres square, treated with sufficient bromine-water to wet them, and then placed on a glass slide with the acid permanganate solution, in four cases out of five gave typical crystals of cocaine permanganate. I also obtained permanganate of cocaine crystals from the Stas-Otto alkaline ether extract of a portion of the ashes.

Though the test as thus carried out is extremely delicate, it cannot be regarded as reliable. Some unknown factors appear to come into play, perhaps connected with the relative amounts of the different reagents, which may in certain cases hinder or prevent the formation of the crystals.

While trying the action of permanganate on certain cocaine substitutes, I discovered an improved method of carrying out the test. I found that in the case of scopolamine, with a dilute solution of permanganate, oily red drops were produced; while if a stronger solution of permanganate was employed, crystals of permanganate of scopolamine were frequently formed. This clue led me to a better method of applying the permanganate. A drop of a strong solution of permanganate was spread out on a glass slide and allowed to dry. The "permanganate film" thus produced was found to be of use in testing, not only for cocaine, but also for certain cocaine substitutes. As will be described below, if a drop of a solution of either alypin, tropacocaine, or scopolamine, is placed on such a permanganate film, covered with a coverslip, and examined with the microscope, characteristic crystals of the permanganate compounds will, as a rule, be seen. On applying this method to cocaine, I found that generally no crystals, but only oily red drops, were produced. It occurred to me to attempt to delay or modify the action of the permanganate by the addition of some indifferent salt. I found that a saturated or half-saturated solution of alum was suitable for the purpose. If a trace of cocaine is dissolved in a saturated solution of alum, and a small drop of this solution is placed on a permanganate film, and covered with a coverslip (which should be dropped into position, and not rubbed about), then, within a minute or two, numerous crystals of cocaine permanganate are formed. This test is extremely delicate, reliable, and easy to carry out. I have had the following opportunities of using it practically:

In a case of illicit dealing in cocaine, the culprit appears to have received information beforehand that his shop was to be raided. Consequently the police found no cocaine. But, by the alum method above described, cocaine was detected by me on ten out of eleven pieces of paper that had been found, and that were supposed by the police to have been used in wrapping up doses of cocaine. In carrying out the test, from the centre of each piece of paper I cut out as small a fragment as could readily be handled with a forceps. This fragment was placed for a minute in a small drop of alum solution, then removed, and the drop of alum solution was transferred to a permanganate film. On covering with a coverslip and examining under the microscope, numerous cocaine permanganate crystals were seen to develop. After carrying out the test, I asked my assistant, Dr. Gore, to repeat my observation. Although his acquaintance with this test was confined to my description, he succeeded in obtaining permanganate crystals from each of the eleven pieces of paper. In another case a telegraph form was sent for examination. On this was a stain, supposed to be of saliva, of a person who had taken cocaine. Scrapings of this stain suspended in alum solution gave the cocaine permanganate reaction.

On applying the permanganate test to various cocaine substitutes, I obtained results that may be summarised as follows:

1. Cocaine and alypin form crystals that often have the form of delicate pink plates.
2. Tropacocaine easily forms crystals that usually have a red or dark red colour.
3. Scopolamine forms with difficulty crystals of red colour.
4. Beta-eucaine and stovaine form reddish oily drops, but no crystals.
5. Novocaine, holocaine, and nirvanine, turn brown instantaneously, with formation of finely granular brown precipitate.

In each of the above four cases in which crystals are formed, these may occur as isolated plates or prisms, or as rosettes, or as larger aggregates. But the crystals differ both in appearance and in the conditions of their formation. The following are details of my observations:

1. *Cocaine.*—As already stated, cocaine permanganate crystals are best formed on a permanganate film, the cocaine having been dissolved in a saturated solution of alum. They are less readily formed, or may not appear at all, if the cocaine is dissolved in water. They are still less likely to develop if the cocaine is dissolved in a strong solution of potassium bromide. Single cocaine permanganate crystals are nearly square in shape. Larger aggregates of these crystals usually have right-angled notches or indentations. In testing for lactate of cocaine, it is advisable to treat its solution with ammonia and shake up with ether. The ether is placed in a

separating funnel and shaken with a small quantity of a solution of alum. The cocaine passes into the alum solution, which may then be separated and tested with a permanganate film.

2. *Alypin.*—These crystals are best formed on a permanganate film. They are most easily obtained if the alypin is dissolved in water. If the alypin is dissolved in a strong solution of potassium bromide, the crystals form readily (differing thus from cocaine), and often assume the form of isolated plates or small rosettes. When alypin is used dissolved in water, the crystals usually take the form of irregular branched aggregates or narrow and dented plates and spikes. Alypin does not readily form permanganate crystals when dissolved in a solution of alum.

3. *Tropacocaine.*—Tropacocaine forms crystals with permanganate more readily and under a greater variety of conditions than any other cocaine substitute. If a minute quantity of tropacocaine is dissolved in a saturated solution of alum and placed on a permanganate film, crystal aggregates are formed of reddish-violet colour, and which, being usually curved, have a feathery or fernlike appearance. If a drop of a dilute aqueous solution of tropacocaine is mixed with a drop of a dilute solution of permanganate, isolated crystals or smaller crystalline aggregates are deposited. These are of varying or irregular shape. In some cases they are of oblong outline, with a slight curvature difficult to see along one side.

4. *Scopolamine.*—Scopolamine permanganate is less easy to obtain in the crystalline form than any of the previously described substances. It is necessary to use a strong aqueous solution and a permanganate film. With more dilute solutions only a granular precipitate or oily drops are, as a rule, obtained. The crystals are dark red in colour usually, and of very variable form. Sometimes they occur as prisms pointed at both ends, thus having an irregular hexagonal outline, or the prisms are pointed at one end and blunt at the other. Smaller crystals may be of irregular oblong shape. Larger aggregates are not often seen.

5. *Saporetti's Bromine Test applied to Other Cocaine Substitutes.*—Saporetti's observation of the effect of bromine-water on cocaine substitutes furnishes a test applicable in those cases in which permanganate is not of use. "Intorno ad una nuova reazione distintiva fra eucaina-alpha e beta. Differenziazone fra cocaina e suoi succedanei" (*Bolletino Chemico-Farmaceutico*, July, 1909, p. 479).

According to Saporetti, bromine-water has the following actions, which accord with my own observations:

1. With cocaine, scopolamine, stovaine, and novocaine, a yellow precipitate is produced, soluble on warming.

2. With beta-eucaine, a yellow precipitate partly soluble on warming, but which comes down again as a white precipitate on boiling.

3. With nirvanine, a yellow precipitate soluble on warming. The liquid then acquires a reddish colour and emits a pleasant smell.

4. With holocaine (not mentioned by Saporetti), I find that bromine-water produces a yellow precipitate. On boiling, the yellow precipitate is dissolved, and the liquid acquires a pinkish-white opalescence.

Conclusions.—1. The permanganate test for cocaine is of great delicacy if, as above described, the cocaine is dissolved in alum solution and the permanganate is used in the form of a dried film.

2. The test forms a ready means of distinguishing between cocaine and certain cocaine substitutes.

3. Of these substitutes, alypin, tropacocaine, and scopolamine, form crystalline permanganates, which can be readily distinguished from each other and from the permanganate of cocaine.

4. Beta-eucaine, stovaine, novocaine, holocaine, and nirvanine, form no crystals with permanganate. Saporetti's bromine-water test furnishes a means of distinguishing these substances.

SOME ANALYSES OF HEVEA LATEX.

BY CLAYTON BEADLE AND HENRY P. STEVENS.

(*Read at the Meeting, December* 7, 1910.)

AMONG the few analyses of *Hevea Braziliensis* latex which have been published, we should like to refer to an analysis of Faraday's, as it is incorrectly quoted in Weber's "The Chemistry of India Rubber," from which it has been copied from one textbook to another, and has just appeared again with the same errors in Hinrichsen and Memmler's "Der Kautschuk und seine Prüfung." The analysis is invariably quoted as that of the latex of *Hevea Braziliensis*, while no statement is made as to its botanical origin in Faraday's original paper (*Quarterly J. of Science*, 1826, **21**, 19); we are only told that it came from Mexico. One of us has experimented with latices of various origins in the East, and we have little doubt but that the latex analysed by Faraday was derived from the *Castilloa elastica.* We base this opinion on the data given by Faraday, who found the sp. gr. to be greater than that of water, while the sp. gr. of *Hevea* latex is always less than unity. Faraday's description of the creaming of his latex, on which he based a method for removing the water-soluble constituents, is characteristic of *Castilloa* latex. It is the principle employed at the present day for the preparation of this class of rubber in Mexico. It is hardly necessary to labour this point any further, beyond mentioning, as further characteristics of *Castilloa* latex, the dark colour, bitter taste, acid reaction, and excellent state of preservation, all of which are noted by Faraday in the paper mentioned above.

The more recent analyses have been carried out in Europe on samples of latex to which a preservative had been added, and there is no guarantee that the latex was either (1) free from added water, or (2) an average sample.

As regards the first point, the common practice of putting a little water in the collecting cups, as well as the possibility of showers during tapping, makes it extremely likely that the analyses, so far published, show too high a percentage of water.

As to the second point, latex from trees to all appearance of similar size and girth, growing in the immediate neighbourhood of one another, give results, on analysis, showing considerable variation in percentage of dry solids. It is therefore necessary to carefully supervise the collection of latex, and to work on the average latex from a large number of trees.

The determinations made consisted of total dry solids, total caoutchouc, and the ordinary commercial analysis of the latex, including the figures for acetone extract, nitrogen, and ash. For the total solids, a weighed quantity of the latex (about 10 c.c.) was evaporated at about 80° C., and then dried in a steam-oven at 100° C. till it ceased to lose weight. The total caoutchouc was obtained by pouring a weighed quantity of latex (about 10 c.c.), in a thin stream, into 50 c.c. of alcohol. After standing, the coagulum was removed, pressed, and dried at 100° C. For further analysis, the total solids obtained as described were put into a small stoppered bottle with well-fitting stopper, and sent home. The acetone extract (resin), the protein (N × 6·25),* and the ash, were estimated in the usual manner.

The percentage of total solids and caoutchouc depends on the manner and frequency of tapping. For trees of an average age of seven or eight years, lightly tapped every other day, the total dry solids were found to be approximately 40 per cent. The sp. gr. varied from 0·980 to 0·972. In another series of experiments where the same trees were more heavily tapped, the total dry solids were approximately 30 per cent. The total solids in the latex, other than caoutchouc, amount to about 2½ per cent. on the latex, so that by subtracting 2·5 from the figure for total dry solids, we obtain the approximate figure for caoutchouc. Of the samples examined, the highest figure for caoutchouc was 43 per cent., and the lowest 18·5 per cent. In all cases the latex analysed was the mixed product of at least one hundred trees. The figures are taken from results obtained when tapping in dry weather only, and in no case was any water put into the cups or added to the latex.

As to the influence, if any, of the age of the tree on the composition of the latex, it is well known to all rubber planters that when tapped for the first time the young *Hevea* tree yields very little latex during the first few days, the amount gradually increasing until, after a time, it remains constant round about a certain figure. Determinations carried out on trees about four years of age, and just brought into tapping, yielded in one series of experiments 22 to 25 per cent., and in another 27 to 33 per cent. of dry rubber in the latex. The trees were tapped every day and on different systems, but not heavily. The results are the average figures over periods of some months. The figures, taken in conjunction with others, where the trees were older, but tapped under similar conditions, show that the latex from very young trees is poorer in caoutchouc than that from older trees.

An examination was made of latex from the primary tissue of the leaves and stems of leaves. If the stem of a leaf be snapped in two, a drop of latex exudes from the exposed tissue. This rapidly coagulates, owing to the abundant acid juices in the sap vessels, which are broken at the same time. The tiny clot of rubber can be picked off with a small pair of tweezers. From several hundred leaves sufficient of the coagulated latex was obtained for analysis. Owing to the rapid coagulation just referred to, the amount of moisture could not be determined; but the mass was dried and analysed in the ordinary manner. The dried latex is at first rather tacky; but on keeping a month or two, and passing once or twice between steel rolls, it is no longer adhesive, and somewhat resembles a high-class purified guayule rubber. It is pale in colour, but rather soft, and much weaker than the rubber from the bark of mature trees. The analyses of this material, together with those of dried latex from four- and ten-year-old trees, are given below.

---

* This factor, as Spence has shown, is probably too high; but as the proteins of rubber have not yet been isolated, the above figure is adhered to. This course has also the advantage of allowing a comparison to be drawn between our analytical results and those of previous workers.

Analyses of the latex are also given for trees of these ages, taking the percentage of moisture 70 per cent. and 60 per cent. respectively, these being the figures arrived at for average results when trees are tapped on a conservative basis. The dried latex contained about 1 per cent. of moisture, but in the analyses the figures are given as calculated for dry material.

	Dried Latex from Stems of Leaves.	Dried Latex from Trees Four Years Old.	Dried Latex from Trees Ten Years Old.
	Per Cent.	Per Cent.	Per Cent.
Acetone extract (resin) ...	7·12	4·06	4·13
Protein	13·02	4·90	5·08
Ash	1·19	0·80	1·75
Caoutchouc (by difference) ...	78·67	90·24	89·04

COMPOSITION OF LATEX.

	Trees Four Years Old. Per Cent.	Trees Ten Years Old. Per Cent.
Water...	70·00	60·00
Acetone extract (resin) ...	1·22	1·65
Protein	1·47	2·03
Ash	0·24	0·70
Caoutchouc (by difference)...	27·07	35·62

We have also examined the aqueous extracts from the total solids of the above latices in respect of their reducing action on Fehling's solution, and have obtained the following results calculated in terms of glucose on the rubber:

	Before Inversion.	After Inversion.
	Per Cent.	Per Cent.
Latex from ten-year-old trees	None	0·34
„ „ four „ „	Trace	0·79
„ „ the petioles or leaf-bases	0·36	2·25

These figures are interesting, as pointing to the much larger percentages of carbohydrates contained in the latex from primary tissue; they are, however, only of relative value, and do not show the actual amounts of sugars in the original latices, as these are partially destroyed by evaporation of the latex to dryness.

The appearance under the microscope of the latex from the petioles of leaves is interesting and suggestive. A relatively small number of caoutchouc globules are to be seen of the ordinary appearance. These stand out brightly, on a groundwork composed of a much larger number of smaller globules of about one-third of the average size of the caoutchouc globules. These small globules are in rapid Brownian movement, and are not so well defined as the caoutchouc globules, having, apparently, a much lower refractive index.

It is interesting to note that the solids contained in the latex from the petioles differ from that from the bark, chiefly in the much higher content of nitrogenous matter. There is also nearly another 3 per cent. of resins or other matter soluble in acetone. The acetone extracted rubber from the latex of the petioles, when allowed to stand for a few months, is fairly tough and elastic, and resembles rubber from the bark of mature trees similarly treated.

THE DEGREE OF ACCURACY WITH WHICH PROTEINS CAN BE ESTIMATED IN MILK BY ALDEHYDE TITRATION.

BY H. DROOP RICHMOND, F.I.C.

(*Read at the Meeting, December* 7, 1910.)

IN a paper on the aldehyde figure of milk, Steinegger (*Zeitsch. Untersuch f. Nahr. Genussm.*, 1905, **9**, 659) gave some determinations showing that this figure was approximately proportional to the total nitrogen. Miller and I (ANALYST, 1906, **31**, 224) modified Steinegger's procedure chiefly by substituting strontia for soda solution as the alkali used for titration, and under our conditions we found a higher "aldehyde figure" than that yielded by soda titration, the ratio being approximately 1·1, but not being constant; we attributed this to the degree of dissociation of the sodium and strontium salts differing.

While the correctness of this view is strengthened by the conclusions of J. B. Robertson (*J. Phys. Chem.*, 1910, **14**, 601), I find that there is another disturbing factor. Formaldehyde solution is almost invariably acid, and when the strong solution is neutralised to phenolphthalein with soda, and then diluted with neutral water, it becomes appreciably alkaline; while, if neutralised with strontia, the reaction is unaltered by dilution. This fact alone would cause the soda aldehyde figure to be lower, to an extent varying with the acidity of the formaldehyde solution, than the strontia figure. I have also found that the amount of formaldehyde recommended by Steinegger (*loc. cit.*) as developing the maximum acidity (6 per cent. of 40 per cent. formaldehyde solution) is not quite sufficient, as the addition of larger quantities results in the development of slightly more acidity.

From the experiments of Miller and myself (*loc. cit.*), I deduced the factor 0·171 for converting aldehyde figures (expressed as c.c. of $\frac{N}{1}$ alkali per litre of milk) into percentages of proteins. As we showed that there was a considerable difference between the aldehyde factors of casein and albumin, it is evident that if a protein estimation is to be calculated from the aldehyde figure, it must be assumed that the ratio of casein to albumin does not appreciably vary, and that other proteins must be present in negligibly small quantities. Among these other proteins must be included the products of hydrolysis due to the action of micro-organisms or of enzymes. Miller and I (ANALYST, 1906, **31**, 328; 1908, **33**, 115) have shown that as milk ages the aldehyde figure rises, doubtless from this cause.

Although we used more formaldehyde than the amount recommended by Steinegger, further experience has led me to believe that we may not in all cases, especially with high aldehyde figures, have employed enough, and again, in some cases we used milks which were of some age; these causes would lead to errors in opposite directions.

I have carried out a series of determinations following the method given below, and using only fresh milk, with the object of ascertaining the agreement between duplicate determinations and the constancy of the factor.

The method is: To 10 or 11 c.c. of milk at least 1 c.c. of 0·5 per cent. phenolphthaleïn solution is added, and the milk neutralised with $\frac{N}{11}$ (approximately) strontia solution; to the faintly pink liquid 2 c.c. or more of Schering's 40 per cent. formaldehyde solution is added, and the titration continued till the same degree of pink colour appears. After deducting the acidity of the formaldehyde solution, the latter titration represents the aldehyde figure. At the same time an estimation of nitrogen by the Kjeldahl method is made, and the proteins calculated by the factor 6·38.

In the experiments given all the aldehyde determinations are the mean of two, three, or, in one case, four titrations. The worst experiment was this: 20·2°, 19·8°, 20·2°, and 21·0°, a maximum difference of 1·2°; while the best consisted of three concordant figures. From forty-eight experiments the probable error of a single titration was calculated to be ± 0·2°.

The table below gives the experiments:

Aldehyde Figure C.C. $\frac{N}{1}$ Acid per Litre.	Proteins N × 6·38.	Ratio $\frac{P}{A}$.	Proteins Calculated.	Difference.
6·6	1·16	0·176	1·12	−0·04
10·1	1·74	0·172	1·72	−0·02
13·6	2·31	0·170	2·31	—
16·1	2·76	0·171	2·74	−0·02
16·8	2·88	0·171	2·86	−0·02
18·5	3·13	0·169	3·14	+0·01
19·0	3·22	0·1695	3·23	+0·01
19·5	3·38	0·173	3·32	−0·06
19·6	3·40	0·174	3·33	−0·07
19·7	3·38	0·172	3·35	−0·03
20·2	3·44	0·1705	3·43	−0·01
20·2	3·47	0·172	3·43	−0·04
20·3	3·44	0·1695	3·45	+0·01
21·4	3·73	0·174	3·64	−0·09
21·7	3·66	0·169	3·69	+0·03
24·0	3·95	0·165	4·08	+0·13
25·0	4·15	0·166	4·25	+0·10
23·7	4·54	0·192	4·03	−0·51

The last sample was of abnormal composition—

Sp. Gr.	Total Solids.	Fat.	Milk Sugar.	Proteins.	Ash.	Solids-not-Fat.	Acidity.
1·0283	13·20	5·00	2·87	4·54	0·89	8·20	12·0°

and I have excluded it from the figures used for calculating the mean factor, not only on this account, but because it would be excluded by the application of Chauvenet's criterion (*cf.* Mellor's "Higher Mathematics," p. 476). A roughly quantitative estimation showed that the nature of the proteins was abnormal.

From the remainder of the figures I calculate the factor 0·170 as the most probable figure to express the relation between proteins and aldehyde figure, which is in practical agreement with that formerly deduced. The maximum errors given in the table are +0·13 and −0·09, and the maximum errors of single determinations are +0·20 and −0·13.

In the experiments given above I have searched for milks which depart from the average as much as possible, and have tried to avoid mixed milks of average composition. I am therefore justified in concluding that the aldehyde determination gives a very rapid and approximately accurate determination of the proteins in milk, with the reservation that with rare abnormal samples the error is considerable. I consider that the method is of the same order of accuracy as the centrifugal methods for the estimation of fat, or the calculation method of deducing the solids-not-fat from fat and specific gravity.

DISCUSSION.

Mr. C. REVIS said that lately he had been making some comparative experiments on the estimation of casein, and had found the aldehyde method to be second in accuracy to the method of precipitation with magnesium sulphate. Personally he preferred soda to strontia for neutralising the acidity of the milk. The factor for calculation was different, but the final results were the same. The extraordinary results obtained in the case to which Mr. Richmond had drawn special attention were no doubt due, not to any fault in the method, but to abnormality of the sample. From its composition he should imagine that the cow had either been abnormally long in milk or was emaciated from disease. He should be inclined to think that the proteins in this case did not consist simply of casein and albumin, but included other proteins, the presence of which was due to disease.

Mr. L. M. NASH asked whether it would be possible to distinguish by means of the aldehyde figure between coagulable and non-coagulable proteins—that is to say, to determine the percentage of casein in presence of lact-albumin, or to determine the percentage of actual casein in commercial casein.

Mr. H. D. RICHMOND said that his reasons for preferring strontia to soda for aldehyde titration had been given in the paper; but, of course, soda could be used if a different factor were employed. In the case of the abnormal sample the suggestion of disease was not tenable, because the cows were regularly examined by a veterinary surgeon and reported healthy. Coagulable and non-coagulable proteins could not be distinguished by this method, because it was simply a method for estimating the acidity developed on the addition of formaldehyde to proteins, and, since both casein and albumin contained amino-acid groups, they both gave the reaction, though their aldehyde figures were not the same. He had, however, used the method for the approximate determination of the proteins in commercial casein, but, since the total volume of alkali used was only 3 or 4 c.c., the results, with a substance that might contain 70 per cent. of casein, could not be expected to be very accurate.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Analysis of Commercial Absinthe. L. Ronnet. (*Ann. Falsif.*, 1910, **3**, 477-480.)—The following process is recommended for the analysis of absinthe and other similar liqueurs, as, in addition to the estimation of the quantity of "essences" present, it affords a means of ascertaining whether brandy or commercial alcohol has been employed in the preparation of the liqueur. A volume of 250 c.c. of the sample is rinsed into a flask with 25 c.c. of water and distilled, 245 c.c. of distillate being collected. The distillate is then diluted with water to a volume of 250 c.c., and the alcoholic strength of the solution is determined (according to French law absinthe liqueur must not contain more than 65 per cent. of alcohol). The iodine absorption of the distillate is now determined, 50 c.c. of the distillate being treated with Hübl's solution for this purpose. As 1 grm. of the mixed oils constituting the "essences" present in absinthe absorbs 1·328 grms. of iodine, the quantity of "essences" in the sample may be calculated from the iodine absorption found (French law requires that not more than 3·5 grms. of total "essences" nor more than 1 grm. of wormwood oil shall be present per litre of liqueur). The remainder of the distillate is now diluted with water until it contains exactly 50 per cent. of alcohol, and 200 c.c. of the dilute alcoholic solution thus obtained are shaken in a separating funnel with about 50 c.c. of olive oil (by volume) which has been washed previously with alcohol, and dried. When separation has taken place, the alcoholic solution is drawn off, and the quantities of aldehyde, furfural, higher alcohols, esters, and acids contained in it are estimated, the usual methods being employed for this purpose. The author has ascertained by experiment that this treatment with oil does not introduce any error in the estimation of these compounds; he also finds that one extraction with olive oil is sufficient to remove the total quantity of "essences" present.

The process may be applied to the analysis of the liqueurs known as "aperitifs amers," the "essences" in which consist chiefly of orange oil; 1 grm. of this oil absorbs 3·42 grms. of iodine, and the amount of "essence" in a sample is calculated accordingly from the iodine absorption. W. P. S.

Detection of Benzoic Acid in Flesh and Fats. K. Fisher and O. Gruenert. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 580-583.)—The following process is described as being an improvement on the method recommended previously by the authors (ANALYST, 1909, **34**, 394). Fifty grms. of the sample (*e.g.*, butter) are shaken with 150 c.c. of a 1 per cent. sodium bicarbonate solution at a temperature sufficiently high to keep the fat in a molten condition. The aqueous solution, while still hot, is separated from the fatty layer and neutralised by the addition of sulphuric acid. Ten c.c. of Fehling's copper sulphate solution, and 10 c.c. of a 3·11 per cent. potassium hydroxide solution are added, and the mixture is filtered. If the mixture be only slightly acid or alkaline in reaction, a clear filtrate is always obtained. This filtrate is then acidified with sulphuric acid, and the benzoic acid is extracted with ether, the benzoic acid obtained being identified by various tests. For the latter purpose Mohler's test as modified by Halphen (ANALYST, 1908, **33**, 420) may be employed. The authors find that this test will not detect the presence of small quantities of benzoic acid in butter unless the benzoic acid has been separated in a pure condition, as above described. A test proposed by Jonescu (*J. Pharm. Chim.*, 1909, **29**, 523), in which the benzoic acid is converted into salicylic acid by the action of hydrogen peroxide, the salicylic acid formed being then detected by the addition of ferric chloride, is also trustworthy, and will detect as little as 0·006 per cent. of benzoic acid in butter. W. P. S.

Analysis of Meat-Juices. K. Micko. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 537-564.)—The present paper deals mainly with means for distinguishing between genuine meat-juices and those products which consist of mixtures of meat-juice, meat-extract, and egg-albumin. For the purpose of detecting the presence of egg-albumin in a sample of meat-juice, advantage is taken of the different temperatures at which meat-albumin and egg-albumin coagulate. The coagulating-point of meat-juice itself varies considerably, and may be as low as 40° C. It contains several different albumins, which coagulate at temperatures varying from 56° C. to 75° C., and other factors also have an influence on this point. As the proportion of salts present has a considerable effect on the coagulation of the albumins, the author recommends that the coagulating-point be determined after the addition of a definite quantity of salt such as ammonium sulphate. Treatment of the meat-juice with ammonium sulphate has the advantage that a clear filtrate is obtained after filtering the mixture, in which the coagulating-point of the albumin may be observed readily. Usually two points are observed when such a solution is heated, one at which a turbidity is developed, and another, at a somewhat higher temperature, when a flocculent precipitate forms. The author terms these the lower and higher coagulating-points of the mixture. When a solution of egg-albumin is mixed with an equal volume of a saturated solution of ammonium sulphate, and the mixture is treated with an equal volume of water (the whole is thus one quarter saturated with ammonium sulphate), the solution becomes turbid when heated to about 60° C., and a precipitate forms before the temperature reaches 70° C. In the case of meat-juices similarly treated, the higher coagulating-point is about 80° C. Another characteristic difference in the coagulating-points of the two albumins is observed when their solution is mixed with its own volume of a saturated ammonium sulphate solution, and a 4 per cent. solution of acetic acid is added. Egg-albumin remains quite clear for a period of fifteen minutes or longer, whilst meat-juice becomes turbid at once, and a precipitate forms after a time. If heat has been employed in the preparation of the meat-juice, the turbidity may not develop for a few minutes, owing to the smaller proportion of albumin present. The presence of meat-extract lowers the coagulating-point of meat-juice which has been treated with an equal volume of a saturated solution of ammonium sulphate, but the addition of an equal volume of water raises the coagulating-point once more to about 80° C. This fact allows mixtures consisting of meat-juice and meat-extract to be distinguished from preparations containing egg-albumin. Analyses are given of various commercial meat-juices. The results obtained show that real meat-juices contain but very small quantities of albumoses as compared with liquid preparations which consist essentially of diluted meat-extract. The species of animal from which any given meat-juice has been prepared may be more or less definitely determined by means of a serum test (ANALYST, 1904, 29, 11).

W. P. S.

Wendler's Method for the Estimation of Fat in Milk. F. E. Nottbohm and J. Angerhausen. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 495-498.)—The authors have investigated the "Neusal" method, described recently by Wendler (*Molkereizeit. Hildesheim*, 1910, **24**, 690), for the estimation of fat in milk. The milk is treated in a Gerber butyrometer tube with a proprietary saline solution and alcohol, and is then submitted to centrifugal action. The average difference between the results found by the new process and those of the Gottlieb method in the estimation of the fat in thirty-one samples of whole and skimmed milk was +0·045 per cent. The method works well with milks containing preservatives, the casein dissolving readily even in the presence of considerable quantities of formaldehyde, but there is considerable difficulty in the case of boiled milk. W. P. S.

Volumetric Estimation of Phenolphthaleïn. V. Zotier. (*Bull. Soc. chim.*, 1910 [iv.], **7**, 993-995.)—The following method of estimating phenolphthaleïn now so largely used in pharmacy is recommended: The weighed quantity (0·1 to 0·2 grm.) of the sample is triturated with a few fragments of sodium hydroxide (free from carbonate), the mixture dissolved in a few c.c. of water, and the solution filtered. The filtrate and washings are made up to 50 c.c., and 25 c.c. of the liquid treated with hydrochloric acid, which is added drop by drop until the phenolphthaleïn begins to precipitate. The precipitate is redissolved by the addition of the exact quantity of $\frac{N}{10}$ sodium hydroxide solution, and the solution titrated with $\frac{N}{10}$ sulphuric acid, with vigorous shaking after each addition of the acid. If n represent the number of c.c. of acid consumed, and v the volume of the solution at the end of the reaction, the amount of phenolphthaleïn in grams may be found by means of the expression—

$$2[(n \times 1{\cdot}59) + (v - n)0{\cdot}0092].$$

C. A. M.

Philippine Terpenes and Essential Oils. IV. R. F. Bacon. (*Philippine J. Science*, 1910, 5, 257-265.)—The following volatile oils are described:

Cinnamon Bark Oil (from bark of *Cinnamomum mindanaense*, Elmer).—This bark, which strongly resembles commercial (Ceylon) cinnamon in its characters, yields at least 0·4 per cent. of a yellow oil, of cinnamon-like odour, having the following characters: Sp. gr., 0·960 at $\frac{30°}{30°}$ C.; $[n]_{D\,30°C.}$ 1·5300; $[\alpha]_{D\,30°C.}$, +7·9°; cinnamic aldehyde content, 60 per cent.

Oil from Elemi Resin (from resin of *Canarium villosum*).—Eleven per cent. of volatile oil is obtained by distillation under reduced pressure. About 25 per cent. of the oil distils at 154° to 158° C., and the oil contains *d*-pinene in considerable quantity, dipentene (small amount), and *p*-cymene. The aqueous distillate contains formic acid. Different trees yield resins containing differing terpenes, pinene, cymene, and phellandrene being among the number.

Ginger Oil.—The Philippine ginger roots (from *Zingiber officinale*) yield 0·07 per cent. of a light yellow oil, having an odour of ginger and orange. Sp. gr. 0·885 $\frac{30°}{30°}$ C.; $[n]_{D\,30°C.}$, 1·4830, and $[\alpha]_{D\,30°C.}$ − 5·9°; saponification value, 14; soluble in two or more volumes of 90 per cent. alcohol.

Oil from Ocimum Sanctum.—The fresh leaves of this plant yield 0·6 per cent. of a green oil of anise-like odour, with sp. gr. 0·952 at $\frac{30°}{30°}$ C.; $[n]_{D\,30°C.}$, 1·5070; and saponification value, 2·8. The oil consists chiefly of methyl-homo-anisic acid (melting-point, 85° C.).

Zedoary Oil (from chopped roots of *Curcuma zedoaria*).—The roots obtained in September and December yielded the following oils:

	September.	December.
Yield, per cent.... ...	0·065	0·25
Colour	dark brown	light yellow
Sp. gr. at $\frac{30°}{4°}$ C.	0·933	0·993
$[n]_{D\,30°C.}$...	1·4920	1·5070
$[\alpha]_{D\,30°C.}$...	—	+1·10°
Saponification value ...	—	2
Solubility in alcohol ...	completely soluble in 2 volumes of 90 per cent.	completely soluble in 2 volumes of 80 per cent.

The oil contains a sesquiterpene alcohol of melting-point, 67° C.

Turmeric Oil (roots of *Curcuma longa*).—A yield of 0·22 per cent. of a brown oil was obtained, of the following character: Sp. gr., $\frac{30°}{30°}$ C., 0·930; $[n]_{D\,30°C.}$, 1·5030; $[\alpha]_{D\,30°C.}$, + 8·6°; ester number, 81; miscible with 75 per cent. or stronger alcohol in all proportions.

Champaca Oil (*Michelia champaca*).—Pure oils distilled from champaca flowers do not contain, according to the author, any benzoic acid, and oils obtained by Schimmel and Co. and containing benzoic acid were undoubtedly distilled from mixtures of flowers, probably with ylang-ylang in some cases. The crude oil (yield, 0·20 per cent.) on standing yields a large quantity of a solid substance, crystallising in white needles, melting-point 165°–166° C., and having the formula $C_{15}H_{20}O_{3}$. Iso-eugenol is also present in the oil. The portion of the oil soluble in ether, on treatment with 70 per cent. alcohol yields a neutral fraction of fine champaca odour, of sp. gr. (*a*) 0·9543, (*b*) 1·020, in two cases. Saponification value, 160 and 180.

Ylang-Ylang Oil.—The ester numbers of many oils distilled during the past season were from 130 to 150. (*Cf.* ANALYST, 1909, **34**, 32, 396.) A. R. T.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Oxydase and Reductase occurring in Cows' Milk. W. D. Kooper. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 564-575.)—The results of an investigation on the enzymes present in cows' milk.

Testing the Porosity of Earthenware Filtering Bougies. F. Grenet. (*Compt. rend.*, 1910, **151**, 941-943.)—The earthenware filtering bougies which are employed for removing micro-organisms from liquids show great variations in their porosity according to the raw material and the mode of manufacture. This variability has an important bearing on their sterilising efficiency. The author has devised a method for comparing the structure of these bougies, depending on the capillarity phenomena produced when the porous bodies are immersed in water. The water penetrates forcibly into the interstices and, displacing the air, creates a pressure inside proportional to the fineness of the pores. A dry bougie in a vertical position is completely filled with mercury; a fine steel tube is then introduced through the orifice extending inside to the middle of the bougie and to a few centimetres outside. The tube is hermetically sealed in the orifice by means of shellac, and the free end of the steel tube is connected with a graduated glass tube of 1 mm. bore and a length of 1 to 2 metres. The apparatus being held in a vertical position, the bougie is completely immersed in water. The mercury is forced up the tube by the pressure of the air displaced in the capillary pores, and its height is observed. From this observation the diameter of the pores of maximum dimensions may be calculated. Commercial bougies occur which give columns of mercury ranging from 18 or 20 cm. up to 2 m. The force with which water enters a dry bougie is so great that micro-organisms may readily be carried through at first. In order to avoid this, it is advisable never to use a bougie in the dry state, but to steep it first in sterilised water before introducing the liquid to be filtered.

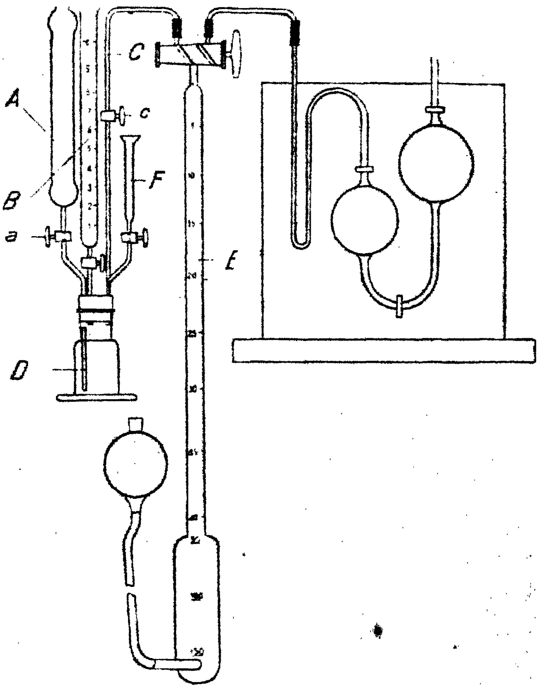
Soda-Water. W. Collingridge. (*Report of the Medical Officer of Health for City of London to Sanitary Committee*, 1910, **141**, 140-145.)—Particulars of results of the bacteriological examination by Dr. Klein of thirty-six samples of soda-water are given. They show that, in the great majority of brands now offered to the public, *Bacillus coli* cannot be found in 10 c.c., and that the total number of microbes capable of growth at 37° C. is usually less than 10 per c.c., half of the samples showing less than 1 per c.c. On the other hand, three samples were swarming with bacteria capable of growth at 37° C., and showed *B. coli* in as little as 1 c.c. The Medical Officer concludes that there can be no serious difficulty in producing soda-water which is substantially sterile, and at all events free from excrementitious organisms, and suggests that the Local Government Board might reasonably draw up a standard of purity, and initiate a system of registration and inspection of mineral water factories, with a view to securing that all mineral waters shall be as wholesome as the majority are now shown to be. G. C. J.

ORGANIC ANALYSIS.

Quantitative Estimation of Aliphatic Amino Groups, and its Application in the Chemistry of the Proteins, Urine, and Enzymes. D. D. van Slyke. (*Ber.*, 1910, **43**, 3170-3181.)—Several attempts have been made to base a quantitative method upon the reaction of amino groups in aliphatic compounds with nitrous acid. The author claims that by the method now described all the previous objections have been overcome, and that an estimation may be made in a few minutes with an error not exceeding 0·05 mgrm. of nitrogen. The apparatus employed is illustrated in the accompanying figure. The glass tubes extending from the vessel, *D*, are all capillaries of 6-7 mm. external diameter, and, with the exception of that leading to *A*, of 1 mm. bore, the latter being 2 mm. The water in the gas burette, *E*, contains about 1 per cent. of sulphuric acid, in order to keep the glass clean. The reaction takes place in the bottle, *D*, of 35 to 37 c.c. capacity. The solution of the amino compound is first placed in the burette, *B*, containing preferably not more than 20 mgrms. of amino nitrogen; 5 c.c. of water are placed in *A*. Into the bottle, *D*, are introduced 28 c.c. of a solution of 3 parts of sodium nitrite in 10 parts of water, and then 7 c.c. of glacial acetic acid. Immediate development of nitric oxide takes place. The stopper carrying the tubes *A*, *B*, and *C* is then inserted and wired down, and the tap, *a*, is opened. Water enters and drives the air out from *D* through *C*. In order to expel the air dissolved in the nitrite solution, the tap, *c*, is closed, *a* is opened, and the bottle shaken; there is a powerful evolution of nitric oxide, and 10 to 15 c.c. of liquid are forced back into *A*. The tap, *c*, is again opened, and the gas containing the air is expelled through *C*. The operation is repeated. Ultimately



a volume of about 20 c.c. of gas is developed in *D* by shaking, the tap, *a*, is closed, and *C* is connected with the gas burette, *E*. The amino solution is then admitted to *D*, the reaction is completed by shaking, and the nitrogen, mixed with nitric oxide, is collected in *E*. The nitric oxide is absorbed in the Hempel pipette by means of an alkaline solution of permanganate, and the purified nitrogen is measured in *E*. The funnel, *F*, is only used when viscous solutions have to be tested, in which case it contains amyl alcohol, a few drops of which prevent frothing. The volume of air contained in the 10 c.c. of amino solution may be allowed for by deducting 0·16 c.c. from the observed volume of nitrogen. The volume of nitrogen evolved represents double that of the amino nitrogen reacting. Each of the natural amino acids evolves 1 molecule of nitrogen, with the exception of proline and hydroxyproline, which do not react, and lysine, which yields 2 molecules. In a mixture of the volatile esters of amino acids containing that of proline, the proline may be estimated by the difference between the total nitrogen and the amino nitrogen. In the analysis of the products of hydrolysis of proteins, the amino acids may be separated into two groups by means of phosphotungstic acid, and the amino nitrogen estimated in each. In the analysis of urine, after elimination of urea and ammonia, the method may be applied for the estimation of amino groups. Lastly, there is an obvious application of the method, in conjunction with estimations of total nitrogen, in studying the progressive hydrolysis of proteins by enzymes. Thus it is possible to calculate the degree (percentage) of hydrolysis, using the expression: $\frac{100\,(A - A^{\circ})}{A' - A^{\circ}}$ in which A = observed amino nitrogen, A° = amino nitrogen of the non-hydrolysed protein, and A′ = amino nitrogen after complete hydrolysis.

J. F. B.

Colour Reactions of Adrenaline and Allied Bases. A. J. Ewins. (*J. Physiol.*, 1910, **40**, 316-326; *Chem. Zentr.*, 1910, ii., 1569-1571.)—It is shown that the colour reactions produced by the action of iodine, mercuric chloride, and potassium di-iodate, on adrenaline are due to oxidation; a colour reaction described by the author, and depending on the red coloration produced when adrenaline is treated with potassium persulphate, is due to the same cause. This persulphate reaction is somewhat more sensitive than the other tests, and will detect the presence of 1 part of adrenaline in 5,000,000 parts of water. The amino base corresponding with adrenaline, dihydroxyphenylethylamine, the corresponding methyl-, ethyl-, and propylamine bases, and amino-acetopyrogallol, also give the reactions.

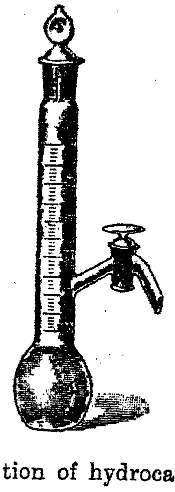
W. P. S.

Detection of Ethyl Alcohol in the Presence of Methyl Alcohol. G. Denigès. (*Bull. Soc. chim.*, 1910 [iv.], 7, 951-952.)—The method is based upon the fact that on treating methyl alcohol with bromine-water only traces of formaldehyde are formed, whereas ethyl alcohol under the same conditions yields an abundant quantity of acetaldehyde. In applying the test, 0·2 c.c. of the methyl alcohol is shaken with 5 c.c. of bromine-water (0·3 c.c. of bromine to 50 c.c. of water) in a long test-tube (about 20 cm. long and 25 mm. in diameter), which is then immersed in boiling water. If the yellow colour persists, the tube is left in the water for five or six minutes; otherwise it is removed as soon as the colour has practically disappeared. The tube is then cooled in water, and if its contents are still coloured, a dilute solution of sodium bisulphite (1 part of the commercial solution of sp. gr. 1·33 to 1·38 with 4 parts of water) is added drop by drop until decolorisation takes place, care being taken to avoid an excess. The liquid is then tested with 5 c.c. of Schiff's reagent (magenta just decolorised with sulphurous acid), and allowed to stand for at least five, but not more than eight, minutes. If ethyl alcohol was originally present, a red-violet colour is produced, the intensity of which is proportional to the quantity of alcohol. In the absence of that alcohol no appreciable coloration is obtained, since the product given by pure methyl alcohol under these conditions does not produce any coloration until after ten minutes' contact with the reagent. By the use of standard solutions of pure ethyl alcohol in methyl alcohol for comparison, the method may be made quantitative. For the detection of minute quantities of ethyl alcohol in dilute alcoholic solutions (0·05 to 3 per cent.), 5 c.c. of the liquid under examination are mixed with 0·2 c.c. of pure methyl alcohol, and 0·03 c.c. of bromine added by means of a capillary pipette. The tube is then shaken to dissolve the bromine, and placed in boiling water as described above. In this way it is possible to detect 2 mgrms. of ethyl alcohol. C. A. M.

Estimation of Ether and Benzene in Alcohol. H. Wolff. (*Chem. Zeit.*, 1910, **34**, 1193.)—For the estimation of ether in alcohol, the author describes the following modification of Holde and Winterfeld's method (ANALYST, 1908, **33**, 242): 100 c.c. of the spirit to be analysed are diluted to a sp. gr. of 0·96, and 20 c.c. are distilled over into a measuring cylinder of 100 c.c. capacity graduated in 0·5 c.c. The tube of the condenser should extend for some distance into the receiver (at least 2 to 3 cm.), and the latter should be well cooled. The distillate is treated with 80 c.c. of concentrated brine, and shaken to and fro about twenty times. After separation, the volume of the ethereal layer is read off, any bubbles which form at the line of separation being broken by turning and tapping the cylinder. The errors are generally less than 0·5 per cent. By this method spirits containing up to about 13 per cent. of ether may be analysed with accuracy, but if the percentage be higher, it is necessary to take only 50 or 25 c.c. of the spirit, dilute to 0·96 sp. gr., and distil off 20 c.c. A similar procedure is followed in the estimation of benzene in spirits, brine being employed instead of water, as prescribed by Holde and Winterfeld. The distillate is collected in a measuring cylinder of 30 c.c. capacity, graduated in $\frac{1}{10}$ c.c., or in a flask with graduated neck immersed in a bath of cold water. The separation of the benzene is sharper when brine is employed, and its volume may be read with an average error of only 0·1 c.c. J. F. B.

Estimation of the Bromine Value of Fats and Oils. Primary and Secondary Bromine Values. W. Vaubel. (*Zeitsch. angew. Chem.*, 1910, **23**, 2077-2080.)—In the course of some experiments on the estimation of the bromine values of oils, the author noticed that, when an oil is dissolved in carbon tetrachloride with the addition of potassium bromide and hydrochloric acid, and the solution is then titrated with potassium bromate solution, the quantity of bromine taken up by the oil is not equivalent to the iodine value of the oil. Further experiments showed that non-drying oils, such as olive oil, absorb little, if any, bromine when thus treated; whilst drying oils absorb the bromine readily up to a certain point, where the addition of a further quantity of bromate solution produces a yellow colour of free bromine in the solution. The quantity of bromine thus absorbed by the oil is termed the "primary bromine value." Only when an excess of bromine is added does the oil absorb a quantity equivalent to the iodine value, and this quantity is called the "secondary bromine value" of the oil. The following values were obtained in the case of three oils: Linseed oil, primary value, 75·2, 80·0; secondary value, 107·7. Wood oil, primary value, 57·0; secondary value, 94·6. Earthnut oil, primary value, 51·9; secondary value, 57·6. The author discusses the relation between these results and the compositions of the oils. For the determination of the total (secondary) bromine values of oils, the author recommends that 5 grms. of the oil be dissolved in 100 c.c. of carbon tetrachloride; potassium bromide solution and about 300 c.c. of water are added, then 10 c.c. of concentrated hydrochloric acid and a small crystal of potassium iodide. After the addition of an excess of standard potassium bromate solution, the mixture is shaken thoroughly for one minute, and the excess of bromine is then titrated with sodium sulphite solution. The small quantity of iodine added in the form of potassium iodide enables the end point of the titration to be observed clearly. The results obtained, when calculated into terms of iodine, agree closely with the iodine values of the various oils as estimated in the usual way.

W. P. S.



Estimation of Total Fatty Acids in Soap. A. Röhrig. (*Zeitsch. angew. Chem.*, 1910, **23**, 2161-2165.)—The use of the apparatus here shown simplifies and renders more accurate the estimation of total fatty acids in soap. From 1 to 2 grms. of the soap (or an aliquot portion of an aqueous solution of 5 to 10 grms.) are introduced into the apparatus, and the solution shaken with a slight excess of sulphuric acid. The liberated fatty acids are brought to the surface by gently heating and shaking the flask, and, when completely cold, are dissolved by the addition of 25 c.c. of a mixture of ether and petroleum spirit (boiling-point 35° C.) in equal parts, and the contents of the flask diluted with water to 100 c.c. An additional 25 c.c. of the mixture of ether and petroleum spirit is now added, and the flask vigorously shaken and allowed to stand. The volume of the ethereal layer is then noted, and one half of it drawn off into a tared basin and evaporated on a moderately hot water-bath until the residue of fatty acids becomes viscous, after which the basin is dried for ten minutes at 100° C. and weighed as soon as it is cold. In the case of cocoanut oil fatty acids, however, the temperature of drying must be kept at 57° to 62° C., concordant results being then obtained in the same time. The apparatus may also be used for the rapid estimation of hydrocarbons in commercial oleine. From 4 to 5 grms. of the sample are heated for ten to fifteen minutes on the water-bath with about 4 grms. of solid sodium hydroxide in about 30 grms. of 50 per cent. alcohol, and the liquid then cooled and made up to the mark with 50 per cent. alcohol. From 45 to 50 grms. of petroleum spirit (boiling-point 35° C.) are now added, in four equal portions, with vigorous shaking after each addition, and the apparatus is allowed to stand five or six hours, until the petroleum spirit layer becomes completely clear. One half is then drawn off and evaporated in a tared basin, and the residue dried for two to three hours at 60° to 70° C. In the case of American oleines the sum of the residue and of the free fatty acids estimated by titration is within $\frac{1}{4}$ to $\frac{1}{3}$ per cent. of 100. In certain French and German oleines, however, there is a difference due to the presence of neutral fat. In such cases 4 grms. of the oleine are titrated in the apparatus with $\frac{N}{1}$ alcoholic sodium hydroxide solution, the contents then made up to 100 c.c., and the estimation continued as described above. The residue from the petroleum spirit layer now consists of neutral fat and hydrocarbons, and the difference between this result and the first estimation gives the quantity of neutral fat. The apparatus may be obtained from F. Hugershoff, Leipzig. C. A. M.

Characteristics of Certain Oils. A. P. Lidoff. (*Chem. Rev. Fett- u. Harz-Ind.*, 1910, **17**, 262-263).—The seeds of *Ulmus campestris* yielded 26·09 per cent. of a non-drying oil, which was remarkable for containing volatile solid fatty acids and readily soluble non-volatile acids:

C. A. M.

Characteristics of some Little-known Vegetable Oils and Fats. C. Grimme. (*Chem. Rev. Fett- u. Harz-Ind.*, 1910, **17**, 263-269; *cf.* ANALYST, 1910, **35**, 536).—The subjoined table gives the analytical values of oils and fats derived from the following plants: (1) *Allophyllus racemosus*, indigenous to Asia and Australia. The seed-kernels yielded 22·3 per cent. of a brown crystalline fat. (2) *Pentadesma butyracea* (West Africa), producing seeds that yielded 46·6 per cent. of a solid white fat. (3) *Garcinia balansæ* (India), from the seed-kernels of which 63·4 per cent. of a dark brown fluid oil was extracted. (4) *Calophyllum inophyllum* (Africa, Polynesia), the seed-kernels of which yielded 60·4 per cent. of a dark green oil, with slight drying properties. It contained 18·26 per cent. of resin. (5) *Bertholletia excelsa* (South America), producing nuts the kernels of which yielded 65·8 per cent. of oil (Brazil-nut oil). (6) *Poga oleosa*, the seed-kernels of which yielded 55·3 per cent. of a light yellow fluid oil. (7) *Telfairia pedata* (East Africa), from the seed kernels of which 60·75 per cent. of a fluid oil with pleasant taste and odour was separated. (8) *Telfairia occidentales* (West Africa). The seed-kernels yielded 48·2 per cent. of a thick viscous oil, with fairly good drying properties. (9) Species of *Citrullus* (South-West Africa), the seeds of which gave 11·8 per cent. of a light yellow fluid oil, with weak drying properties and pleasant taste. (10) Oil nuts from Singapore, probably derived from a species of *Lauraceæ*. The kernels yielded 38·5 per cent. of a grey-green crystalline fat.

† Without resin.

Separation of Solid from Liquid Fatty Acids. David. (*Comptes rend.*, 1910, **151**, 756-757.)—The method is based upon the author's observation that the ammonium salts of solid fatty acids are completely insoluble in a large excess of ammonia at 13° to 14° C., whereas the ammonium salts of liquid fatty acids are completely soluble therein. About 2 grms. of the mixed fatty acids are dissolved in 5 c.c. of 95 per cent. alcohol, the solution treated with 50 c.c. of ammonia solution at 22° C., and the mixture heated until bubbles of ammonia gas appear. The solution is now left for several hours at 14° C., and then filtered from the insoluble deposit of ammonium palmitate and stearate. The filter and its contents are washed with ammonia, until the filtrate ceases to give the slightest turbidity with baryta-water, after which a mixture of pure hydrochloric acid (sp. gr. 1·17) and water

1 : 1) is poured over the filter. The ammonium chloride solution which is formed passes through the filter, whilst the solid fatty acids are left. They are washed with water acidified with hydrochloric acid until free from ammonium salts, and then with water, detached from the filter, dried at 100° C., and weighed. In test experiments with a mixture of fatty acids containing 60 per cent. of solid acids, the amounts found were 59·7 and 59·8 per cent. Hydroxystearic acid, iso-oleic acid, lauric acid, and arachidic acid, also yield ammonium salts insoluble in a large excess of ammonia. The liquid fatty acids in the filtrate may be estimated by difference, or they may be liberated from their ammonium salts, washed, and dried at 120° C., with the usual precautions to prevent loss. C. A. M.

Separation of Oleic Acid from Stearic and Palmitic Acids. P. Falciola. (*Gazz. Chim. Ital.*, 1910, 40, 217-229.)—A method of separating oleic acid from stearic and palmitic acids is based upon the difference in solubility of their respective ammonium salts in alcohol, as is shown in the following results, obtained with specimens of the pure compounds:

SOLUBILITY IN GRMS. PER 100 C.C.

	Absolute Alcohol, ° C.					75 per Cent. Alcohol, °C.				50 per Cent. Alcohol, ° C.			
	50°.	40°.	30°.	20°.	10°.	40°.	30°.	20°.	10°.	40°.	30°.	20°.	10°.
Stearic acid	—	13·8	4·5	2·0	0·9	0·77	0·39	—	0·15	0·12	0·10	0·08 (23°C.)	—
Ammonium stearate	5·5	1·8	0·9	0·5	0·3	5·00	1·83	—	0·56	3·21	1·16	0·51	0·25 (12°C.)
Palmitic acid	—	31·9	—	9·2	2·8	3·59	1·19	0·43	0·24	0·31	0·12	0·09	0·05
Ammonium palmitate	11	4·5	—	1·4	0·7	14·84	11·02	4·33	1·78	6·69 (?)	—	5·33	—
Ammonium oleate	100	—	—	—	59	—	10·86	—	8·20	—	—	—	—

Ether dissolved 0·1 grm. of ammonium stearate, 0·29 grm. of ammonium palmitate, and 16·9 per cent. of ammonium oleate, per 100 c.c. at the ordinary temperature; whilst in acetone there dissolved, per 100 c.c., 0·08 grm. of ammonium stearate at 13° C., 0·20 grm. of ammonium palmitate at 13° C., and 4·7 grms. at 15° C. For a quantitative separation of these fatty acids the mixture is dissolved in warm ether, and the solution treated with ammonia gas, and cooled to the ordinary temperature. The solvent is then evaporated, and the residue thoroughly mixed with about four times its volume of ammoniacal alcohol at about 0° C., and filtered with the aid of a pump. The residue is washed with the smallest possible quantity of chilled absolute alcohol, the filtrate and washings treated with dilute hydrochloric acid, the solvent evaporated, and the liberated liquid fatty acids washed, dried, and weighed. The solid fatty acids upon the filter are also decomposed with hydrochloric acid, and estimated in the usual manner. The following results illustrate the degree of accuracy thus obtainable:

Taken.	Grms.	Found.	Grms.
Oleic acid ...	1·92	Oleic acid ...	2·08
Palmitic and stearic acids ...	1·28	Solid fatty acids ...	1·18
	3·20		3·26
Oleic acid ...	4·95	Oleic acid ...	4·89
Palmitic acid ...	2·55	Solid fatty acids ...	4·97
Stearic acid ...	2·48		
	9·98		9·86

C. A. M.

Iodine Values of Linoxyn. Meister. (*Chem. Rev. Fett- u. Harz-Ind.*, 1910, **17**, 260-262.)—Glacial acetic acid (98 per cent.) dissolves linoxyn, and is therefore the best solvent for estimating the iodine value of that substance. Old varnish films are not completely soluble in the cold acid, and gentle heat is required to dissolve them. The older the linoxyn, the greater the tendency to the formation of a slight residue insoluble in glacial acetic acid. Hence it is not possible to follow the drying process of linseed oil completely to the end, although the iodine values may be estimated to a stage at which no further material increase in weight by oxidation takes place. The hot glacial acetic acid does not have any appreciable effect upon the results, as is shown by the fact that linseed oil fatty acids gave the same iodine value whether dissolved in chloroform or in hot glacial acetic acid. The following results were thus obtained with two samples of boiled linseed oil, the iodine values (Hübl) in the sixth column being only approximate, owing to the separation of traces of insoluble matter towards the end of the titration:

	Original.	After 2 Hours' Drying.	After 4 Hours.	After 6 Hours.	After 8 Hours.	After 10 Hours.	After 12 Hours.
Boiled Oil I.:							
Iodine value ...	153·8	131·6	105·0	73·9	47·3	26·9 (?)	—
Increase in weight per cent.	—	5·4	10·2	16·8	17·9	18·5	18·6
Boiled Oil II.:							
Iodine value ...	156·8	136·1	104·0	74·8	48·8	29·1 (?)	—
Increase in weight per cent.	—	5·1	10·0	16·2	17·4	18·0	18·1

It was not possible to examine tung oil varnish in this way, as after four hours' drying the moist film was insoluble in glacial acetic acid and all other solvents.

Acids Suitable for Use as Standards in Acidimetry. J. H. Kastle. (*Amer. Chem. J.*, 1910, **44**, 487-493.)—The author recommends three organic acids of the aromatic series which are eminently suitable for use as standards in acidimetry. These bodies are *p*-nitrotoluene sulphonic acid, *p*-amino-*o*-sulphobenzoic acid, and monopotassium *o*-nitro-*p*-sulphobenzoate. They are all well-defined substances, easily prepared in a perfectly pure condition. The two last are anhydrous, and can therefore be thoroughly dried by any convenient means without the danger of alteration in composition. The first, *p*-nitrotoluene sulphonic acid, crystallises with 2 molecules of water, but the crystals are very stable under ordinary atmospheric conditions. They all yield sharp end reactions on titration with phenolphthaleïn. For all practical purposes, the quantity of sodium hydroxide required for neutralisation coincides closely with the theoretical quantity, whilst with *p*-amino-*o*-sulphobenzoic acid the agreement is such as to meet the most exact requirements of volumetric analysis.

J. F. B.

The Alcohol-Soluble Constituents of Litmus. P. Scheitz. (*Zeitsch. anal. Chem.*, 1910, **49**, 736-739.)—The alcohol-soluble constituents of litmus, which are rejected in the course of the usual process of purification, include a small quantity of a colouring matter which is a more sensitive indicator than azolitmin. Dilute hydrochloric acid is added to powdered litmus until no more carbon dioxide is evolved and the liquid is distinctly red. The mixture is heated on the water-bath until a dark brown precipitate separates. This is filtered off, well washed with hot water, dried, and reduced to a fine state of division. A kilogramme of good litmus will yield from 120 to 180 grms. of this powder, which contains most of the valuable constituents of the original litmus, both the azolitmin and the alcohol-soluble colour. The finely-divided substance is boiled for half an hour with 4 to 5 litres of water, and then allowed to stand an hour, when the supernatant liquor is syphoned off, carrying with it a quantity of a very finely divided red substance, which will remain in suspension for weeks. Washing by decantation is repeated until, after standing an hour, the supernatant liquor is seen to be free from particles of the finely divided red substance. The liquors containing the red substance in suspension are evaporated to dryness, and yield 20 to 25 grms. of substance, about half of which is soluble in warm dilute alcohol. The residue from the elutriation experiment contains most of the azolitmin, contaminated, however, by a small quantity of the alcohol, soluble substance. Both the crude azolitmin and the product separated from it by elutriation are boiled for half an hour with 60-65 per cent. alcohol and the solution filtered hot. The extraction with dilute alcohol is repeated three or four times. The alcoholic extracts deposit a gelatinous precipitate on cooling. This is washed with aqueous alcohol, dried, and extracted with acetone, to remove erythrolein and erythrolitmin. Finally, the product is freed from inorganic matter by dissolving again in hot 60-65 per cent. alcohol, filtering hot, and allowing to cool, when it separates as a gelatinous, ash-free substance, of which 15 grms. may be obtained from 1 kilogramme of litmus. When ammonia gas is led over this substance it takes up some 8 or 9 per cent. of its weight of ammonia very rapidly. The ammonium salt, freed from excess of ammonia in a vacuum desiccator, is a sensitive indicator. One c.c. of a 0·1 per

cent. solution imparts a colour of convenient intensity to 100 c.c. of water, and the tint of this coloured water is changed sharply from red to blue by 0·4 c.c. of $\frac{N}{100}$ caustic potash, and back again to red by 0·3 of $\frac{N}{100}$ hydrochloric acid. Azolitmin forms a similar ammonium salt; and it is said that the azolitmin of commerce, which yields 8·5 per cent. of ammonia on warming with caustic alkali, is such an ammonium salt.
G. C. J.

Sensitive Indicator. J. F. Sacher. (*Chem. Zeit.*, 1910, **34**, 1192-1193.)—An extremely sensitive indicator is obtained by extracting the colouring matter from the fresh, undried skins of red radishes by means of 96 per cent. alcohol in the cold. The filtered extract possesses a dull-red colour, which, however, is more intense if traces of plant acids be present. In the latter case a little alkali is added until the coloration is less pronounced. This extract, when used as an indicator, gives a red coloration with acids, more intense than that afforded by methyl orange. With alkalis it gives a green coloration, which is blue at higher concentrations. The indicator is more sensitive to alkalis than methyl orange or phenolphthaleïn; 2 c.c. of the alcoholic extract showed a distinct green coloration with 15 c.c. of water containing 15 parts of calcium carbonate per 100,000. In titrations it gives a sharp change; it is preferable to titrate to the red point. Like litmus and phenolphthaleïn, it is sensitive to carbonic acid.
J. F. B.

Method for Purifying and Drying Organic Liquids by Wiping. C. L. Jackson and A. H. Fiske. (*Amer. Chem. J.*, 1910, **44**, 438-441.) — In the course of a research, the authors obtained a very small quantity of an oily liquid, far too small to dry and distil in the ordinary way. Since it was also volatile, it could not be dried in a desiccator. It was found possible to get it sufficiently dry to serve for elementary analysis, by merely wiping it with filter-paper strips which were previously moistened slightly to prevent their taking up the oil. The method was then tried on substances of known composition, such as wet chloroform containing 0·2 per cent. of iodine. It was found possible to remove the whole of the iodine from this solution by means of filter-paper strips moistened with potassium iodide solution. When 0·5 grm. chloroform was taken for the test, not much more than 0·2 grm. remained by the time the iodine and the last of the wash-water had been removed; but this small quantity was sufficient for analysis, which showed that the chloroform contained less than 0·5 per cent. of water and no other impurity.
G. C. J.

Valuation of Logwood. G. Grasser. (*Collegium*, 1910, 461-463.)—An approximate valuation of logwood may be made by extracting a weighed quantity (4 to 6 grms.) of the ground wood (containing 10·5 per cent. of moisture) with 200 c.c. of water for one and a half hours, diluting the solution to 250 c.c., and treating an aliquot portion (50 c.c.) with 20 c.c. of a 20 per cent. solution of lead acetate. The volume of the precipitate (separated with the aid of centrifugal force) is then noted, and its amount compared with that obtained under parallel conditions with a standard sample of logwood.
C. A. M.

Critical Investigations on the Analytical Methods for Raw Rubber. O. Korneck. (*Gummi-Zeit.*, 1910, **25**, 4-9, 42-46, 77-88; through *J. Soc. Chem. Ind.*, 1910, **29**, 1321.)—Working under the direction of Harries on eleven different sorts of rubber, the author has compared the various methods which have been proposed for the analysis of raw rubber. He concludes that—(1) Spence's method furnishes very similar results to the modified nitrosite method (see below). (2) The tetrabromide method (Budde, *Gummi-Zeit.*, 1909, **24**, 4) in its present form does not yet appear suited for the quantitative determination of rubber. (3) All other methods examined cannot be compared with the above. Spence's method consists essentially in the estimation of resin by complete extraction with acetone, determination of insoluble matter by solution in benzene without limitation of time, and estimation of rubber by evaporation of the filtered solution of the resin-free rubber. The methods mentioned in (3) include those of Schneider (*J. Soc. Chem. Ind.*, 1903, **22**, 1885), Fendler (alcohol precipitation, *ibid.*, 1904, **23**, 1117, modified by the use of carbon tetrachloride as solvent, as recommended later by Fendler and Kuhn), and Fendler-Harries nitrosite method (*Ber. deut. Pharm. Ges.*, 1904 [5]). The author especially emphasises the importance of treatment till the weight remains constant, instead of for a specified time, in both vacuum drying and acetone extraction. It is shown that the resins must be quantitatively removed in the Fendler-Harries method. Fendler prescribes six hours' extraction, but the author urges that this is not sufficient for all rubbers. The new form of Harries' nitrosite method which obviates this difficulty is as follows: 1 grm. of finely divided technically pure rubber (best dried and acetone extracted) is dissolved as far as possible in 75 c.c. of benzene in a beaker. Nitrous fumes are passed in till a dark green colour is obtained, stirring meanwhile to break up the precipitate. After settling a moment the clear green solution is decanted through a Gooch crucible. The precipitate is washed with benzene several times, 75 c.c. of benzene are added, and nitrous fumes are again passed. The beaker and leading tube, covered with a clock glass, are allowed to stand for twenty-four hours. The precipitate is kneaded together, pressed on the walls of the beaker, the clear green solution decanted through the Gooch crucible, and the precipitate washed with benzene till the filtrate is colourless. The nitrosite is then transferred to the crucible and washed with absolute ether till a homogeneous, fine bright yellow powder is left. The beaker, tube, nitrosite, and crucible, are dried for half an hour *in vacuo* and then at 80° C. in an ordinary oven to constant weight. 50 c.c. of acetone are then placed in the beaker, which is warmed on the water-bath till nothing more dissolves. The liquid is filtered through the Gooch crucible, and the precipitate washed with acetone. The beaker, tube, and crucible, are again dried to constant weight; the difference gives the weight of nitrosite. Pure rubber = nitrosite × $\frac{136}{259}$. The nitrous fumes are prepared from nitric acid (sp. gr. 1·3) and arsenic trioxide in pieces the size of hazel-nuts. The flask, provided with a dropping funnel, is warmed in an air-bath at first, and afterwards cautiously with a small flame. The gas is passed through a washing-flask to remove nitric acid, and is then dried over phosphorus pentoxide. The values obtained for pure rubber by this method, when added to those for insoluble matter (Spence's method) and resins (in this case determined by a new method using ozone), approximate very closely to

100 per cent., whereas the values for pure rubber by Budde's method are from 1·5 to 10 per cent. lower.

Starch-Iodine Reaction. W. Harrison. (*Proc. Chem. Soc.*, 1910, **26**, 2523.)—The author finds that in the formation of the blue iodide of starch the presence of iodides is not necessary. The blue colour is formed with pure iodine, but the depth is increased by the presence of any salt or weak acid. The gradual addition of alcohol changes the blue to violet, red, orange, and yellow, and the reverse change takes place on dilution with water. The same colour change is produced by carefully heating the blue solution, and the reverse phenomena are observed on cooling. This colour change is analogous to the colour change of colloidal gold solution, investigated by Zsigmondy, which changes from red to blue on adding salts.

The author succeeded in preparing a blue colloidal solution of iodine in water containing glycerol and no starch, but the colour only remained for a fraction of a second, the iodine being precipitated.

It was shown that all the iodine can be removed from starch iodide by washing with pure water, and the conclusion is drawn that the blue solution of iodine and starch is a colloidal solution of iodine, the starch acting as a protective colloid. It was further shown that the reactions of dextrins and starch celluloses can be obtained with starch under certain conditions, from which the conclusion is drawn that dextrins and starch celluloses are all different colloidal states of starch, and not chemically different compounds.

New Method of Estimating Sucrose in the Presence of Other Sugars. A. Jolles. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 631-638.)—The process described depends on the fact that the optical activity of practically all sugars, other than sucrose, is destroyed when the sugars are heated in dilute solution with sodium hydroxide. The sugars thus affected are arabinose, rhamnose, dextrose, lævulose, galactose, mannose, invert sugar, maltose, and lactose. The conditions governing the reaction are simply that the solution shall not contain more than 2 per cent. of these sugars, and that the alkalinity of the solution shall be approximately one-tenth normal. The destruction of the optical activity is brought about by heating such an alkaline solution to boiling for forty-five minutes either under a reflux condenser or in a pressure flask; the same change is affected by maintaining the mixture at a temperature of 37° C. for twenty-four hours, and this procedure has the advantage that the solution does not become dark in colour. The concentration of the sucrose is without effect on the accuracy of the process. As applied to the estimation of sucrose in wine, the details of the process are as follows: 100 c.c. of the wine are neutralised, evaporated to a volume of 50 c.c., treated with 5 c.c. of lead acetate solution, diluted with water to a volume of 100 c.c., and filtered. Twenty c.c. of the filtrate are then treated with sodium phosphate to remove the excess of lead, filtered, and sufficient sodium hydroxide (16 per cent.) solution is added to render the alkalinity of the mixture approximately one-tenth normal. The mixture is then heated as above described, and, after cooling, the polarisation is determined. If the mixture has been boiled, it may be treated with a further quantity of 5 c.c. of lead acetate solution and filtered before being examined in the polariscope, a correction being made for the dilution thus caused. The polarisation of the solution is now due solely to sucrose, and the quantity of the latter present in the wine is found by a simple calculation. In the case of condensed milk, 10 grms. of the sample are dissolved in water, lead acetate solution is added, and, after the excess of lead has been removed by means of sodium phosphate, the solution (filtrate) is diluted to a volume of 200 c.c. A portion of this solution is then heated as described after the addition of the requisite quantity of sodium hydroxide, and the polarisation of the solution is determined subsequently. The results obtained agree closely with those yielded by the ordinary polarimetric method for estimating sucrose.

W. P. S.

Examination of Wool-Grease Oleines. J. Marcusson. (*Mitt. Königl. Materialprüfungsamt*, 1910, **28**, 469-471.)—Wool-grease oleine contains little or no cholesterol, for, on distilling the unsaponifiable matter under reduced pressure, the whole of the fractions are dextro-rotatory, whilst their rotation steadily rises. Moreover, the original dextro-rotation is not changed by long-continued extraction with acetic anhydride, as would be the case in the presence of any notable proportion of cholesterol. Absorption of oxygen from the air by unsaturated bodies is quite sufficient to account for the presence of oxygen in the unsaponifiable matter of wool-grease oleine. Samples of English wool-grease oleine examined by the author had approximately the same characteristics as samples of French or German origin, although in one case the iodine value of the former was somewhat lower. Two samples were found to contain 48 and 54 per cent. of unsaponifiable matter, the iodine values of which were 65·4 and 51·3, and the optical rotation $[\alpha]_D = +24{\cdot}8^\circ$ and 24·1° respectively. As a rule, pure wool-grease oleine is soluble in its own volume of 96 per cent. alcohol at 20° C., whereas in the presence of 20 per cent. (or in some instances less) of mineral oil the liquid remains turbid. The optical rotation of pure wool-grease oleine of different origin was found to range from $[\alpha]_D = +10^\circ$ to 19°. If a sample has a rotation exceeding $[\alpha]_D = +10^\circ$, and gives a clear solution in the solubility test, it cannot contain any notable quantity of mineral oil. If, however, the presence of the latter be indicated by either of these tests, a further examination of the unsaponifiable matter must be made. C. A. M.

Detection of Mineral Oil in Wool-Grease Oleine. G. Winterfeld and W. Mecklenburg. (*Mitt. Königl. Materialprüfungsamt*, 1910, **28**, 471-474.)—By increasing the proportion of solvent in Marcusson's alcohol test (preceding abstract) to one and a half times the volume of the oleine it is possible to detect 10 per cent. and in some cases 5 per cent. of mineral oil. A still more sensitive test is to treat the sample with an equal volume of a mixture of 90 per cent. methyl alcohol and 10 per cent. of ordinary alcohol, a turbidity and ultimate separation of an oily layer taking place at 20° C. in the presence of 10 per cent. and in most cases of 5 per cent. of mineral oil, whilst pure wool-grease oleine usually gives a clear solution. In the case of certain samples of English wool-grease oleine, however, a mixture of oil and solid substances separated in this test, although in other respects the samples appeared pure. This abnormal behaviour is to be attributed to the very high proportion of solid unsaponifiable matter: and in this connection it is mentioned that very little wool-grease oleine of English origin is used in Germany, owing to the difficulty of removing it subsequently from the material. It is also stated that it is difficult to obtain English samples that have not been adulterated. C. A. M.

Detection of Rosin Oils in French Wool-Grease Oleines. G. Winterfeld. (*Mitt. Königl. Materialprüfungsamt,* 1910, **28**, 474-476.)—The methyl-ethyl alcohol solubility test (preceding abstract) enables an addition of 20 per cent. and in some cases of 10 or 5 per cent. of refined rosin oil to be detected in wool-grease oleine, a turbidity or separation of oil being obtained after the mixture has stood for an hour at 20° C. This test, however, usually fails to detect the presence of even 20 per cent. of crude rosin oil (rich in colophony). An addition of 10 per cent. or in some instances of 5 per cent. of either crude or refined rosin oil produces a material increase in the refractive index, which in the case of pure French wool-grease oleine is usually less than 1·480 at 20° C. C. A. M.

INORGANIC ANALYSIS.

Elimination of Ammonium Salts prior to Estimation of Alkali Metals. J. Jámbor. (*Zeitsch. anal. Chem.,* 1910, **49**, 733-734.)—The following method is recommended for the removal of large quantities of ammonium salts. The solution is evaporated on the water-bath until a crust of crystals appears. It is then allowed to cool, half its bulk of concentrated sulphuric acid is added, and the solution evaporated to dryness over a small flame. In this way the ammonium salts can be almost completely eliminated without attention or fear of creeping or spirting. G. C. J.

Detection and Estimation of Arsenic Acid in Presence of Arsenious Acid by Means of Magnesia Mixture. J. C. Brünnich and F. Smith. (*Zeitsch. anorg. Chem.,* 1910, **68**, 292-296.)—This method having been discredited by the work of Lutz and Swinne (Analyst, 1910, **35**, 76), the authors have re-investigated the conditions which determine the precipitation of arsenic acid whilst leaving arsenious acid in solution. They conclude that arsenic acid can be estimated in presence of arsenious acid by means of magnesia mixture, provided (*a*) the solution does not contain much more than 0·5 grm. As_2O_3 in each 100 c.c., (*b*) alkali salts are not present in greater quantity than corresponds to 1 per cent. NaOH, and (*c*) the magnesia mixture used contains in each 100 c.c. not more than 1·4 grms. NH_3 nor less than 10 grms. NH_4Cl, together with the usual 5·5 grms. of crystallised magnesium chloride. Experiments are described which show that if the addition of ammonia, recommended by Fresenius, Treadwell, and others, be avoided, and a magnesia mixture of the above composition (*i.e.*, with less ammonia than the usual reagent) be used, the method as a qualitative test is rendered more sensitive. The quantitative results show *minus* errors of the order of 1 per cent., and these errors increase greatly when alkali salts are present in quantity. G. C. J.

Estimation of Carbon and Sulphur in High-Grade Alloys of Tungsten, Molybdenum, and Vanadium, with Iron. E. Müller and B. Diethelm. (*Zeitsch. angew. Chem.*, 1910, **23**, 2114-2124.)—Experiments are described which show that, in alloys containing large proportions of tungsten, molybdenum, or vanadium, carbon and sulphur can be estimated accurately only by the direct dry combustion method. Wet combustion methods depending on the use of chromic and sulphuric acids, which give excellent results with ordinary steels, may, in the case of such alloys as have been named, lead to the carbon being underestimated to the extent of 20 to 80 per cent. The error in a sulphur determination made by a wet process is very much less, but the dry method is preferred both on the ground of accuracy and because the determination can then be combined with that of carbon. G. C. J.

Estimation of Carborundum in Coke Crucible Scrap. H. Wdowiszewski. (*Chem. Zeit.*, 1910, **34**, 1209-1210.)—At the temperature of the Siemens crucible furnace, notable amounts of carborundum may be formed in crucible bodies into the composition of which coke, as distinguished from graphite, has entered. Since the proportion of carborundum in new crucibles has a marked influence on their behaviour and life, it is important to be able to estimate the proportion present in old crucibles which it is proposed to incorporate with new materials. No direct method is found to be so satisfactory as the following indirect one: Uncombined carbon is estimated by ignition to constant weight. The residue is fused with alkali carbonate, and silica, alumina and iron oxide, lime and magnesia, estimated with the utmost accuracy attainable, since the sum of all the errors will fall ultimately on the carborundum, the quantity of which it is wished to estimate. Potash and soda may be estimated, but in any one works their amount will be found to approximate a constant, in the author's works 0·5 per cent. The results of many analyses of new crucible bodies made by the author add up to 99·5 per cent. in nearly every case, so that he regards 0·5 per cent. as a proper allowance for error in analysis. In the case of an analysis of material containing carborundum, the results of analysis add up to more than 100 per cent., since, for every 40 parts of SiC, 60 parts of SiO_2 are weighed. The results of analysis, *plus* 0·5 per cent. (unavoidable analytical error), are therefore summed; and if the sum be represented by $100 + x$, then the percentage of carborundum in the original material is given by $2x$. G. C. J.

General Method for the Preparation of Anhydrous Chlorides, and its Application in Chemical Analysis. F. Bourion. (*Annal. Chim. Phys.*, 1910, **20**, 547-573; *Chem. Zentr.*, 1910, ii., 1360-1361.)—The method consists in heating metals or metallic oxides in a current of sulphur chloride or a mixture of sulphur chloride and chlorine. For the preparation of thorium, chromium, and uranium chlorides and tungsten oxychloride, the use of sulphur chloride (S_2Cl_2) is recommended; whilst the mixture of sulphur chloride and chlorine is more suitable for the preparation of silicon, zirconium, and beryllium chlorides. The chlorides of many of the metals of the rare-earth groups may be prepared by this method.

Separation of Tungsten from Silica.—The process depends on the fact that tungstic acid is completely volatilised when heated to a temperature of 150° to 280° C. in a current of sulphur chloride and chlorine, whilst precipitated silica is not volatilised or attacked at temperatures below 525° C.

Separation of Cerium, Thorium, and Beryllium.—The mixed oxides are placed in a quartz boat, which is then heated in a silica tube to a temperature of 700° to 780° C., while a current of sulphur chloride and chlorine is passed through the tube; the thorium and beryllium chlorides are volatilised, whilst the cerium chloride remains in the boat. The condensed volatile chlorides are allowed to drop into hot sodium hydroxide solution, which is stirred meanwhile; thorium hydroxide is thus precipitated, whilst the beryllium remains in solution. After cooling, the mixture is diluted with water, filtered, and the thorium hydroxide is washed with dilute sodium hydroxide solution. The thorium hydroxide is then dissolved in acid, and both it and the beryllium are precipitated with ammonia from their solutions.

W. P. S.

Citrate-Solubility of Phosphoric Oxide in Basic Slag. E. V. Flack. (*Trans. Cape Chem. Soc.*, Aug. 26, 1910.) — The author shows that, as is well recognised, there is a large difference between the proportion of phosphoric acid dissolved from basic slag by Petermann's neutral ammonium citrate solution and the proportion dissolved by 2 per cent. citric acid solution, the latter being the solution chiefly used in Europe for determining the proportion of presumably readily available phosphoric acid in this material; and he recommends that the latter process should be used in South African laboratories, in order that the results obtained may be comparable with those of English and Continental chemists. The author points out that, in analysing the citric acid solution of the slag, if the phosphoric acid be determined by "direct" precipitation with magnesia mixture in presence of ammonium citrate, reliable results cannot be obtained unless the silica is first removed by evaporation of the solution to dryness with strong hydrochloric acid. Unless this precaution is observed, the percentage of soluble phosphoric acid indicated is, in his experience, on the average about 0·5 per cent. too high.

Electrolytic Separations. I. H. Buckminster and E. F. Smith. (*J. Amer. Chem. Soc.*, 1910, **32**, 1471-1477.)—Information is given concerning some twenty electrolytic separations, as to which the literature is conflicting, but which are shown to be quite practicable under assigned conditions. As the result of nearly a hundred experiments, the following directions are given for the electrolytic separation of silver and bismuth: To a solution containing not more than 0·2 grm. silver or 0·2 grm. bismuth as nitrate, 3 c.c. of nitric acid is added, and the mixture diluted to about 75 c.c. A dish anode is employed, and placed 3 mm. from the dish cathode. The liquid is maintained at a temperature of 60° C., and the anode rotated about 250 times a minute. At a pressure of 3 volts and current $\text{N.D.}_{100} = 0{\cdot}15$ to 0·20 ampère, 0·1 grm. of silver may be deposited quantitatively and free from bismuth in twenty-five minutes. The addition of chrome alum or iron alum to the electrolyte is not only unnecessary, but actually disadvantageous.

It is found that zinc may be separated from uranium by the use of a mercury cathode and rotating anode. The latter is conveniently given 200 turns per minute. With a current of 3·5 ampères at 5 volts, 0·2 grm. of zinc may be separated from an equal weight of uranium in from fifteen to sixty minutes. G. C. J.

Electrolytic Determination of Chlorine in Hydrochloric Acid with the Use of a Silver Anode and Mercury Cathode. J. S. Goldbaum and E. F. Smith. (*J. Amer. Chem. Soc.*, 1910, **32**, 1468-1471.)—Gooch and Read have stated (*Amer. J. Science*, 1909, 544) that when attempts are made to determine chlorine in hydrochloric acid with the use of a silver anode, results are obtained which are very irregular and always low. Gooch and Read used a platinum cathode. It is now shown that when a mercury cathode is used, results can be obtained of a high order of accuracy. The silver anode is prepared by plating platinum gauze from a potassium silver cyanide electrolyte. If this be then dipped in dilute hydrochloric acid, washed and ignited to incipient redness, any admixed cyanide is destroyed. The anode must not be strongly ignited, lest the silver be fused or its porous nature destroyed. Porosity favours retention of chlorine, whereas a smooth silver surface introduces a risk that molecular chlorine may be liberated, with consequent production of hypochlorites and chlorates. The deposit of silver chloride is liable to be contaminated by silver oxide due to a secondary action; but this secondary action involves no loss of chlorine, and the silver oxide is easily decomposed at temperatures above 250° C. For this purpose the authors use an electric oven, which can be maintained at 300° C., ten to fifteen minutes at this temperature being sufficient. It is convenient to rotate the anode some 300 times a minute, and high current densities must be avoided, lest the silver chloride become too loosely adherent. At the pressures usually employed (2·5 to 5 volts) the anode should be placed at least 15 mm. from the level of the mercury. The method is equally applicable to hydrobromic acid. G. C. J.

Analysis of Enamel. R. D. Landrum. (*Chem. Engineer*, 1910, **12**, 142-145.)—A detailed scheme of analysis for enamel is given, including the determination of silica, iron, alumina, lime, magnesia, alkalis, boron, fluorine, manganese, cobalt, antimony, tin, phosphorus, and lead. Little originality is claimed for the methods themselves, but only for their adaptation to the very difficult problem of enamel analysis.

The following method is described for stripping the several films of which an enamel is usually composed, and which must be analysed separately if useful results are to be obtained. The article is scratched lightly with emery-cloth or a file, and then coated with gum acacia or glue. The article is next heated in an air-bath and the hardened glue chipped off, carrying with it some of the outer coat of enamel. The glue is dissolved in water and the enamel recovered for analysis, and the process is repeated several times, to strip first the remainder of the outer coat and subsequently enough of the ground coat for analysis. G. C. J.

Estimation of Gold by Means of Hydrogen Peroxide. L. Rössler. (*Zeitsch. anal. Chem.*, 1910, **49**, 739-740.)—Vanino and Seemann (*Ber.*, 1899, **32**, 1968) showed that gold could be precipitated quantitatively in the cold and in a few minutes by means of hydrogen peroxide in presence of caustic alkali. It is now shown that precipitation is complete in acid solution in something less than twenty-four hours, and that, in presence of potassium carbonate in place of caustic alkali, it is not only complete, but rapid. G. C. J.

Delicate Test for Hydrogen. C. Zenghelis. (*Zeitsch. anal. Chem.*, 1910, **49**, 729-732.)—The gas, previously freed from other gases which might give the same reaction, is passed through a solution of sodium molybdate contained in a test-tube, in which is also placed a piece of recently-ignited platinum (or, better, palladium) gauze or foil. A single bubble of pure hydrogen produces an intense blue colour if the solution be warm; whilst, if it be cold, a greenish-blue colour results, and the same greenish-blue colour results on leading in a stream of gas containing traces only of hydrogen. The molybdate solution is made by dissolving 1 grm. of molybdenum trioxide in dilute caustic soda, rendering just acid with hydrochloric acid, and diluting to 200 c.c. If intended for use with palladium, the smallest possible excess of acid must be used. The gas to be tested must not only be freed from reducing gases, such as hydrogen sulphide and P_2H_4, but also from carbonic oxide. Neither methane, ethylene, acetylene, nor their homologues interfere. Methods and apparatus are described for concentrating on palladium sponge the hydrogen from large quantities of gas containing only minute traces of hydrogen, and subsequently demonstrating the presence of this hydrogen by means of the molybdate reagent.

G. C. J.

Volumetric Estimation of Mercuric Chloride. G. Bressanin. (*Anal. Chim. analyt.*, 1910, **15**, 413-415.)—The method described by Archetti (ANALYST, 1901, **26**, 108) is empirical, and the neutral point of the titration, as shown by phenolphthaleïn, does not correspond with the formation of any definite mercury ammonium compound, or rather, it appears that a number of mercury ammonium complexes are formed. Operating with $\frac{N}{10}$ solutions, it is found that the neutral point to phenolphthaleïn is reached when 8·55 c.c. of $\frac{N}{10}$ ammonia have been added to 10 c.c. of $\frac{N}{10}$ mercuric chloride solution. If, however, an excess of ammonia be added to the mercuric chloride solution, and the excess of ammonia be titrated in an aliquot portion of the clear solution after the precipitate has settled, it will be found that exactly equivalent quantities of ammonia and mercury chloride have been used in the formation of the precipitate. Litmus paper should be used as indicator in the titration, and at least 4 molecules of ammonia (NH_3) must be present for each molecule of mercuric chloride. W. P. S.

Volumetric Determination of Nitric Acid in Nitrocellulose, Nitroglycerol, and other Compounds. E. Brouvert. (*Bull. Soc. Ind. Mulhouse*, 1910, **80**, 254-263.)—The gasometric method of Lunge or of Schloesing is generally employed, or the sample may be distilled, with concentrated sulphuric acid or phosphoric acid, into standard alkali, with subsequent back-titration. The author's method consists in setting free the nitric acid with sulphuric acid, and running in standard stannous sulphate solution from a burette, until the blue coloration produced by diphenylamine is discharged on the reduction of the nitric acid. The solution of nitrocellulose, even of hard powder-grains, is more easily effected by this method than by the others, as the acid may be warmed; any excess of it may be used, and the substance may be crushed, if necessary. The standard tin solution is prepared by dissolving stannous sulphate, or the double sulphate of tin and potassium, in a mixture of equal volumes of sulphuric acid and water, and adding just enough concentrated hydrochloric acid for solution. It is standardised by running it from a burette into a solution made by dissolving 0·15 grain of pure potassium nitrate in a small quantity of water, and adding to it rapidly 50 c.c. of concentrated sulphuric acid, and 1 drop of diphenylamine in water. It is claimed that the method is simpler and more rapid than the others, and at least as accurate. Sample analyses: for a nitrocellulose from cotton, 10·58, 10·60 per cent., against 10·70, 10·60 by Lunge's method; for a wood nitrocellulose, 10·59, 10·56, against 10·20, 10·30 by Lunge's method; for pure potassium nitrate, 99·7, against 98·84 by Lunge's method; for spent acids, 9·73, against 9·7 by Lunge's method; and 9·7 by distillation at 170° C. with phosphoric acid.

O. E. M.

International Standard Units for the Measurement of the Radio-activity of Radium. A. Jaboin. (*J. Pharm. Chim.*, 1910, ii., 494-497.)—Two methods are employed for the valuation of radio-active substances—viz., (1) measurement of the quantity of γ rays emitted by a given weight of the radium, etc., by means of a sensitive electroscope; and (2) measurement of the emanation emitted within a given time from a definite weight of the substance. For purposes of comparison it is necessary to have a standard sample of radium, and it was decided at the recent Congress of Radiology in Brussels that Madame Curie should prepare a specimen of radium, containing about 20 mgrms. of the element, and that this should be kept in Paris as a specimen upon which other preparations could be standardised. It was decided further that the unit of weight should be 1 grm. of radium (element), and that the unit of emanation, to be termed a "curie," should be the quantity of emanation in equilibrium with 1 grm. of radium. By radio-active equilibrium is understood the moment at which a given quantity of radium gives its maximum emanation—*i.e.*, when this quantity of emanation developed in a closed vessel becomes constant. The quantity of emanation given off by a mgrm. of radium (element) is, in like manner, to be termed a "milli-curie," and that emitted by a microgramme of radium (element) a "micro-curie."

C. A. M.

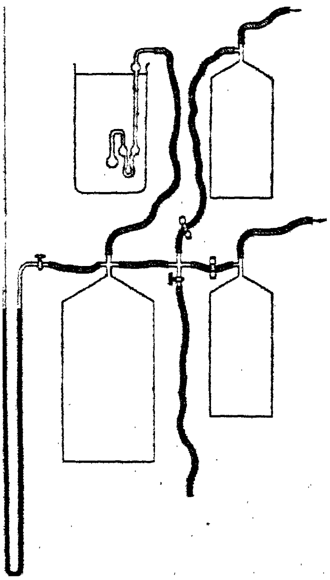
Precipitation of Vanadic Acid as Silver Vanadate, and Estimation of Phosphoric and Vanadic Acids in Presence of each other. G. Edgar. (*Amer. Chem. J.*, 1910, **44**, 467-472.)—In solutions of alkali vanadate containing an excess of carbonate, but no other substance precipitated by silver nitrate, vanadium may be estimated as follows: The solution is acidified with nitric acid, and boiled to expel carbon dioxide. A yellow colour, at first deep and then fading somewhat, is developed by this treatment. Dilute caustic alkali is added to the boiling solution until this yellow colour just disappears. The solution is then faintly alkaline to phenolphthaleïn. Excess of standard silver nitrate is next added, the resulting precipitate, which is of variable composition, is dissolved in ammonia, and the solution then boiled until the odour of ammonia has disappeared. The resulting red precipitate is silver orthovanadate, free from pyrovanadate. After cooling, the precipitate is filtered off and washed, and the excess of silver in the filtrate and washings determined by titration with ammonium thiocyanate, after acidifying with nitric acid. Each c.c. of $\frac{N}{10}$ silver nitrate = 0·00304 grm. V_2O_5. The method as described gives results accurate to 0·05 c.c. $\frac{N}{10}$ silver solution. Under other conditions the silver precipitate may consist wholly of pyrovanadate or be a mixture of ortho- and pyrovanadate.

Phosphoric acid may by precipitated in a similar manner as yellow silver phosphate, Ag_3PO_4, and the following method is recommended for the estimation of phosphoric and vanadic acids in presence of each other. Both acids are precipitated by means of standard silver nitrate exactly as described for vanadic acid alone, and the excess of silver nitrate determined by titration with thiocyanate. The difference between the quantity so found and that taken for the precipitation is the measure of the combined phosphoric and vanadic acids. The vanadic acid is then estimated separately by dissolving the silver precipitate in sulphuric acid, reducing the vanadic acid by means of sulphur dioxide and titration of the lower oxide of vanadium with permanganate in the usual manner. The phosphoric acid is estimated by difference. One c.c. $\frac{N}{20}$ permanganate = 0·00456 grm. V_2O_5 and 1 c.c. $\frac{N}{10}$ silver = 0·00304 grm. V_2O_5 = 0·002367 grm. P_2O_5. The error of the method is no greater than corresponds to 1 drop of the standard solutions employed. G. C. J.

APPARATUS, ETC.

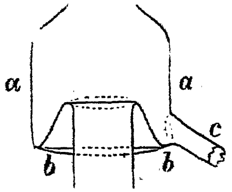
Static Method for Determining Vapour Pressures of Solids and Liquids. A. Smith and A. W. C. Menzies. (*J. Amer. Chem. Soc.*, 1910, **32**, 1412-1434.)—The apparatus is shown diagrammatically in the sketch. The substance, of which about 1 c.c. suffices, is contained in the bulbed tube, termed an isoteniscope, and, if a liquid, acts as its own confining liquid. Owing to the low sp. gr. of most liquids compared with that of mercury, when the levels in both limbs of the U-tube appear to be identical, the error, converted into mercury height, is negligible. The isoteniscope, which is about 24 cm. long over all, is placed in a tall 2-litre beaker containing some suitable liquid, together with a platinum resistance thermometer and a mechanical agitator capable of imparting violent movement to the liquid. Only by violent stirring can thermal equilibrium be obtained. The isoteniscope and the mercury gauge are connected with a large iron bottle. Another piece of tubing leading from this bottle gives connection at will with (1) the atmosphere, (2) a vacuum reservoir and pump, or (3) a pressure reservoir and compression pump.

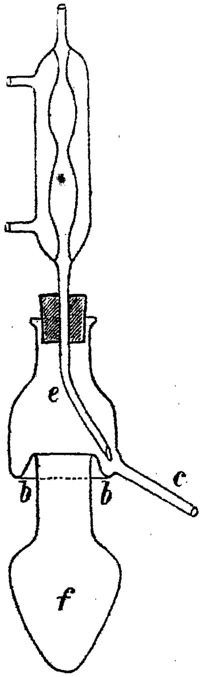
When the temperature of the bath in which the isoteniscope is immersed has reached the desired point and is constant, the exit to the suction bottle and pump is opened and kept open until the substance in the bulb boils, and the vapour passes freely through the confining fluid, which is the liquid phase of the substance itself when a liquid is under examination. (To determine the vapour pressure of a solid, the end bulb of the isotemiscope must be cut off, the solid inserted, and the bulb re-fused to the U-tube. A confining liquid is then chosen, such as has no appreciable vapour pressure of its own at the temperatures to be employed, does not dissolve the vapour of the substance experimented with and does not interact chemically with the vapour.) The confining fluid is driven into the remote side of the U-tube and the bulb above it. When the air in the bulb and the gases adhering to the bulb and dissolved in the liquid have been driven out, air is cautiously admitted to the iron bottle by connecting this with the atmosphere until the levels of the liquid in both limbs of the U-tube are identical. On account of the cooling of the substance by evaporation, equilibrium is not reached at once, so that the adjustment has to be repeated until the levels remain constant. The stopcock on the gauge is then closed, the temperature reading is confirmed, and the gauge and (since this is an open gauge) the barometer are read. The whole process of boiling out, adjusting, and reading is repeated until constant values are obtained. The temperature of the bath is then raised and a new observation taken.



Older methods are criticised, and the several advantages of the present apparatus fully set out. The manipulations involved are incomparably simpler than those of any other static method, and figures are given showing that the method may be made to yield numbers of a high order of accuracy. A series of determinations made with water agree more closely than do those of Regnault, Magnus, Battelli, or Wiebe with the smoothed values of Holborn and Henning (*Ann. Physik.*, 1908, [iv.] 26, 833), which are undoubtedly the most accurate in existence, and the comparison was made, not with smoothed values obtained by graphical or other methods, but with individual results, subject to the irregularities which individual observations usually show. G. C. J.

Microdistillation Apparatus. A. Gawalowski. (*Zeitsch. anal. Chem.*, 1910, 49, 744-745.)—The left-hand drawing illustrates, half-size, a glass vessel in one piece for the distillation of small quantities of liquid. It is closed at the top [illegible] by a glass ball, a narrow-necked funnel, or a cork carrying a condenser, and the distillate flows away at *c*. The right-hand drawing represents (one-third natural size) a similar





apparatus, with the difference that the lower part, instead of being a simple tube, is given a shape which militates against frothing. G. C. J.

REVIEWS.

The Extra Pharmacopœia. By W. H. Martindale, Ph.D., and W. Wynne Westcott, M.B. H. K. Lewis. Pp. 1054. Price 12s.

The fourteenth edition of this well-known work appears in a new and condensed form; and now, although much fresh matter has been added, the contents have been compressed, without any loss of clearness, into a volume of a little more than half the original size.

The scope of the book is sufficiently familiar to most. It appeals mainly to the physician and the pharmacist; but there is much matter relating to analytical work, and there are many paragraphs dealing with topics somewhat off the beaten track on which the practising analyst may find information, the value of which is increased by references to original papers.

The main bulk of the work is taken up with an account of the properties and uses of medicinal substances, the ground covered being similar to that dealt with in Squire's "Companion to the British Pharmacopœia"; but, in addition to this, there are pages or paragraphs dealing with the following: Analysis of urine, blood, stomach contents, water (chemical and bacteriological), milk, butter; tests for carbon monoxide poisoning; bacteriological notes dealing with the characters and methods of cultivating and staining the chief organisms associated with specific diseases; the preparation of culture media; embalming; and the antiseptic power of chemical substances. There are also notes on the Poisons and Pharmacy Acts, a list of scheduled poisons, and a glossary in six European languages of words and phrases likely to be met with in prescriptions.

Amongst the new subjects dealt with are lactic acid bacilli and curdled milk preparations and methods for their examination, organic arsenic compounds, the introduction of drugs into the system by electrical means (iontophoresis), and the use of radium and its preparations in medicine. A list of some two or three hundred proprietary medicines, giving the chief active ingredients stated to have been found in them, is the more valuable because the source from which the information is derived is in almost every case given.

It will thus be seen that there is a vast mass of information with much of which the practising analyst has little direct concern, but a good deal of which he might on occasion find of use. The extremely wide scope is the *raison d'être* of the book, and at the same time one of its weakest points, so far as the inclusion of analytical matters is concerned.

Condensation has obviously had to be carried to its extreme limits, and, although the style is admirably clear (though not always elegant), it is quite impossible, in such brief space as could be afforded to any single subject, to point out the danger that may lurk in even the simplest analytical process when in inexperienced hands, such as those of the majority of "medical practitioners and students," for whom the analytical notes are said in the Preface to be mainly intended. When, for instance, the whole art and science of water analysis is dealt with in the space of a page and a half, including the preparation of the standard solutions and notes on the interpretation of results, the inexperienced person, with no other book at hand, is naturally led to believe that the subject is a very simple one. How far he might be led astray will be obvious when it is mentioned that only a qualitative test for nitrates is given—viz., the brucine reaction.

It is fair to add that such serious omissions are the exception, and that the book must be allowed the defects of its qualities. Moreover, it is as a general book of reference, and not as a manual of analytical chemistry, that it will appeal to the readers of this journal.

Regarded simply as universal providers of medico-chemical learning, it must be admitted that the authors have done their work well, and few books of this kind contain a greater volume of useful information to the cubic inch.

CECIL H. CRIBB.

ORGANIC ANALYSIS CHART. By W. HARRISON MARTINDALE, Ph.D. H. K. Lewis. Pp. 80. Price 3s. 6d.

This is a supplement to the above work (p. 39), intended to assist in the recognition of a number of organic chemicals used in medicine.

The first sixty-three pages are devoted to a series of tables, which give in the briefest possible manner the result of certain chemical and physical tests on the selected substances.

In addition to tests involving the use of certain specified reagents, the action of heat, the specific gravity, the melting-point and the solubility or miscibility with water or alcohol, are also given. The reagents include acids, alkalis, Fehling's solution, and certain general alkaloidal reagents, and the substances about which the information is given—319 in all—include a very large number of bodies not at all commonly met with, such, for instance, as enesol, ephedrine, hetraline, largin, neurodin, and tylmarin. It is, however, rather difficult to account for the selection made by the author, because, along with the out-of-the-way substances just mentioned, such common things as cane sugar, lævulose, and dextrose are also referred to, and yet others equally common — *e.g.*, glycerol, maltose, and lactose — are missed out.

It is obvious that identification is hardly likely to be arrived at in this way, but to render this possible the final fourteen pages of the book are devoted to corroborative tests, one or more being given for most of the substances mentioned in the tables, or else references are given to larger works.

The idea is a practical one, and as it is applied to many bodies about which little information is available, it is likely to be useful to those confronted with the problems with which it is meant to deal. CECIL H. CRIBB.

LA CHIMICA DELLE SOSTANZE ALIMENTARI. P. E. ALLESANDRI. Published by U. Hoepli, Milan. Price 6 lire, 50.

Although this book is only a small octavo volume of 600 pages, the author has endeavoured to compress within these limits an enormous quantity of material; for it includes not only full descriptive methods for the analysis of water, wine, milk, and food products of every description, but also contains sections upon air, petroleum, coal-gas, perfumes, and cosmetics.

The section dealing with water occupies about a quarter of the available space, and gives a most valuable outline of the methods of examination and of the various points upon which a judgment of the results should be based. It includes illustrations of the unicellular and amœboid organisms of most common occurrence in water.

The section on wine is also excellent, and includes a description of the various maladies to which wine is subject; but in most of the other parts of the book the evils of compression are obvious, and in many instances the methods are not up to date. Thus, of the twenty pages devoted to oils, a good deal of the space is occupied by descriptions and tables of special hydrometers and of obsolete colour reactions with phuric acid, etc., while no reference is made to Wijs' method of determining the ine value.

In the section upon butter the reader is directed to take 2·5 grms. of fat for the ermination of the Reichert-Meissl value, and the author is evidently under the)ression that "Reichert-Meissl" was the compound name of one man, whose thod was subsequently modified by Wollny.

Points such as these, which might be largely multiplied, are sufficient to show t the book is of unequal merit, and does not reach the standard of its first portion. most of the sections useful facts and methods may be gleaned, but the reader will many cases have need to refer to other books upon the analysis of food.

C. A. MITCHELL.

E SPARK SPECTRA OF THE METALS. By Admiral GEORGE E. GISSING. 1910. London: Baillière, Tindall and Cox. Demy 4to. Price 7s. 6d. net.

is book the author has described the spark spectra of all the metals, with f aiding those engaged in the qualitative investigation of alloys or minerals. of all the spectra are quite uniform, and will serve as very handy references rison when any substance is examined spectroscopically with a view of ng its metallic constituents. Only the visible region is dealt with, but the park spectra are sufficiently characteristic over this range for the particular n view. Among the spark spectra are included the vacuum-tube spectra of elium, hydrogen, and carbon dioxide. In the text are given careful ions for the use of those who are novices in this particular branch of work. are also added notes of the most important and characteristic lines of each of ectra illustrated. If any criticism were needed, [illegible] might perhaps be said that thor is unduly severe when he remarks that spectrum analysis is of no use at quantitative analysis. He is hardly fair to his own subject in saying this, it would certainly seem that we have in our hands, as the result of Pollok's d that of Count de Gramont, the basis of an accurate quantitative method. course, this little book, with its fifty reproductions of spectra, good as they are, ank among the well-known spectrographic atlases. This, however, may be as a virtue, for it is far easier to recognise a spectrum by comparison with tographs as those of Admiral Gissing rather than with the big maps given atlases.

E. C. C. BALY.

NEW BOOK.

THE SCIENTIST'S REFERENCE BOOK AND DIARY FOR 1911. For James Woolley, Sc and Co., Ltd., Manchester. By CHAS. LETTS and Co. London. 1911. P 1s. 6d.

Part I. contains lists of Associations, Institutes, Congresses, International Ex bition (Turin), etc., Scientific Societies, Data as to First Aid in poisoning ca A calendar, and a "daily wants" dictionary then follows, also a series of blank pa for memoranda, telephone numbers, etc. A Diary for 1911, and blank pages addresses, complete the part. Part II. is back to back with this, as a duplic pocket-book, and forming the "Scientist's Reference Book," with numerous ite such as Astronomy; Meteorology; British Weights and Measures; Metric Weig and Measures, etc.; Chemical Terms, Synonyms, etc.; Atomic Weights; Speci Gravities; Physical Constants of the Elements; Formulæ and Solubili Water; Factors for Use in Volumetric Analysis, etc.; Alloys; Scientific Te in general use; Laws and Definitions in Chemistry and Physics; also Human Physiology; Hygiene; Chemical Composition of Food. A serie blank pages completes the booklet.

FEBRUARY, 1911. Vol. XXXVI., No. 417

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

ANNUAL ADDRESS OF THE PRESIDENT.

(*Delivered at the Annual General Meeting, February* 1, 1911.)

In presenting my annual address, it is my first duty to refer to the losses we have sustained during the session. The year 1910 was shadowed by the tragically sudden and deeply mourned death of a Sovereign who had so firmly attached to himself the affections, not only of his own peoples, but those of foreign nations also. Your Council presented a loyal and dutiful address of sympathy to His Majesty King George V., and this address was graciously received and acknowledged.

Of the members of our Society, two have passed away, both of them men of mark. One, Dr. J. Campbell Brown, was an original member of our Society, and Public Analyst for Lancashire. The second member whose loss we deplore was Oscar Guttmann, the well-known expert on explosives, who was a comparatively recent member of our Society. Four others have ceased to continue their membership; but we have had, on the other hand, an addition of twenty-one new members, including one honorary member, Dr. J. J. Dobbie, Principal of the Government Laboratory, whose accession is a source of great satisfaction and pleasure to us.

Our total membership now amounts to 380, and we are in the healthy condition of having a much heavier birth-rate than death-rate. The increase in our membership is, however, not as large as I could wish, although it is very encouraging, especially from the point of view of the *personnel* of our new members.

I cannot help feeling that there are many of our professional brethren whose inclusion in our ranks would very materially add to our usefulness, and I feel sure that if members would make a personal effort, an increased membership would be obtained. We carefully avoid holding out any pretensions that we, as a Society, are a "qualifying body" in any way; but, at the same time, it is imperative to the well-being of our profession that we should strictly uphold the dignity of our Society, and we are entitled to insist that anyone proposed as a member should be scientifically and socially qualified. I would, therefore, urge members to exercise the greatest care in the matter of signing proposal forms. It is undoubtedly often difficult and unpleasant to refuse to do so; but I would remind members that, in affixing their signature to a form, they are accepting a personal responsibility that the candidate is strictly complying with the requirements laid down in our Articles of Association.

That membership of our Society does confer a distinction, I would be the last one to question, but I very strongly deprecate any attempt to make use of the membership of this Society as a qualification, and I would appeal to members to avoid any appearance of this. One instance occurs to me, and one which I think we must all condemn, where a gentleman, who resigned his membership many years ago, still describes himself, when he appears in print, as a "Past Vice-President" of our Society. In connection with the increase of our membership, it has been suggested that possibly a resumption of those country meetings, which used to be held in former days, would materially assist in creating a greater interest in the Society among provincial analytical chemists. The matter is one which I would suggest might be carefully considered by the Council.

The financial statement which our Treasurer has laid before you is, I venture to say, extremely satisfactory; and although the available balance at the end of the year is less than it was a year ago, it must be noted that there are items of extraordinary expenditure, which largely account for this—for example, our contribution of fifty guineas to the Building Fund of the Institute of Chemistry. There is also the item of expenses in connection with the visit of our delegate to the International Conference held at Paris, to which I shall subsequently refer.

Our Treasurer is making timely provision for a serious expenditure which we shall in a few years have to face in connection with a new General Index of the ANALYST. The Society may congratulate themselves on having secured the services of a Treasurer who is not merely careful of our present resources, but who looks forward to proper provision for future expenditure. You will observe that he has taken a step which I am sorry that I failed to do when I held the like office. I allude to the exchange of our holding in Government securities to that in Colonial securities, yielding a better return of interest, and having practically equal security. Consols, as you are aware, have persistently declined in value, and we have had more than once to seriously write them down in our books. It is to be noted that, since the change effected by Mr. Richmond came into effect, the Consols disposed of have fallen in value, while the newly-purchased stocks have appreciated.

Our Journal, the ANALYST, continues year by year to increase, not only in substance, but in quality, and it is now more and more widely recognised as the most valuable Journal of analytical chemistry. Our most cordial thanks are due to the Editor, Mr. Julian L. Baker, for the able manner in which he conducts our Journal, and for the care which he exercises in securing abstracts of all important papers appearing in foreign and other scientific journals. During each of the last two years nearly seven hundred abstracts have appeared in our Journal, while four years ago, when Mr. Baker first took over the editorship, only about four hundred abstracts appeared.

The work under our analytical research scheme continues to flourish, and so far thirty-four investigations have been undertaken, the results of many of which have been published in the ANALYST. During 1910 nine investigations were commenced, five of which have been completed, and the results published during the year; thirteen are not yet completed, and arrangements have been made for several new subjects to be taken in hand. I consider that this research scheme is doing most useful and valuable work, and is one which ought to be more actively supported than it is.

You will notice in the Treasurer's statement that there is a small deficit in the Research Fund, the income of which has not been sufficient to meet the calls upon it. As you are aware, the scheme was suggested by our Hon. Secretary, Mr. Chapman, and the fund was started by the members of the Publication Committee, and no definite appeal for funds has been made to the general body of our members. The time has now arrived when I think such an appeal might be made, and I venture to do so in the hope that many of our members who recognise —as they must—the enormous importance and value of the work which is carried out under this scheme will generously support it, and put it in such a position that the income derived from its Capital Fund will be sufficient to meet the calls upon it.

At the seven meetings held during the past session, thirty-six papers were communicated to the Society, and as the records of these appear in our Journal, I depart from the usual practice of my predecessors of giving the list of these papers. It is sufficient to say that many of them have been of exceptional interest, and that they have dealt with a very wide range of subjects.

One of the great disadvantages of our scientific journals of the present day is the amount of overlapping which takes place. Abstracts of papers are found dotted about here and there, and appear over and over again in different journals, thus involving a great waste of time. It would be a great advantage to the scientific world if a serious effort could be made to concentrate this work, and to avoid this overlapping. Not only is this the case with abstracts, but papers of a purely analytical interest are communicated to societies which are not really directly concerned in the subject. I would appeal to members to forgo the natural temptation to come before a larger public than our own society can command, and to remember that our meetings are those to which such papers ought to be communicated.

Early in June we received, at the instance of the Foreign Office and of the Local Government Board, an invitation to send a representative to an International Conference which was to be held in Paris at the end of that month. This Conference had been summoned by the French Government to discuss two questions—first, that of the Unification of Methods of expressing the Analytical Results obtained in the Analysis of Food Products; and secondly, that of the Unification of the Methods of Analysis.

The British Government had not been officially represented at previous International Conferences on these and kindred subjects, and the Foreign Office thought it desirable that on this occasion this country should be officially represented.

On receipt of the invitation from the Local Government Board, the Council of the Society delegated our Hon. Secretary, Mr. Chapman, as their representative. The other British delegates to the Conference were: Dr. G. S. Buchanan and Dr. G. W. Monier-Williams, of the Local Government Board; Dr. J. J. Dobbie, Director of the Government Laboratories; Mr. E. J. Connah, Chief Chemist of the Customs Laboratory; and Dr. Nestor Tirard, Secretary of the Pharmacopœia Committee of the General Medical Council.

The following countries were also represented: Argentina, Belgium, Bulgaria, China, Denmark, Greece, Holland, Hungary, Italy, Mexico, Norway, Portugal, Sweden, Switzerland, and Uruguay, in addition to the French delegates. Dr. Bordas, the Principal of the Laboratories of the French Ministry of Finance, was appointed President. The first four meetings of the Conference were occupied with the discussion of the Unification of the Methods of Expressing Analytical Results, a matter on which it would appear that it should be possible and advantageous to come to an International agreement. The French delegates had prepared a statement of their proposals which served as a basis for deliberation. Mr. Chapman, in consultation with his colleagues on our Council, had prepared an extremely careful and able memorandum on the subject, and it is a matter of congratulation to know that his suggestions not only had the approval of the British delegates, but also that many of them were adopted by the Conference. As a result, the final report on this portion of the Conference was signed by all the British delegates who, however, were obliged to make it clear that, however strongly they might feel as to the desirability and advantage likely to result from the adoption of the recommendations, they could not be answerable for their adoption in Great Britain.

The question of the unification of methods of analysis was one on which there was little probability of any sort of agreement, and the matter was only discussed in general terms at the last two meetings of the Conference. It was, however, finally resolved that the French Government should consider a scheme for the creation of a permanent International Bureau, with laboratories, where the study of methods of the analysis of food products, with a view of their possible unification, should be carried out, and that this scheme should be submitted as soon as possible to all the Governments represented at the Conference. It is a matter to be noted, in connection with this International Conference, that Germany, a country particularly addicted to "Conferences," did not send any delegates.

Mr. Chapman desires to gratefully acknowledge the very courteous and kindly manner in which he, as the Society's representative, was received by the French authorities.

In October the Second International Congress of Food Hygiene met at Brussels, the Congress being divided into seven sections, when a programme embracing Physiology, Physiological Chemistry, Hygiene, Bacteriology, the Analysis and Adulteration of Foods, Legislation for the Repression of Frauds, Water Supplies, and Alcoholic Liquors was put forward.

The report of the proceedings of this Congress has not yet been published, but it is difficult to believe that a programme so ambitious, and covering so wide a field of inquiry, could possibly be adequately dealt with in the four days allotted to it. I must confess that I am very sceptical as to the practical value of these International Congresses, and I doubt whether they result in any definite progress being made. Indeed, conclusions may be arrived at completely subversive of progress, as was the case at the International Food Congress held in Paris in 1909, when it was decreed that boracic preservatives were absolutely necessary in the manufacture of butter, and that the "standard water-content" of butter should be "raised from 16 to 18 per cent." We had appointed delegates to this Congress, but, as they were unable to be present, we had to be content with publicly protesting against the decisions arrived at.

There has been, during the past year, a considerable agitation with the view of directing attention to the administration both of the Sale of Food and Drugs Act, and of the Fertilisers and Feeding Stuffs Acts. In March a Conference, organised by the County Councils' Association, was held in London, at which, although we, as a Society, were not officially represented, several of our members holding appointments under these Acts attended at the request of the County Councils. A number of resolutions were passed at this Conference, to some of which I will now briefly refer.

With regard to the Fertilisers and Feeding Stuffs Acts, a resolution was passed to the effect that, in cases where samples are taken by an official sampler, "the ten days' limit should be extended to twenty-one days." It was also resolved that it was a matter of urgency that the question of "standards" under the Fertilisers and Feeding Stuffs Acts should be dealt with by an expert Board of Reference.

Under the Sale of Food and Drugs Acts it was recommended, (1) That it would be desirable if wholesale manufacturers could be brought within the provisions of the Food and Drugs Acts with regard to the taking of samples; (2) that the powers of vendors to contract themselves out of the Acts by means of a notice should be severely restricted; (3) that the British Pharmacopœia should be made a legal standard for medicinal articles, but not until the new edition was compiled by the General Medical Council. On the question of "standards and definitions," it was resolved that the Local Government Board should have power to fix standards and definitions of purity for articles of food, and to order the nature and amount of preservative or other ingredient in any article of food to be declared on the label. It was also resolved that the Board of Agriculture should have power to fix "standards" for milk, cream, butter, or cheese, which should be conclusive evidence as to their not being genuine, and not merely raise a presumption until the contrary were proved. They also recommend that an expert Board of Reference should be constituted to decide controversial questions of chemistry, hygiene, or physiology.

The questions of standards and definitions was referred to two of the Public Analysts who were present at the meeting, Mr. Hinks and Mr. Duncan, with a view to obtaining the opinion of representative analysts as to the framing of a list of articles for which it would be advantageous that there should be official fixed standards and definitions of purity. These gentlemen reported that the result of their inquiries did not justify them in making specific recommendations, and that the consideration of these questions could only be taken in hand in detail by a representative body such as the Society of Public Analysts or by an expert Board of Reference.

The President of the Local Government Board subsequently received a deputation of the County Councils' Association, and expressed himself as being in complete sympathy with their objects. He pointed out the difficulty of introducing fresh legislation on the subject, and the enormous amount of opposition any amendment of the Acts would give rise to. He suggested that a simple Bill, giving the Local Government Board the power of determining questions of trade practices, and enabling it to issue regulations which would have statutory effect, would be a possible solution of the difficulty, and informed the deputation that he would arrange that some of the staff of his Department should confer with members of the deputation to see whether it would be possible to introduce legislation to meet the case.

The question of any amendment of the Sale of Food and Drugs Acts is one in which we as a Society are profoundly interested, and I venture to say that our views, as representing the Public Analysts of the kingdom, must have the most prominent and careful consideration if any real advance is to be made.

The difficulty of getting Parliament to move in the matter is well known. There are, no doubt, advantages in engineering a popular crusade against adulteration. The danger, however, lies in the tendency of all such movements to run riot in the effort to attract public attention and interest. As an example of this I would remind you of what took place last year at the Pure Food Exhibition, when most outrageous statements were made in the public Press as to the manner and extent to which different foods, as supplied to the public, are adulterated.

There is no question that there is a crying need for revision of our Food Acts, and to strengthen them in such a way as will enable the widespread and skilful tampering with our food products to be checked. It is, I think, most unfortunate that, when the amended Act of 1899 was introduced, the most important recommendation of the Select Committee of the House of Commons on Food Products Adulteration (which reported to Parliament in 1896) was not acted upon. I refer to the formation of a Court of Reference, which should have power to decide as to what does or does not constitute adulteration, and which would be competent to deal with the question as to whether the many trade practices which have grown up in connection with the manufacture and preparation of so many of our foodstuffs are legitimate or otherwise.

With all endeavours in the direction of bringing pressure to bear on the authorities responsible for the administration of the laws against adulteration, we as a Society have the most cordial sympathy; but, at the same time, we recognise that the whole subject bristles with difficulties, and requires handling with the greatest care, and by people who are thoroughly conversant with all sides of the question. The protection of the public against adulteration is a function of the State, and cannot be delegated to any self-constituted body, no matter how good and disinterested the motives of that body may be. I think it is necessary to point out to Public Analysts that their duty lies solely in the direction of the detection and prevention of fraud.

It has been urged sometimes that it is not fair that the vendor of any article coming under the Food and Drugs Acts should be held liable for any occasional fault which can be discovered, while he is prevented from utilising the benefits which would accrue to him as a trader were equal prominence given to the satisfactory reports received upon his products. I maintain most strongly that it is no part of the duty of the Public Analyst to push the business of trade rivals in this way, and that it is especially incumbent upon members of our profession who hold official public appointments to avoid giving reports to traders for the purpose of advertising their wares.

The suggestion that official standards should be laid down for all articles coming under the Food and Drugs Acts and the Fertilisers and Feeding Stuffs Acts is one which appeals to many as the simplest and most satisfactory solution of the difficulty; but, apart from the practical impossibility of definitely fixing the composition of food products which naturally show very wide variations, there is in some cases the objection that the fixing of such standards will inevitably tend towards the lowering of the general quality of the article. That this has actually taken place is strikingly shown in the case of butter. The fixing of a maximum limit for the percentage of water has undoubtedly resulted in an enormous increase in the number of samples which are found to contain an amount of water closely approximating to this maximum.

During the past year there have been, so far as I am aware, no High Court decisions in food and drugs cases which have had an important bearing upon the carrying out of the Acts.

In the inferior courts, however, several cases have occurred which strikingly show the necessity of an authoritative tribunal which will enable courts to decide whether a particular practice of a trade is legitimate or otherwise. It is satisfactory to note that a magisterial decision has been given to the effect that "golden syrup" is a definite article, and is understood by the public to be "refined treacle." Convictions for selling as "golden syrup" a syrup containing large admixtures of glucose syrup have been obtained, in spite of the contention that such syrups were "improved" commercial products.

The cases dealing with the question of what is cocoa are of special interest. Public Analysts who have been investigating this matter very thoroughly found that there was an increasing trade practice of mixing the ground shell, removed in the manufacture of high-class cocoa, with much of the other cocoa sold to the public. Several prosecutions were instituted in cases where the samples of cocoa were certified to contain from 35 to 60 per cent. of cocoa-shell, and the magistrate, after hearing evidence to the effect that the maximum amount of shell which cocoa would naturally contain if none of the shell were removed in the manufacture was about 12 per cent., decided that cocoa containing added cocoa-shell was not cocoa, and convicted the vendors. This decision, however, has not long remained unchallenged, for in a recent prosecution for the sale of cocoa containing 18 per cent. of added shell, the same magistrate, after hearing much conflicting evidence from experts and manufacturers, dismissed the summons.

It must be welcomed as a significant sign of progress that during the term of office of the present President of the Local Government Board a special Food Department has been organised, under the direction of Dr. Buchanan as Chief Inspector of Foods.

Dr. Buchanan, in addition to receiving the assistance of several Medical Inspectors, has now been able to add to the equipment of the Board a well-appointed chemical laboratory, and it is gratifying to state that a member of our profession and of our Society, Dr. Monier-Williams, has been chosen to co-operate with Dr. Buchanan in the direction of this laboratory.

Several most useful and important investigations have been undertaken, and reports dealing with the facing of rice, the use of preservatives in cream, and the various methods of preserving meats imported into this country, have been issued, and others are in course of preparation.

One cannot help feeling that, if some such step had been taken thirty years ago, it would have been of immense advantage; but we must, at any rate, be glad that so necessary a step has at length been taken.

The position of the Public Analyst is one which gives rise to a feeling of considerable anxiety as regards the future. The responsibility and the amount of work devolving on him increases year by year, and he has to be constantly on the alert in order to be able to cope with new and subtle forms of food sophistication. It cannot be denied that the Public Analyst has never had that recognition which he ought to have had. This I attribute in great measure to the indifference of the State to science in general and to chemistry in particular, which has so long prevailed.

When the Sale of Food and Drugs Act was first brought in, the science of food analysis was in its infancy, and the number of men really competent to undertake the responsible work of Public Analysts was extremely limited. The department, moreover, responsible for the Act—the Local Government Board—was guided, and always has been, in great measure, by medical authority, and, in controlling the appointments under the Act, has too often in the past failed to recognise the all-importance of chemical qualifications. Indeed, I believe that their former ideal of a Public Analyst was a medical man who had acquired some chemical training.

We are fully alive to the fact that there are, and have been, medical men with chemical qualifications of the highest order, who have rendered most valuable service to the profession of analytical chemistry, but it must be admitted that such men are the brilliant exceptions, and that the training in chemistry of the average medical man—even when supplemented by special work in connection with Public Health diplomas—cannot be regarded as in any way sufficient to qualify him for carrying out the duties of a Public Analyst.

We gratefully recognise that a very great change has been effected in the views held by the Local Government Board as to the importance of a proper chemical training such as is insisted upon by the Institute of Chemistry, and that now the diploma of this body is treated as a necessary qualification. The attitude of the Local Government Board in the past has naturally tended to shape that of local authorities, and the office of Public Analyst is too frequently regarded as an altogether inferior department of the Medical Officer of Health.

The Local Government Board has shown itself to be in accord with the efforts of the Institute of Chemistry and of our own Society to improve the status of the Public Analyst, and by their refusal to confirm appointments of men who have not the requisite chemical training, and by their clearly expressed disapproval of the practice of many local authorities of offering the position of Public Analyst to competitive tender, have done much to remove serious grievances. The Board, however, have not the control over local authorities which it is desirable they should have, and the Public Analyst has not that security of tenure of office which it is not only in his interest, but in that of the public, which he should have.

In the matter of the remuneration of the Public Analyst, the Board profess themselves unable to interfere, even when the remuneration is, in their opinion, utterly inadequate. The difficulty of this question is aggravated by the fact that so many analysts have, in their anxiety to secure positions, indulged in a system of wholesale undercutting of fees. Local authorities cannot be blamed if, regarding—as they naturally do—the question of economy in the administration of the Acts as one of the most important points, they take advantage of the willingness of properly qualified men to work under unremunerative terms. Recent cases which have occurred in Ireland show to what a deplorable condition things may be brought by this altogether unprofessional competition to secure appointments.

The proper training of a Public Analyst involves a long and expensive course of study and practice, and if in future the professional emoluments of Public Analysts is to be placed on a low scale, it is difficult to believe that the rising generation of chemists will be willing to undergo the severe course of training required of them.

There is no use shutting our eyes to the fact that the obvious tendency of the present day is for local authorities to make the Public Analyst a "whole time" officer, and with this it would appear that the Local Government Board is in complete sympathy. In a Memorandum recently issued by the Board, there was a strong recommendation to local authorities that Medical Officers of Health should not be engaged in private practice, and that appointments should be arranged so as to secure the "whole time" services of this officer. Special stress, however, was laid on the necessity of local authorities offering adequate remuneration in order that the services of well qualified men might be secured and retained. One could wish that similar directions as to remuneration could be given in the case of the appointments of Public Analysts, for it would be a misfortune if these appointments were in the future to be so inadequately paid as to fail to attract the services of men of standing in the profession.

Personally, I cannot help feeling that there are decided disadvantages from the point of view of the public interest in placing the analyst in a position of complete dependence upon local authorities.

Another point which I think has acted detrimentally to our interests is the lamentable ignorance of the public generally as to the proper meaning and function of a "chemist." Unfortunately, the title of "chemist" is, by Act of Parliament, ear-marked as belonging to pharmacy, and a large proportion of the public consider that the profession of analytical chemistry and the compounding and sale of medicines are occupations properly carried on by one and the same person. This idea is not confined to the man in the street, who may be excused for ignorance, but is shared in by intelligent people who ought to know better. I have a painful recollection of the remark made by one of the most learned Lord Justices—on the occasion of one of the dinners of the Institute of Chemistry at which he was an honoured guest—who, in replying to a toast, clearly showed that he confused the functions of an analytical chemist with those of the druggist.

When the legislation was introduced which gave rise to the term "chemist" and "druggist," the professional chemist, as we understand him, may be said not to have existed, but I think the time has now come when it would be very desirable if some steps could be taken to correct this confusion, and that the term "chemist" should be confined to its proper meaning.

In concluding my address, I must express my most heartfelt appreciation of the honour that has been conferred upon me, and the fact that the Society has seen fit to do this in the case of two members of the same family, confers on that family a unique distinction. To my colleagues on the Council, and especially to our secretaries, I would wish to express my most grateful thanks for the assistance they have so continuously given me during my term of office.

WALDEMAR FISCHER'S MODIFICATION OF VOLHARD'S METHOD FOR THE VOLUMETRIC ESTIMATION OF MANGANESE, AND ITS COMPARISON WITH OTHER WELL-KNOWN METHODS.*

By EDWARD CAHEN, A.R.C.Sc., F.I.C., and HARRY F. V. LITTLE, A.R.C.Sc., B.Sc.

(*Read at the Meeting, December* 7, 1910.)

An examination has been made of the modification recommended by W. Fischer (*Zeitsch. Anal. Chem.*, 1909, **48**, 751; Analyst, 1910, **35**, 80) of Volhard's well-known method for the determination of manganese, with the object of determining its degree of accuracy and of applying it to the estimation of manganese in high-grade ores and alloys. A detailed account of the results is recorded below, from which it will be seen that the process compares very favourably with several other well-established methods.

1. Examination of Fischer's Modification of Volhard's Method.

Volhard's method (*Annalen*, 1879, **198**, 318) for the estimation of manganese consists in titrating a hot solution of manganous sulphate containing zinc sulphate with potassium permanganate, when manganese dioxide is precipitated, a reaction occurring which is essentially represented by the equation

$$3MnSO_4 + 2KMnO_4 + 2H_2O = 5MnO_2 + K_2SO_4 + 2H_2SO_4.$$

The end of the titration is recognised by the supernatant liquid acquiring a faint permanent pink coloration.

Few analytical methods have been subjected to more criticism and modification than that just outlined, and the numerous though frequently conflicting statements concerning it that have appeared from time to time at least indicate that the method is one that appeals to the practical chemist. It has been generally recognised that the method gives low results, which is not surprising when the extreme difficulty of precipitating manganese exclusively in the form of dioxide is remembered (*cf.* Wright and Menke, *J. Chem. Soc.*, 1880, 37, 22; Gorgeu, *Bull. Soc. Chim.*, 1893, **11** [iii.], 490; Gooch and Austin, *Amer. J. Sci.*, 1898, **5**, 260). The presence of chloride is generally held to lower the results still further. An often-used modification of Volhard's procedure consists in titrating in the presence of suspended zinc oxide or calcium carbonate, which neutralises the acid formed during the titration. The temperature of titration also influences the results. It will therefore be apparent that accurate results cannot be expected from any of the usual modifications of Volhard's method unless the working value of the permanganate solution is empirically fixed by titration against a known amount of pure manganese salt.

---

* This work was carried out according to the terms of the Analytical Chemistry Investigation Scheme, and part of the cost was covered by a grant from the Research Fund.

The procedure recommended by Fischer (*loc. cit.*) claims to yield accurate results even in the presence of chloride in high concentration, while the permanganate may be standardised with sodium oxalate; it is said that the precipitated manganese dioxide contains the theoretical amount of available oxygen. The following account of the method is quoted from the ANALYST (*loc. cit.*):

"The solution of manganese in hydrochloric or sulphuric acid is diluted to 500 c.c., neutralised with caustic soda until a slight precipitate persists on shaking, and the precipitate just redissolved by cautious addition of dilute sulphuric acid. One grm. of freshly ignited zinc oxide and 10 grms. of zinc sulphate are next added, the solution heated to boiling, and titrated hot with permanganate. When the colour of the permanganate is no longer discharged, 1 c.c. of glacial acetic acid is added. The colour usually disappears, and the precipitate settles instantly. Permanganate is then added drop by drop until the solution becomes permanently pink, when the total consumption of permanganate accurately measures the manganese present."

To the above description it should be added that Fischer directs that the titration should be performed with frequent boiling and shaking, and that in the absence of chloride the quantity of zinc sulphate should be increased (about 10 grms. for each 10 c.c. $\frac{N}{10}$ $KMnO_4$ required).

From the equation given above it will be seen that 1 c.c. of $\frac{N}{10}$* permanganate only corresponds to 0·001648 grm. of manganese present as manganous salt; and, consequently, an error of 0·2 c.c. only corresponds to 0·00033 grm. of manganese. Nevertheless, this means an error of 0·6 per cent. in a titration requiring 33 c.c. The relatively large percentage error corresponding to an actual error of a fraction of a milligram of manganese does not appear to have been properly appreciated by several other workers (*cf.* von Longi and Camilla, *Gazz.*, 1897, **27**, 97), who have reported favourably of procedures which lead to actual errors of several times the magnitude mentioned above.

Materials Employed—(*a*) *Potassium Permanganate.*—The purest commercial salt was twice recrystallised from water at 65° to 70° C., and the product dried over sulphuric acid.

(*b*) (*c*) (*d*) *Manganous Sulphate, Sodium Chloride, Zinc Sulphate.*—The purest commercial preparations were used. Filtered solutions of the two latter salts of known concentration were measured out as required.

---

* By *decinormal* permanganate is here meant the usual solution, containing 3·16 grms. of the salt per litre, which is decinormal in *acid* solution.

(*e*) *Zinc Oxide.*—Pure precipitated zinc oxide was calcined in a muffle furnace. It was tested for impurity by de Koninck's method (*J. Soc. Chem. Ind.*, 1905, **24**, 152), with negative results.

(*f*) *Glacial Acetic Acid.*—Kahlbaum's purest preparation was usually employed, but the best commercial acid was found to contain nothing oxidisable by permanganate.

The majority of the test analyses were carried out by the following method, which was used in a series of experiments by Fischer: An approximately $\frac{N}{10}$ permanganate solution was prepared, and portions of 50 c.c. accurately measured out and evaporated to dryness with concentrated hydrochloric acid. The resulting manganous chloride was dissolved in water, rinsed into a litre flask, the requisite amounts of sodium chloride and zinc sulphate added, and the solution titrated by Fischer's process with the remaining permanganate solution. The theoretical volume of the latter required is 33·33 c.c., as will be seen at once from the equation, and three times the actual titration error in c.c. gives the percentage error.

It was originally intended to observe accurately the end-point obtained before the introduction of the acetic acid, and then to finish the titration in acetic acid solution; but it was soon found that this would consume considerable time without yielding results of any practical value. The accurate observation of the first end-point was therefore given up; the titration was carried out in the presence of zinc oxide until within about 1 c.c. of the theoretical value, when the acetic acid was added and the titration accurately finished.

As the result of a large number of test experiments, which frequently led to most curiously inconsistent results, it was eventually concluded that the titration cannot be completed in boiling solution, as directed by Fischer, since under these circumstances it is not possible to rely upon obtaining a definite end-point. Subsequently, it was discovered that this point had been insisted upon by von Longi and Camilla (*loc. cit.*) in their interesting review of Volhard's method. The disappearance of the permanganate end-point in boiling solution is probably accelerated by contact with the manganese precipitate, in view of the well-known instability of permanganate in the presence of the solid dioxide (Morse, Hopkins and Walker, *Amer. Chem. J.*, 1896, **18**, 401).

The following method, differing very slightly in detail from Fischer's, can be relied upon to afford satisfactory results:

The neutral solution of manganese salt, containing 10 grms. of zinc sulphate, is diluted to 500 c.c. and heated to boiling. One grm. of freshly ignited zinc oxide is then added, and the solution titrated with permanganate, with frequent heating to boiling, and shaking, until the permanganate is no longer decolourised. The solution is then cooled under the tap for a minute or two, 1 to 2 c.c. of glacial acetic acid are added, and the liquid thoroughly shaken. The hot but not boiling liquid is then titrated further with permanganate, added a few drops at a time, with vigorous shaking for half a minute after each addition, until the supernatant liquid retains its pink colour after being well shaken several times. The end-point is then reached, and the pink coloration will persist, as a rule, for one or two hours.

In this form, Fischer's process leaves little to be desired as far as accuracy is concerned, while the remarkable manner in which the precipitate subsides after the addition of acetic acid enables the titrations to be finished with the greatest ease.

The results obtained are summarised in Tables I. to IV. Those given in Tables I., II., and IV., represent mean values, each experiment having been repeated several times, with concordant results. The weights of zinc sulphate specified refer to *anhydrous* salt; it is not clear from Fischer's paper whether he means anhydrous salt or heptahydrate. The results have not been corrected by "blank experiments," which fact may partly account for the rather high results obtained in the presence of large amounts of sodium chloride and zinc sulphate.

Table I. shows that accurate results are obtained when chloride is present to the extent of 10 grms. of sodium chloride; further, that there is little necessity to increase the quantity of zinc sulphate beyond 5 grms. The comparative results of Table II. show that an increase in the amount of chloride present from 10 to 40 grms. of sodium chloride has no influence on the accuracy of the results. Also, that in the total absence of chloride the quantity of permanganate required for titration increases slightly with an increase in the quantity of zinc sulphate present, the results being rather low when little zinc sulphate is added. The quantity of this salt recommended by Fischer (*loc. cit.*, p. 53) seems, however, unnecessarily large, and it is preferable to operate in chloride solution rather than increase the amount of zinc sulphate present beyond 10 grms.

TABLE I.

These values were obtained from manganous chloride, prepared, as described on p. 53, from 50 c.c. of the same $\frac{N}{10}$ permanganate used for the titration.

$KMnO_4$ (theory for titration) = 33·33 c.cm.

Table IV. summarises the results of experiments made to determine the oxidising power of the precipitate. After titrating in the manner previously described (p. 54), a slight excess of permanganate was added to the solution, and the whole shaken vigorously for several minutes. The solution was then cooled, the precipitate filtered off on asbestos, and its available oxygen determined by dissolving in dilute hydrochloric acid and potassium iodide (Pickering, *J. Chem. Soc.*, 1880, **37**, 128), and titrating the liberated iodine with sodium thiosulphate, itself standardised against the permanganate solution. The excess of permanganate in the filtrate was also determined iodimetrically. The results obtained by these two processes are seen to be in substantial agreement with those obtained by direct titration with permanganate.

In applying Fischer's process in actual practice, a difficulty arises unless the volume of permanganate required is known to within 3 or 4 c.c., since, owing to the slowness with which the finely divided precipitate settles in the presence of zinc oxide, the time required for a titration is unduly prolonged, and the first end-point is difficult to observe. The simplest method of avoiding this is to conduct duplicate titrations, as recommended by Fischer. If the acetic acid is added in one case before the addition of any permanganate, a low result is obtained; but the titration is rapidly effected, and the result serves as a useful guide in the titration proper. An alternative procedure to obtain a preliminary result quickly consists in adding several grams of zinc oxide, omitting the zinc sulphate, and titrating in nearly boiling solution. The experiments recorded in Table IV. naturally suggest a backward titration method; the procedure necessary will be obvious from what has been already said.

2. Comparison of Fischer's Method with Other Methods.

The practical value of Fischer's method has been tested by applying it to the estimation of manganese in three specimens of ferromanganese.

The finely divided samples (1 grm.) were dissolved in 25 c.c. strong hydrochloric acid, the solutions oxidised with 10 c.c. nitric acid, and evaporated to a small bulk; 25 c.c. hydrochloric acid were again added, and the evaporation to a small bulk repeated. The solutions were diluted to 300 c.c. with cold water, and zinc oxide added little by little, with shaking, until the precipitate suddenly coagulated. The liquids were then diluted to 1 litre, filtered through dry papers from ferric hydroxide and zinc oxide, and aliquot parts (100 c.c.) of the filtrates measured out and titrated. The error caused by neglecting the volume of the precipitate is inappreciable. The permanganate solution was conveniently made to contain 3·5 grms. per litre, and was standardised against pure sodium oxalate (Sörensen), which is undoubtedly one of the most accurate methods that can be employed for this purpose.

It should be mentioned, in passing, that the commonly-employed zinc oxide method of separating iron from manganese does not always lead to satisfactory results, although it is not possible to assign the reason.

The method outlined above can be easily carried out in an hour and a half, and, of course, a number of analyses can be finished in proportionately less time.

For purposes of comparison, the samples have also been analysed for manganese by the following three well-known methods:

(*a*) *Basic Acetate Separation and Subsequent Gravimetric Estimation of Manganese as* Mn_3O_4.—The separation of the iron was effected twice with ammonium acetate in the usual manner. The manganese precipitate was crushed to powder after a preliminary ignition, and then ignited in the muffle to constant weight. This method appears to give much better results than the statements of some of its critics would lead one to expect (*cf.* Saniter, *J. Soc. Chem. Ind.*, 1894, **13**, 113).

(*b*) *Bismuthate Process.*—This was carried out according to the procedure of Reddrop and Ramage (*J. Chem. Soc.*, 1895, **67**, 268), except that only half the amount of manganese was employed, and ferrous sulphate was substituted for hydrogen peroxide, as recommended by Brearley and Ibbotson (*Chem. News*, 1901,

84, 247). For accuracy, rapidity, and simplicity, this method leaves nothing to be desired.

(*c*) *Pattinson's Process.*—This was carried out as described by Pattinson (*J. Soc. Chem. Ind.*, 1891, **10**, 337); bromine-water was the oxidising agent employed. It was preferred to standardise the bichromate solution employed upon the precipitate obtained from a known amount of manganese chloride (prepared by reducing a weighed quantity of pure permanganate) rather than with iron wire or ferrous ammonium sulphate; the latter procedure led to slightly higher results. It is necessary to point out, moreover, that commercial ferric chloride contains an appreciable quantity of manganese; consequently, if ferric chloride is added to the solution as Pattinson directs, the amount of manganese contained therein* should be allowed for, or an error of 0·4 to 0·5 per cent. manganese may be thereby introduced in dealing with an 80 per cent. ferromanganese. By standardising the dichromate on pure permanganate to which has been added an amount of ferric chloride equal to that used in an estimation, and arranging that the volume of standard solution required shall be approximately equal to that used in an actual analysis, the error due to this cause may be eliminated.

The results obtained are summarised in Table V. The agreement is very satisfactory; the data given are the mean values derived from several concordant analyses, and not "selected" from a number of results. It will be observed that the results obtained by Pattinson's method, employing ferrous ammonium sulphate as standard, are rather higher than those obtained by the comparative method or by other methods. It has not been found possible to duplicate the results obtained by Mr. J. E. Stead,† and which he forwarded after the results by the first three methods mentioned in Table V. had been obtained. It was at his suggestion that Pattinson's method was then tried, with the foregoing results. For very kindly supplying the samples of ferromanganese for analysis, and forwarding his own analytical results for the manganese, the authors wish to express their cordial thanks to Mr. Stead.

In confirmation of the substantial accuracy of the results set out in Table V., the following analytical results are appended (Table VI.). The results for *iron* are probably rather high, since the alloys were dissolved in hydrochloric acid and the iron determined gravimetrically; but they are sufficiently accurate for the purpose. For assistance in estimating the *carbon*, and for the loan of the necessary apparatus, the authors wish to acknowledge their indebtedness to Mr. A. E. Wraight.

Fischer's method has also been tried on two samples of pyrolusite; the results, with comparative data by two other methods, are set out in Table VII. It will be seen that here, again, the agreement between the volumetric methods is very satisfactory, while the gravimetric results are distinctly higher. This is in accordance with Saniter's remarks upon the gravimetric method as applied to ores (*J. Soc.*

---

* This is readily determined by boiling with ammonia and a little hydrogen peroxide, dissolving the washed precipitate in nitric acid and a little sulphurous acid, and estimating the manganese by the bismuthate method.

† The results obtained by Mr. Stead were 82·02 per cent., 80·06 per cent., and 60·50 per cent., respectively.

Chem. Ind., 1894, **13**, 113); in the above analyses the manganese was precipitated with bromine and ammonia directly in the filtrate from the basic ferric acetate. The volumetric methods are therefore to be preferred to the gravimetric process, unless the latter is carried out in a more refined manner, taking the necessary precautions to prevent co-precipitation of other metals, and analysing the final precipitate for impurities; it then becomes too tedious for technical work.

The authors' grateful acknowledgments to Mr. J. E. Stead and Mr. E. A. Wraight have been already expressed; it remains, in conclusion, for them to express their thanks to Miss Helen Cunningham for kindly translating von Longi and Camilla's paper, to Messrs. Riley and Harbord for supplying the pyrolusites, together with their own analytical results for the same, and, finally, to Mr. A. Chaston Chapman for the generous help he has afforded them throughout the course of the work.

NOTE ON THE COMPOSITION OF BRITISH WINES.

By EDWARD RUSSELL, B.Sc., F.I.C., and T. R. HODGSON, M.A., F.I.C.

(*Read at the Meeting, December* 7, 1910.)

The absence of any analytical data bearing upon the composition of British wines, and the infrequent submission of these substances under the Food and Drugs Act, led us to obtain a few specimens for the purpose of comparing the analyses with those from two samples collected under the Act.

The wines were supplied to us under ordinary retail conditions of purchase.

The following table gives the composition of the specimens:

GINGER WINE.

	1.	2.	3.	4.	5.	6.	7.	8.
Specific gravity	1027·74	1062·60	1062·47	1088·60	1139·27	1059·37	1060·60	1062·75
Total solids, grms. per 100 c.c.	12·60	21·19	20·80	28·93	43·23	20·09	20·78	21·14
Ash, grms. per 100 c.c. ...	0·183	0·422	0·128	0·123	0·321	0·317	0·306	0·418

Alcohol by weight ...	11·85%	9·29%	8·98%	10·23%	11·31%	9·93%	9·56%	10·15%
,, by volume ...	14·65%	11·52%	11·11%	12·68%	13·99%	12·31%	11·80%	12·58%
Proof spirit	25·65%	19·84%	19·54%	22·27%	24·52%	21·55%	20·78%	22·07%
Nitrogen, grms. per 100 c.c.	0·011	0·022	0·013	0·013	0·028	0·027	0·032	0·018
Proteins, grms. per 100 c.c.	0·069	0·138	0·082	0·082	0·175	0·169	0·201	0·113
Phosphates	Trace	Trace	Trace	Trace	Trace	Trace	Trace	Trace
Ethers, grms. per 100 c.c. as acetic ether	0·070	0·018	0·030	0·019	0·067	0·028	0·046	0·060

The samples varied in colour, from a light yellow to a brown, and were free from sediment except in one case in which yeast cells and a few dead acari were discovered.

It will be necessary to obtain a far larger number of analyses before any standard can be formulated; but it seems obvious that in a fermented liquor such as this which is frequently offered to children, the amount of alcohol should not exceed 25 per cent. of proof spirit, and there should be no trace of salicylic acid or other preservatives.

⁂

NOTE ON GORGONZOLA CHEESE.

By EDWARD HINKS, B.Sc., F.I.C.

(*Read at the Meeting, December* 7, 1910.)

GORGONZOLA cheese is a whole-milk cheese made in various Italian provinces, the best cheeses coming from Gorgonzola and its environs. The old name for it was Stracchino. The milk is curdled with rennet when still warm, and drained in hemp cloths, and the paste is "crumbled" and placed in a mould formed of laths of wood with hemp inside. After a few days the wrappings are removed, and the cheese salted by rolling and pressing in salt, this treatment being continued for a number of days. The formed cheese is put aside to ripen—often in caves—preferably at a temperature of from 12° to 18° C., ripening taking from two to six months. The characteristic green mould of this cheese was at first considered a defect; it is now intentionally developed by spearing the cheese to allow access of air. During the ripening Gorgonzola generally develops a reddish-brown crust, which is said to be sometimes imitated by rubbing in oxide of iron or brick-dust. The best cheese is made in early autumn. It appears to have been first introduced into England about fifty years ago.

Gorgonzola cheese is peculiar in that an addition to it of an artificial mineral coat or rind is practised, so that in commerce there are two classes of cheese—the "natural coated" and the "coated" This practice of adding a mineral coating is an old one, and there is evidence that these two varieties have been imported into England during the last twenty-five years: it is said to be the case that before that date all Gorgonzola cheese was thus coated, but it is impossible to speak with certainty as to the nature and weight of the coating in those days. During the last few years, about half the Gorgonzola imported into this country has been naturally coated and half artificially coated.

There is usually a considerable difference between the prices to the purchaser of the two varieties, and, taking an average, the price has lately been from 7½d. to 8½d. per pound for the coated and 9d. to 11d. for the naturally coated, though it is true that the coated is sometimes sold at the higher price.

The mineral coating now always consists, in my experience, of the natural mineral barytes, mixed generally with tallow, though lard is stated to be sometimes used, and coloured, usually on the outer side only, with oxide of iron. This coating or plaster has amounted, in twenty different purchases, to from 16 to 27 per cent. of the whole weight of the cheese, and was from $\frac{3}{16}$ to $\frac{1}{4}$ inch thick.* The coat is applied to the cheese after the natural rind has formed, and the latter may usually be found to a greater or less extent under the former, though very often the cheese immediately beneath the coat has undergone decomposition, resulting in a glue-like slimy layer, in some cases considerably blackened; it is thus entirely an addition, and not present in place of the natural rind. A point that is of importance, in that it might lead to the actual consumption of the mineral, is that the coat is forced into the holes in the cheese, with the result that plugs of barytes were found running into the cheese up to ⅝ inch beyond the inner surface of the rind.

---

* The cheeses were carefully divided so as to get a true and fair proportion of coating to cheese.

There is no difference between the manufacture of the cheeses that are to be sold as naturally coated and those that are to receive a coat; the coat is often applied only a few days before shipment, and is at times applied in England.

The composition of the coat of eight samples of cheese was:

Barytes ...	81·0 to 86·7 per cent.	...	average 83·6 per cent.
Fat (tallow)	12·7 to 19·0 „	...	„ 15·6 „
Moisture ...	0·6 to 1·5 „	...	„ 0·8 „

The barytes was the natural mineral, and contained from 91 to 96 per cent. of barium sulphate, the rest being varying proportions of sulphates of calcium, strontium and sodium, of silica and oxide of iron.

The natural coat or rind amounts to little, from 2 to 4 per cent. of the whole cheese if carefully removed, though more than this would as a rule be cut from the cheese. The following is a typical result of the partial analysis of a rind:

	Per Cent.
Fat	3·0
Ash	22·0
Containing—	
Soluble in water	4·7
Chlorine (as sodium chloride)	2·5
Alkalinity (as sodium carbonate)	1·2
Insoluble in water	17·7
Lime	7·6
Phosphoric acid (P_2O_5)	6·3

Starch is often present in the natural rind, and it would not be surprising to find small quantities of barytes in it, as this mineral is sometimes dusted over the surface of the cheese to dry it if it has "sweated"; the starch may be added for the same purpose.

The following are the results of analyses of the interior portion of five Gorgonzola cheeses:

	Water. Per Cent.	Fat. Per Cent.	Protein (N × 6·37). Per Cent.	Ash. Per Cent.
Coated, A ...	32·1	35·2	28·1	4·6
„ B ...	35·9	34·0	24·7	4·5
„ C ...	30·5	36·3	27·9	4·7
„ D ...	35·1	33·3	24·6	5·1
Natural ...	37·3	31·6	—	—

It is interesting to note that a Commission sat at Milan in 1909 and reported that a mineral coating was considered useful but not necessary for Gorgonzola cheese, especially for lengthy transit, following which report the Italian Minister of Agriculture requested the manufacturers to discontinue the use of barium sulphate. The importation of coated cheese into France is prohibited altogether; the prohibition by the United States has been rescinded, and coated cheese can be imported if labelled as such.

DISCUSSION.

Mr. BODMER said that in cheese coated in the manner described fermentation was liable to take place just inside the coating, producing a disagreeable, slimy, malodorous layer. Moreover, the barytes being very heavy, though it might not add very greatly to the thickness of the rind, caused it to constitute a much larger proportion of the total weight of the cheese than was indicated by its appearance to the eye.

Mr. A. E. PARKES said that he had found the fat of Gorgonzola cheese to differ considerably in composition, as indicated by the proportion of volatile fatty acids, from butter-fat and from the fat of ordinary cheese. He had never found, in the case of Gorgonzola cheese, a higher Reichert-Wollney figure than 25 (generally 23 to 25), the Polenske figure being from 3 to 4, and the Valenta number being low. The Reichert-Wollny figure of the fat of Gorgonzola cheese had been given by Allen ("Organic Analysis," vol. iv., p. 242) as 22, but that was the only reference he had been able to find. Gorgonzola cheese, of course, contained a number of moulds, the chief being *Penicillium glaucum*, which secreted a lipase, and it seemed quite likely that the presence of this mould might affect the composition of the fat. At any rate analysts should be cautious in certifying the presence of foreign fat in such cheese until the matter had been more thoroughly investigated.

Mr. H. D. RICHMOND asked if Mr. Hinks had any information as to whether Gorgonzola cheese was made wholly from cow's milk, or whether sheep's or goat's milk was ever employed. He (Mr. Richmond) had an impression that a proportion of sheep's milk was sometimes used. He was also under the impression that the mould of Gorgonzola cheese had been found to be, not *Penicillium glaucum*, but the modification of *Penicillium* identical with that found in Roquefort cheese.

Mr. E. M. HAWKINS, as an illustration of the deceptive appearance of the rind of coated Gorgonzola cheese, said that, in the case of one sample which he had examined, the inspector who purchased it expressed to him the opinion that it was uncoated, whereas the actual weight of the rind was found to be as much as 21 per cent. of the total weight.

Mr. P. A. E. RICHARDS remarked that, in the case of nearly all the samples of Gorgonzola cheese which he had recently examined under the Act, the rind had been almost entirely removed by the vendors. In several cases the small portions left on the cheese consisted largely of barytes.

Mr. HINKS said that in these cases he had not made an extended investigation into the composition of the fat, but as far as he had gone it seemed to be normal. He gathered from such information as could be obtained in London that the milk used was entirely cow's milk. The mould certainly seemed to be a species of *Penicillium*, but he did not feel able to state definitely whether it was or was not *Penicillium glaucum*.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Comparison of Beef and Yeast Extracts of Known Origin. F. C. Cook. (*U.S. Department of Agriculture, Bureau of Chemistry, Circular* 1910, *No.* 62, 1-7.)—Examination of six samples of known origin shows that yeast extracts contain approximately 1 per cent. of ether-soluble material, whilst beef extracts may contain large amounts (6 to 8 per cent.). Sarcolactic acid was found in the beef extracts, but not in the yeast extracts. When all the results were reduced to a fat-free and water-free basis, the following points of difference between yeast and beef extracts were brought out. The total ash of the yeast extracts was in every case higher (27·3 to 30·4 per cent.) than that of the beef extracts (18·2 to 24·9 per cent.). The nitrogen content of the yeast extracts lay between 7·4 and 7·5 per cent., whilst that of the beef extracts in no case fell below 11·5 per cent. The phosphoric acid, whether total, organic, or that found in the ash, is, on the average, higher in yeast extracts than in beef extracts, but the differences are not great. The phosphoric acid remaining in the ash shows the greatest difference—namely, 3·7 to 3·9 per cent. for yeast, and 2·6 to 3·4 per cent. for beef. It is suggested that the above points of difference may be found useful where it is desired to gain some evidence as to the origin of an extract beyond that afforded by the creatinine test. G. C. J.

Digestibility of Bleached Flour. E. W. Rockwood. (*J. Biol. Chem.*, 1910, 8, 327-340; *Chem. Zentralbl.*, 1910, 2, 1833.)—Artificial digestion experiments on unbleached flour and on portions of the same flour bleached with nitrogen peroxide showed that the bleaching causes no loss of digestibility; in certain cases the bleached flour, and the gluten and starch separated from it, were more readily digested by pepsin and pancreatin than was the unbleached flour. Bread made with bleached flour was found to be as digestible as bread prepared with unbleached flour. W. P. S.

Loss of Soluble and Volatile Fatty Acids during the Ageing of Butter. D. Crispo. (*Bull. Soc. Chim. Belg.*, 1910, 24, 436-438.)—Samples of butter, wrapped in parchment paper and enclosed in tin boxes, showed a decrease in their proportion of volatile acids (Reichert-Meissl values) of 2·3 to 4·3, whilst three samples that had been kept for three years showed decreases of 2·6 to 12·8. In the case of melted and filtered butter-fat kept in flasks closed with an ordinary cork for periods of one to three years, eight samples out of twelve showed a slight gain in the proportion of volatile acids, +0·2 to +1·6, whilst one sample remained the same, and three showed a loss, −0·3 to −1·5. The author therefore concludes that dry butter-fat separated from the other constituents of the butter remains sufficiently constant for further analyses for a period of at least three years, when kept under the conditions described. C. A. M.

Toxic Substances in Vegetable Fats and Butters. J. Hertkorn. (*Chem. Zeit.*, 1910, **34**, 1381-1382.)—A substitute for butter, known as "backa-margarine," has recently produced symptoms of poisoning, and this led to an investigation of the possibility of other instances of the kind taking place. In the case of animal fats that have been properly purified there is no risk, whilst most of the compounds sold for the production of a butter-aroma or flavour in margarine are harmless. Recently, however, amyl esters of fatty acids and preparations consisting of the lower fatty acids of the oleic-acid series or their esters have been sold for this purpose; and since these are prepared by the interaction of potassium cyanide with alkyl halides, ketones, etc., by way of nitriles (cyanides, oxycyanides) as intermediate products, they are usually more or less poisonous even when used in the degree of dilution suitable for perfumery. There is also the risk of traces of the intermediate cyanogen compounds being present as impurities, and it is therefore suggested that the use of these flavouring agents in margarine should be prohibited. Poisonous fatty acids of the acrylic series also occur as glycerides in many crude vegetable oils and fats used in the manufacture of margarine. As a rule they may be eliminated, together with other toxic substances, by heating the fat to a high temperature. This should be followed by a treatment with alkali and acid and washing with water, and physiological tests should always be applied to the vegetable fats intended for butter substitutes. C. A. M.

The Valuation of the Antiseptic Properties of Hops. A. J. Brown and G. B. Ward. (*J. Inst. Brewing*, 1910, **16**, 641-664.)—The authors used in their work an organism closely allied to, if not identical with, Van Laer's *Saccharobacillus Pastorianus*, isolated from a sample of acid beer, and which proved to be capable of rapid multiplication in suitable media, and was very susceptible to the toxic influence of hop extract. Five grms. of the hop it was desired to investigate were extracted for one hour in a steam steriliser with 500 c.c. of distilled water. The medium in which growth of the bacillus is to be observed is prepared by digesting equal weights of malt and cold water for two hours, and then filtering, boiling, again filtering and diluting to a sp. gr. of 1030. It is important that this solution should be quite bright. A number of tubes are filled with 10 c.c. of this solution, plugged with wool and again sterilised in a steamer for ten minutes. Amounts ranging from 0·25 c.c. to 2·5 c.c. of the standard hop extract are pipetted into a series of the tubes containing the cold malt extract, and the tubes are again sterilised for ten minutes. After cooling, each tube is inoculated with a loopful of a freshly-grown culture of the bacillus; they are then incubated at 30° C. for eighteen hours and the growth, if any, noted. The "neutral" value is taken as the least volume of hop extract which just prevents growth of the organism in the malt extract, and when this volume is 0·25 c.c. the toxic or antiseptic value of the hop employed is taken as being 100. The whole experiment is carried out in a manner somewhat analogous to a Lintner diastatic determination. Growth in the tubes can be easily seen by noting the characteristic "silky" sheen of the liquid. Using these standards, the toxic value of a hop can be determined from the formula—$a = \frac{25}{x}$ where a = relative toxic value, and x = c.c. required just to prevent growth—*i.e.*, "neutral" value.

Working in this manner, the following values were obtained:

Hop.	"Neutral" Value.	Relative Toxic Value.
Oregon, 1909; very good quality	0·28	90
Marzells (hops from English Golding sets grown in Bavaria)	0·3	83
Columbians, 1909	0·5	50
Farnham, 1909; very good quality	0·75	33
East Kents, 1909	0·75	33
East Kent Goldings, 1909; fair quality ...	0·9	28
Bavarians, 1909; very poor quality	1·2	21
East Kents, 1909; very medium quality ...	1·3	19
Mid-Kents; fair quality	1·3	19
East Kents, "Old olds"	4	below 6

The above order is much in accordance with that in which ordinary empirical methods would place the hops.

A "hop extract" sold as a partial substitute for copper hops was found to be devoid of antiseptic action on the bacillus employed. A good quality sample of Oregon hops was extracted with petroleum spirit and then with ether, and it was found that on applying the method above described to the soft and hard resin thus obtained, the antiseptic value of the soft resin was about 50 times greater than that of the hard resin, whose activity is almost negligible. The extracted hops left in this experiment, when again extracted with a little water, proved to be devoid of antiseptic value. It was noticed that the organism employed was not killed even by prolonged exposure (sixteen hours) to the hop extract, although its development in malt wort is entirely suppressed by a very small volume. H. F. E. H.

New Reaction of Morphine. G. Denigès. (*Comptes rend.*, 1910, **151**, 1062-1063.)—On treating 10 c.c. of a dilute solution (down to 0·03 grm. per litre) of a morphine salt with 1 c.c. of hydrogen peroxide solution (5 to 10 vols.), followed by 1 c.c. of ammonia solution and a single drop of copper sulphate solution (1 to 4 per cent. according to the amount of morphine), the liquid when shaken gives a rose to intense red coloration. The test may be applied to morphine syrups, and by comparing the intensity of the coloration with that given by standard solutions of morphine hydrochloride in sugar syrup a colorimetric estimation may be made. For the identification of the alkaloid in the form of its hydrochloride the dry salt is mixed with 1 drop of a reagent consisting of 1 c.c. of 3 to 4 per cent. copper sulphate solution, 5 c.c. of ammonia solution, and 5 c.c. of water. In the presence of morphine a pronounced red coloration is immediately produced. No reaction is obtained with codeine, thebaine, papaverine, narceine, or narcotine, but similar colorations are obtained with the direct derivatives of morphine, such as oxymorphine and paramorphine, and with its readily hydrolysable esters such as heroine. The copper appears to act as a catalytic agent in the reaction, but its place cannot be taken by iron or manganese. The reaction may also be employed to localise the alkaloid in plants, the morphine being first converted into its hydrochloride. C. A. M.

Detection and Estimation of Nitrates in Milk by Means of the Diphenylamine-Sulphuric Acid Test. J. Tillmans. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, 20, 676-707.)—The author has investigated the diphenylamine-sulphuric acid test for nitrates, and gives the conditions under which this test is capable of detecting very small quantities of nitrate, more particular attention being paid to the detection of nitrates in milk, as a positive reaction in such case leads to the assumption that the sample is adulterated with water containing nitrates. As is well known, the test depends on the development of a deep blue coloration when a nitrate solution is treated with diphenylamine dissolved in sulphuric acid. The reagent recommended by the author is prepared as follows: 0·085 grm. of diphenylamine is mixed with 190 c.c. of dilute sulphuric acid (1 : 3) in a 500 c.c. flask, and a quantity of concentrated sulphuric acid is added; the mixture becomes heated, and the diphenylamine dissolves. Concentrated sulphuric acid is now added in sufficient quantity to make the volume of the mixture nearly 500 c.c., and, after cooling, the whole is diluted to the mark with the concentrated acid. When this reagent is used in the proportion given subsequently, the mixture of reagent and test solution will contain approximately 60 per cent. of sulphuric acid, in which concentration the blue coloration is relatively stable. In applying the test to milk, the latter is treated with calcium chloride, boiled, and the serum separated. Twenty c.c. of the serum are now shaken with 5 c.c. of lime-water and about 25 c.c. of pure ether, this operation being necessary for the removal of traces of milk-fat and proteins which interfere with the reaction. Two c.c. of the reagent are then mixed in a test-tube with 0·5 c.c. of the purified serum, the mixture is cooled, and placed aside for one hour; the blue coloration produced in the presence of nitrates reaches its full intensity after this lapse of time. Serum obtained from milk free from nitrates yields only a yellowish or pink coloration. The presence of chlorides is essential for the detection of small quantities of nitrate by the test; water containing a relatively large quantity of nitrate, but free from chlorides, does not yield a coloration with the reagent. Nitrites also give a blue coloration, which reaches its full intensity almost immediately, and in this case the presence of chlorides is not necessary. Water containing 0·1 mgrm. of N_2O_5 per litre, and milk serum containing 0·25 mgrm. of N_2O_5 per litre, both yield distinct colorations, and it is possible to detect the presence of 5 per cent. of added water in milk by means of the test, if the water contains not less than 10 mgrms. of N_2O_5 per litre. The test may be rendered quantitative by comparing the coloration obtained with those yielded by quantities of water or milk serum containing known amounts of nitrate. Milk containing an abnormal quantity of dirt may yield a nitrate reaction, but the traces of extraneous matters found in ordinary milk do not interfere with the test.

W. P. S.

Essential Oil of Orange Flowers. G. Laloue. (*Bull. Soc. Chim.*, 1910 [iv.], 7, 1101-1107.)—During the autumn of 1909 the second crop of orange flowers was sufficiently large to be collected for the extraction of the essential oil, and the author was thus enabled to make a comparative study of the oil yielded by the flowers produced in May and in October by the same plants. In each case the flowers were extracted with petroleum spirit, and the residue from the extract separated from the colouring matter and wax by distillation under reduced pressure in a current of steam. The total yield of oil from the earlier flowers was 0·7363 kilo., and from the October flowers 0·6636 kilo. per 1,000 kilos. The oils had the following characteristics :

	May.	October.	Oils freed from Methyl Anthranilate.	
			May.	October.
Sp. gr. at 15° C.	0·8899	0·8887	0·8882	0·8784
Refractive index $[n]_{D\,15^\circ\,C.}$	1·478	1·476	—	—
Optical rotation ($l=100$ mm.)	−0° 48′	−4° 6′	−0° 52′	−4° 6′
Solubility in 80 per cent. alcohol...	over 1 vol.	over 1 vol.	over 1 vol.	over 1 vol.
Acid value	0·7	1·0	—	—
Saponification value ...	70·2	95·8	63·0	86·8
Total esters (as linalyl acetate)	24·6 per cent.	33·4 per cent.	21·3 per cent.	29·5 per cent.
Total alcohols (as linalol)	51·0 „	57·0 „	50·7 „	58·0 „
Free alcohols	—	—	34·0 „	34·9 „
Methyl anthranilate ...	3·53 per cent.	2·74 per cent.	—	—
Geraniol and nerol ...	—	—	5·4 per cent.	6·9 per cent.

The dextro-rotation (about +5°) of ordinary neroli oil is shown to be due to the action of the steam in the distillation under the ordinary pressure. The results given above show that the oil produced in May is richer in terpenic esters and combined alcohols than the October oil, whilst the latter contains more of the primary alcohols, geraniol and nerol, and less linalol than the oil extracted from flowers produced at the normal period. C. A. M.

Essential Oil of Schinus Molle (L.). G. Laloue. (*Bull. Soc. Chim.*, 1910 [iv.], 7, 1107-1109.)—The plant *Schinus molle* (L.), which is popularly known as the American pepper plant, occurs abundantly in different areas in Central and South America, and is cultivated in Senegal, Teneriffe, and Algiers. A sample of the oil distilled from the twigs, flowers, and fruit of a plant grown at Grasse and two Algerian samples gave the following results :

	Algerian Oils.		Oil Distilled at Grasse.
	From Leaves only.	From Twigs, Leaves, and Fruit.	
Sp. gr. at 15° C.	0·8658	0·8634	0·8696
Optical rotation ($l=100$ mm.)	+65° 20′	+50° 51′	+46° 13′
Solubility in 90 per cent. alcohol	3 vols.	5 vols.	10 vols. turbid
Acid value	0·7	—	2·1
Saponification value ...	4·1	5·5	10·3
Esters (as linalyl acetate)...	1·2 per cent.	1·9 per cent.	2·8 per cent.

The terpenes, pinene, and phellandrene, were separated by fractional distillation, and a large fraction (about 20 per cent.) appeared to contain sesquiterpenes. The French oil contained more pinene than the Algerian oils. C. A. M.

Essential Oil of Spanish Marjoram (Thymus Mastichina, L.). B. Dorronsoro. (*Chem. Zeit.*, 1910, **34**, 1299.)—Samples of the pure oils from *Thymus mastichina*, grown in Spain in the four years 1898, 1902, 1908, and 1909, were examined. They were transparent, and of a light yellow to greenish colour, and had an odour recalling that of camphor, with a suggestion of thyme. They gave the following results on analysis: Sp. gr. at 20°/15° C., 0·907 to 0·945; refractive index, $[n]_{D, 23^\circ C.}$ 1·4630 to 1·4654; optical rotation, $[\alpha]_{D, 25^\circ C.} = -1{\cdot}4^\circ$ to $+9^\circ$; solubility in 70 per cent. alcohol, 1 : 5 to 1 : 30; saponification value, 12·7 to 18·5; and acetyl value, 29·2 to 45·6. Examination of the fractions obtained by fractional distillation showed that the oil had the following composition: *d*-pinene, 7·0 to 8·0; cineol or eucalyptol, 64·0 to 72·0; phenols, less than 0·1; ketones (?), less than 0·1; esters (linalyl acetate), 4·44 to 6·47; and free alcohols (linalol), 8·2 to 14·1 per cent.

C. A. M.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Contribution to Study of Chemical Disinfectants. S. Delépine. (*J. Soc. Chem. Ind.*, 1910, **23**, 1344-1354.)—It is known that organisms subjected for a certain time to the action of certain dilutions of mercuric chloride may resist this disinfectant. If a quantity of hydrogen sulphide be added, the suspended growth of the bacteria is resumed. Experiments in this direction (by the silk-thread method) appeared to show that the albuminate of mercury, which is probably formed by the action of this disinfectant on the test organism (*B. coli* in this case), remains localised and superficial when the bacteria are treated with strengths less than 1 : 100; but that even the small amount of toxic product thus formed can bring about the death of the bacterium in sixty minutes when dilutions between 1 : 4,000 and 1 : 2,000 have been used, and in thirty-five minutes after exposure to 1 : 1,000 and 1 : 500 dilutions. Again, the existence of this "antelethal inhibitory period" is well shown by taking threads loaded with spores of anthrax, and leaving them for one hour and for twenty-four hours in emulsions of certain phenoloids. If after one hour the threads are washed in water, transferred to broth tubes, and incubated, no growth usually occurs even in seven days. If the threads after twenty-four hours' contact with the emulsion be inoculated into guinea-pigs, the animals contract anthrax, and die almost as rapidly as those treated with threads not subjected to the action of disinfectant. Thus it is not easy to prove by simple cultural experiments whether a disinfectant in given doses has really brought about the death of the organism. The three main factors in disinfection may be taken to be: (1) The organism; (2) the disinfectant; (3) the associated matter, which are discussed at length in the original paper.

1. *The Organism.*

It is shown to be highly improbable that all the descendants of a non-sporing bacterium are equally resistant to disinfectants. Thus, morphological differences are well known; and in many cases (*e.g.*, *B. typhosus*) the mass of certain individual organisms may be ten times as great as that of the average individual. These differences must affect the relative resistance of the individual bacteria to chemical agents, for mass is an important factor in chemical actions. Thus, the number of bacteria surviving after the addition of a germicidal agent may indicate either the number with which the germicide has not yet combined, because contact has not been possible or sufficiently long, or the number of bacteria which have been able to resist on account of their greater resistance or greater mass. Again, the differences between the resisting powers of an organism and its spores are enormous.

If the individual organisms of a pure culture may vary in resisting power to chemical and physical agents, it is still more probable that this will be the case with different organisms; and account has therefore to be taken of the action of physical agents which influence the action of chemical agents. "Drying" has a differing effect upon organisms (Buckley, Thesis, 1907). Thus, for instance, when exposed on cotton-wool to air dried over sulphuric acid, the *Sp. choleræ* lived only three hours (died in four hours), the *B. pestis* lived twenty-five days (died in thirty-four days), and the *B. diphtheriæ* eighty-one days (died in one hundred and three days).

The *action of heat* upon organisms varies according to the nature of the bacteria, and it is obvious that the influence of temperature upon the germicidal power of a disinfectant may be considerably modified by the action of temperature alone upon the bacteria exposed to the action of the disinfectant. Differences also exist with regard to the resistance of spores to heat and to chemical disinfectants.

Experiments upon these organisms showed that the *B. pestis* is much less resistant to phenol than *B. typhosus*, which latter is less resistant than *B. coli*.

Young agar or broth cultures of *B. coli* are more resistant than older cultures. Experiments designed to show the effect of age on the cultures as regards their resistance to phenol showed evidence of diminished resistance (in solid and fluid media) after the first few days, after which, in broth, the resistance remains almost constant for over two months, and in agar media the alteration of resistance is still more slow. Further experiments showed that *dry*-thread cultures of *B. coli*, kept in the dark for three months at 14° to 18° C., and tested occasionally during this period, remained almost constant in resisting power for seventeen days, when more than half of the threads had lost some of their resistance. At 18° to 22° C. this loss was more clearly shown, this slight difference in temperature causing a measurably larger loss of resistance of the organism to phenol.

2. *The Disinfectant.*

A large number of different classes of chemical products have been suggested and used for disinfecting purposes, but only a few are practically efficient. The table on p. 62 of commercial disinfectants, quoted by the author and published by Woodhead and Vasey (*The Lancet*, 1909, p. 1457), is of interest.

Properties of Chemical Disinfectants.—These, of course, act as protoplasmic poisons, but in different disinfectants the antiseptic action is obviously due to reactions widely different. The mode of action of emulsions of almost insoluble phenoloids is difficult to understand. If these act only when in solution, the toxicity of the soluble part must be very considerable. It seems remarkable that higher cells should be so little affected by these disinfectants, for bacteria are almost invariably more resistant to poisons than more differentiated cells. The application of ultramicroscopy to the study of such difficulties has yielded but disappointing results.

ANALYSIS OF VARIOUS DISINFECTANTS ON THE MARKET (S. A. VASEY).

	Phenol and Phenoloids.	Resins and Fatty Acids.	Water.	Soda.	Potash.	Gelatin.	Dextrin.	Inert Bodies (Hydrocarbons) by Difference.

Zotul	10·00	35·42	21·60	2·49	—	—	—	30·49

The table on p. 63 shows the results obtained from the action of various disinfectants on the *B. typhosus* by the thread and suspension methods. The germicidal power remains practically the same by each method with the soluble disinfectants, but the action of insoluble disinfectants is largely impeded by the protective action of the thread. The results show the relative power of various types of germicide (see also A. H. Burgess, *The Lancet*, June 23, 1900).

Effects of Dilution.—The degree of dilution of the disinfectant, together with the duration of exposure to its action, is an important factor. By prolonged exposure of an organism to a disinfectant it is possible to obtain a germicidal effect with doses which are quite inefficient in shorter exposures; but there is a limit to this, and after a certain dilution has been reached the duration of exposure is immaterial, no germicidal action being observed. The smallest dilution effective after prolonged exposure is termed the *ultimate lethal dilution*.

RESULTS OF TESTS APPLIED SIMULTANEOUSLY TO SEVEN DISINFECTANTS.

Disinfectants.	THREAD METHOD. With *B. typhosus*, 48 hours' culture, on peptone bouillon agar (+5), at 37° C. Solutions of phenol prepared with distilled water. Two threads, 2 cm. long, in 10 c.c. phenol solution. Temperature, 17° C. for 20 minutes' exposure.		SUSPENSION METHOD. With *B. typhosus*, 24 hours' culture, on peptone bouillon (+5), at 37° C., $\frac{1}{20}$ c.c. culture added to 10 c.c. phenol solution. Temperature, 17° C. for 10 minutes' exposure.	
	Minimal Lethal Dilution observed.	Maximal Non-lethal Dilution observed.	Minimal Lethal Dilution observed.	Maximal Non-lethal Dilution observed.
	Parts per 100,000.	Parts per 100,000.	Parts per 100,000.	Parts per 100,000.
Boric acid	— —	$\frac{1}{20}$ = 5,000	— —	$\frac{1}{20}$ = 5,000
Phenol	$\frac{1}{70}$ = 1,428	$\frac{1}{80}$ = 1,250	$\frac{1}{80}$ = 1,250	$\frac{1}{90}$ = 1,111
Lysol	$\frac{1}{90}$ = 1,111	$\frac{1}{100}$ = 1,000	$\frac{1}{200}$ = 500	$\frac{1}{300}$ = 333
Phenoloid A	$\frac{1}{150}$ = 666	$\frac{1}{200}$ = 500	$\frac{1}{500}$ = 200	$\frac{1}{800}$ = 125
Phenoloid B	$\frac{1}{150}$ = 666	$\frac{1}{200}$ = 500	$\frac{1}{500}$ = 200	$\frac{1}{800}$ = 125
Chlorinated lime (32 per cent. available Cl)	$\frac{1}{1600}$ = 62	$\frac{1}{2000}$ = 50	$\frac{1}{2000}$ = 50	$\frac{1}{3200}$ = 31
Mercuric chloride	$\frac{1}{6400}$* = 15	$\frac{1}{10000}$* = 10	$\frac{1}{3200}$* = 31	$\frac{1}{6400}$* = 15

If dilution is pressed beyond the ultimate lethal dose, a degree is reached when disinfectants actually excite the growth of bacteria. Thus, if a thread soaked in mercuric chloride solution be placed on the surface of a gelatin plate sown with *B. coli*, after two days' incubation a clear zone (without organisms) near the thread will be seen, beyond which the gelatin is crowded with colonies, and between these two zones is a narrow, dense marginal zone containing more crowded colonies. Phenol of the strength of $\frac{1}{8000}$ stimulates the multiplication of *B. coli*.

3. *Associated Material.*

Disinfectants which are used up in combining with the organic matter always associated with the organisms, in practical disinfecting obviously may be rendered largely useless, and the important property of phenol and the phenoloid bodies in this connection is that their action is but little affected by the presence of protein and allied matters. The relative value of disinfectants is therefore determined by their action, not on pathogenic bacteria alone, but on the bacteria plus various associated organic matters. A. R. T.

Estimation of Chlorine in Blood. B. Oppler. (*Zeitsch. physiol. Chem.*, 1910, 70, 198–204.)—A portion of the blood (about 10 c.c.) is introduced into a weighing bottle containing a quantity of ammonium oxalate, the bottle and oxalate having been weighed previously; after again weighing to obtain the weight of the blood, the contents of the bottle are rinsed into a stoppered flask and diluted with from ten to twenty times their volume of water, the total volume of water used being measured. A freshly-prepared 1 per cent. solution of metaphosphoric acid is now added from a burette until the solution is rendered distinctly acid to litmus paper; on shaking the mixture the precipitated proteins become red in colour. A further quantity of metaphosphoric acid is next added, the addition being continued as long as a precipitate forms, and, after the lapse of four hours, the mixture is filtered. The chlorine is then estimated in an aliquot portion of the filtrate by precipitation with silver nitrate and weighing the resulting silver chloride. It is recommended that the precipitate of silver chloride be collected on a filter, then dissolved in ammonia and reprecipitated with nitric acid before being finally collected and weighed. The silver chloride may also be dissolved in potassium cyanide solution, and the silver estimated electrolytically. Attempts were made to combine the estimations of chlorine and dextrose in blood, but metaphosphoric acid cannot be used when the sugar is to be estimated, and clarification of the blood with phosphotungstic acid interferes with the estimation of chlorine.

---

* Beyond thorough washing and shaking, and the use of large quantities of nutrient fluid, no attempt was made to neutralise the action of the disinfectants at the end of the exposure.

W. P. S.

Estimation of Sugar in Blood. K. Moeckel and E. Frank. (*Zeitsch. physiol. Chem.*, 1910, **69**, 85-88.)—With slight modifications the process described previously by the authors (ANALYST, 1910, **35**, 260) may be applied directly to the estimation of sugar in blood without first subjecting the blood to clarification. Five c.c. of the blood, to which a small quantity of sodium fluoride has been added, are placed in a 100 c.c. flask, and diluted with 40 c.c. of water. Thirty c.c. of colloidal ferric hydroxide solution, diluted previously with an equal volume of water, are added, the solutions are mixed but not shaken violently, a small quantity of powdered Rochelle salt is added, and, after the whole has been well shaken, a sufficient quantity of the diluted ferric hydroxide solution is added to make the mixture up to a volume of 100 c.c. The contents of the flask are shaken for two minutes, and filtered after the lapse of a further five minutes. Fifty c.c. of the filtrate are used for the titration of the sugar, Bertrand's method being employed. The authors find that it is necessary to cool the boiled mixture of sugar solution and Bertrand's solution before collecting the cuprous oxide on a filter. While the solution is hot, a portion of the cuprous oxide remains in a finely divided condition in the liquid, and often passes through the asbestos filter. Only when the mixture is cooled does the cuprous oxide precipitate completely.

L. Michaelis and P. Rona (*Zeitsch. physiol. Chem.*, 1910, **69**, 498) state that they were the first to use colloidal ferric hydroxide for the clarification of blood.

W. P. S.

Detection of Colchicine in Toxicology. H. Fuhner. (*Archiv. exp. Pathol. Pharm.*, 1910, **63**, 357-373; *Chem. Zentralbl.*, 1910, **2**, 1838.)—Colchicine may be isolated from animals poisoned with this substance by extracting the stomach and intestinal contents and the excreta with ether; the residue obtained on evaporating the ethereal extract is dissolved in water, the fat is removed by treatment with petroleum spirit, and the colchicine is finally extracted from the residue with chloroform. It may be identified by means of the coloration it gives with ferric chloride after hydrolysis with hydrochloric acid (Zeisel's test), or by its toxic action on mice and frogs. A white mouse dies within twenty-four hours after having been given 0·1 mgrm. of colchicine, and the same quantity will kill a frog in from two to four days if the frog be kept at a temperature of 30° to 32° C. At this temperature colchicine is about 500 times more poisonous to frogs than it is at the ordinary temperature. W. P. S.

Detection of Amylolytic Enzymes in Fæces. M. Hirschberg. (*Deut. med. Wochenschr.*, 1910, **36**, 1992-1997; *Chem. Zentralbl.*, 1910, **2**, 1726.)—The functional activity of the pancreas may be tested by determining the amylolytic powers of the enzymes (lipase and trypsin) in the fæces, and the following process is recommended for this purpose. A weighed portion of the fæces is well mixed with a 1 per cent. sodium chloride solution, and the mixture is subjected to centrifugal action. The liquid portion is measured, and quantities of it are introduced into test-tubes containing 5 c.c. of 1 per cent. starch solution, each tube in the series receiving a somewhat larger quantity of the fæcal extract than the preceding one. The tubes are then maintained at a temperature of 38° C. for twenty-four hours, and the contents of all the tubes are then brought to the same volume by the addition of water. Iodine solution is now added to each tube, and note is taken of the tube where all the starch has been changed by the least possible quantity of the extract. The diastatic power of the extract may then be expressed in terms of c.c. of extract per 5 c.c. of starch solution. W. P. S.

Preservation of Fæces. P. E. Howe, T. A. Rutherford, and P. B. Hawk. (*J. Amer. Chem. Soc.*, 1910, **32**, 1683-1686.)—Experiments are described which show that when fæces are preserved in a particular manner, no appreciable change, and in particular no change in moisture or nitrogen content, need be feared, even if it becomes necessary to preserve the material for as long as three weeks. The method of preservation consists in collecting the fæces in "ordinary friction-top paint pails," which have previously been rinsed with a 10 per cent. alcoholic solution of thymol, and then dried. The pails are then kept in a cold store until their contents are required. After as long a period as eight months, the moisture will not be found to have changed as much as 4 per cent., whilst the fæces may in the same time lose one-twentieth, but not more, of their nitrogen. The changes recorded in some cases within twenty days of defecation are so small as to be within the limits of experimental error. G. C. J.

Incineration of Microtome Sections. R. E. Liesegang. (*Biochem. Zeitsch.*, 1910, **28**, 413-417; *Chem. Zentralbl.*, 1910, **2**, 1835.)—Experiments were made with the object of localising various elements in microtome sections by incinerating the latter. Whilst in certain cases incineration rendered the structure of the tissue more visible, it was not possible to localise iron, iodine, or phosphates. W. P. S.

Distribution of Fluorine in the Human Body. E. Zdarek. (*Zeitsch. Physiol. Chem.*, 1910, **69**, 127-137.)—The following quantities of fluorine were found in the various organs, etc., of two healthy men who had been accidentally killed. The figures express grms. of fluorine per kilogrm. of dry substance :

	1.	2.
Heart	0·0046	0·0045
Kidneys	0·0154	0·0134
Brain	0·0023	0·0027
Lungs	0·0022	0·0070
Pancreas	0·0082	0·0235
Liver	0·0068	0·0080
Blood (not dried)	0·0035	—
Femur „	0·0029	0·0035
Humerus „	—	0·0045

The fat obtained from the bones contained about one-half of the amount of fluorine present in the bones. W. P. S.

Histological-Chemical Detection of Peroxydase. R. Fischel. (*Wien. Klin. Wochenschr.*, 1910, **23**, 1557-1558; *Chem. Zentralbl.*, 1910, **2**, 1837.)—When a specimen of pus is allowed to dry at the ordinary temperature on a cover-glass, and is then treated with a 2 per cent. sodium benzidinemonosulphonate solution containing 0·01 c.c. of a 0·3 per cent. hydrogen peroxide solution, a blue coloration is produced, and the leucocytes, in particular, are coloured blue. The same result is observed in the case of the myelocytes of bone-marrow, but lymphocytes do not give a reaction unless the quantity of hydrogen peroxide is increased. Red corpuscles from human blood give the coloration when 0·5 c.c. of the hydrogen peroxide solution is employed. Leucocytes may be distinguished from erythrocytes by the fact that the former no longer give a peroxydase reaction after being heated to a temperature of 100° C., whilst the latter are not affected by the heating. W. P. S.

ORGANIC ANALYSIS.

Direct Estimation of Caoutchouc in Vulcanised Rubber Goods. G. Hübener. (*Chem. Zeit.*, 1910, **34**, 1307-1308, 1315-1316.)—In a previous paper (ANALYST, 1909, **34**, 365) the author described a method for the estimation of caoutchouc in vulcanised goods, depending on the estimation of the bromine-combining value and the sulphur of vulcanisation. In the present article a number of examples are given showing the influence exerted by admixtures of foreign substances on the validity of the method. The addition of rubber substitute has no influence, the substitute does not yield an insoluble bromine derivative under the conditions adopted for bromination, and the whole of its sulphur goes into solution, and is calculated as free sulphur. Guttapercha and balata, likewise, have no influence on the results, and yield no insoluble bromine derivatives. In carrying out the bromination with 0·1 grm. of the finely divided sample, it is best to boil the material with a little water in order to wet it thoroughly before digesting with bromine water. Bromine-tion is to be repeated, if necessary, until the particles of material become quite friable on pressure. In the case of the addition of barium sulphate or lithopone as a loading material, the total sulphur is increased by the amount of that present in the barium sulphate, and a correction must be applied for this. The estimation of the barium sulphate may be effected on the ash of the rubber, or may be made by oxidising a separate portion of the sample, first with nitric acid, and then with bromine, filtering and incinerating the residue. If lead oxide and antimony sulphide be also present, the wet method of oxidation converts these into soluble products, and the barium sulphate alone remains. Likewise in the prescribed method of bromination these and similar bodies are entirely soluble, and have no influence on the results. The same applies to calcium salts, even to calcium sulphate. The author has likewise proved that his method is applicable for the estimation of the caoutchouc in regenerated rubber, and, consequently, when such products are present in the sample, the method shows the total caoutchouc, both regenerated and new. Theoretically, the chief objection to the method is the possible influence of proteins on the results, but it is doubtful whether this objection is a valid one in the case of vulcanised goods. J. F. B.

Analysis of Commercial Calcium Cyanamide. N. Caro (and B. Schück). (*Zeitsch. angew. Chem.*, 1910, **23**, 2407-2411.)—Commercial calcium cyanamide (Kalkstickstoff) contains about 21 per cent. of nitrogen, principally (nearly 20 per cent.) as cyanamide, together with about 0·1 per cent. as dicyandiamide, 0·7 to 0·8 per cent. as urea, and 0·6 to 0·8 per cent. in insoluble combinations. The following is found to be the best method for the separate estimation of the cyanamide, dicyandiamide, and urea. Seven grms. of the sample are shaken with 400 c.c. of water for two to three hours at 20° C., and the mixture is made up to exactly 500 c.c., and filtered. In 250 c.c. of the filtrate the cyanamide is precipitated by addition of an excess of an ammoniacal solution of silver acetate (10 per cent. silver acetate, 4 per cent. ammonia), the mixture is made up to exactly 400 c.c. and filtered, and 300 c.c. of the filtrate is collected for the estimation of dicyandiamide and urea. The precipitate contains an amount of silver which varies with the conditions of the precipitation, but the whole of the cyanamide is thrown down. After washing free from ammonia by means of water, the cyanamide in the precipitate is estimated from the nitrogen content as determined by Kjeldahl's method. In the 300 c.c. of filtrate retained for the estimation of the other constituents, the dicyandiamide is estimated as follows: A 10 per cent. solution of caustic potash is added in excess, and the solution boiled until all ammonia has been expelled. As the amount of dicyandiamide is always small, there will usually be enough silver present to precipitate the whole of it, again as a compound of variable silver content. In case of doubt, a little silver solution may be added, but the solution used in this case must not be an ammoniacal one, since the silver compounds of dicyandiamide are soluble in ammonia, a fact on which the previous separation of the cyanamide depends. The mixture is diluted to 400 c.c. and filtered, and the first 300 c.c. of the filtrate preserved for the estimation of urea. The precipitate, which contains the whole of the dicyandiamide, is washed and dried, and its nitrogen content determined by Kjeldahl's method. From this the percentage of dicyandiamide in the original substance is calculated. In the 300 c.c. of filtrate reserved for estimation of urea, excess of silver is precipitated by means of hydrogen sulphide and filtration, and the excess of hydrogen sulphide expelled by a current of carbon dioxide. The solution is diluted to 400 c.c., and an aliquot portion is evaporated, and the nitrogen in the residue determined by Kjeldahl's method and calculated as urea. If in another aliquot portion the urea be estimated by Liebig's method, using a very dilute solution of mercuric nitrate on account of the small amount of urea to be estimated, an identical result will be obtained. That, at least, is the experience of the authors, and they therefore conclude that, apart from cyanamide and dicyanamide, urea is the only other soluble nitrogenous body in the calcium cyanamide produced by the works whose products they have examined.

G. C. J.

Estimation of Cellulose by Simon and Lohrisch's Method. H. Lohrisch. (*Zeitsch. physiol. Chem.*, 1910, **69**, 143-151.)—In reply to Scheunert and Lotsch's criticism of this method (ANALYST, 1910, **35**, 263), the author agrees with the statement that cellulose is, to some extent, attacked by the reagents employed, and admits that the method is not strictly quantitative. At the same time, he has never met with such large deficiencies as mentioned by Scheunert and Lotsch, and considers that the method is quite suitable for the estimation of cellulose in such substances as fæces, etc., provided that control estimations be made. The cellulose obtained is pure and uncontaminated with other substances, and the time required for the estimation is short. In cases where it is desired to ascertain the proportion of cellulose digested during feeding experiments on animals, the method yields sufficiently accurate results, as the cellulose present in the fodder and in the fæces is estimated under exactly similar conditions.

W. P. S.

Estimation of Cyanogen Compounds in the Gases from Coke Furnaces. E. Lecocq. (*Bull. Soc. Chim. Belg.*, 1910, **24**, 439-445.)—The gases are aspirated through two washing flasks charged with a solution prepared by dissolving 2·5 grms. of pure lead acetate in 200 c.c. of a 10 per cent. solution of pure potassium hydroxide. The aspiration of 50 to 100 litres of the gas is continued for six hours on two consecutive days, when the flasks will contain the hydrocyanic and thiocyanic compounds in solution. The insoluble lead sulphide is rapidly separated and washed with a few c.c. of 10 per cent. potassium hydroxide solution. The filtrate and washings are rendered faintly acid with dilute sulphuric acid (1 : 5), the flask being meanwhile kept cold, and are then made up to 500 c.c., shaken, allowed to stand, and filtered from the precipitated lead sulphate. An aliquot portion (400 c.c.) of the filtrate is used for the estimation of the cyanogen compounds. For this purpose the liquid is treated with 10 c.c. of a 10 per cent. solution of a mixture in equal parts of ferrous and ferric sulphates slightly acidified with sulphuric acid, after which potassium hydroxide solution is added, little by little, until a large proportion of the ferroso-ferric salts are precipitated without the reaction becoming alkaline. Under these conditions Prussian blue is slowly formed, and after the liquid has been left for an hour in a warm place it is acidified with 10 to 20 c.c. of sulphuric acid (1 : 5), then heated for fifteen minutes on the water bath, and allowed to stand for several hours. The liquid is now decanted, and the precipitate of Prussian blue washed on a filter, and dissolved in a little sodium hydroxide solution; the solution is then treated, as in Feld's method (*cf.* Colman, ANALYST, 1910, **35**, 295), with magnesium chloride and mercuric chloride to obtain mercuric cyanide. The mixture is distilled with dilute hydrochloric or sulphuric acid, and the hydrocyanic acid absorbed in a solution of sodium hydroxide, which is subsequently titrated by Denigès' method with $\frac{N}{10}$ silver nitrate solution, with potassium iodide as indicator. The filtrate and washings from the Prussian blue are titrated directly by Volhardt's method with $\frac{N}{10}$ silver nitrate solution to obtain the amount of thiocyanate. Or the latter may be estimated colorimetrically with a solution of a ferric salt, a solution of potassium plumbate (containing a known quantity of thiocyanate), which has been subjected to the same treatment as the liquid under examination, being used as the standard for comparison. Analyses of the gases from eight Belgian coke furnaces showed that they contained on the average 0·093 grm. of cyanogen and 0·189 grm. of thiocyanogen per cubic metre.

C. A. M.

Normal Weight of Dextrose. C. A. Browne. (*J. Ind. and Eng. Chem.*, 1910, **2**, 526-527.)—The normal weight of dextrose, as given by different authorities, varies very considerably. For instance, Landolt gives 32·65 grms. for true c.c. and 32·73 grms. for Mohr c.c., whilst Sidersky gives the figures 32·82 grms. for true c.c. and 32·765 grms. for Mohr c.c. The reason for these differences is due largely to the fact that each worker has taken a different specific rotation of dextrose as a basis of calculation. There is no other sugar which shows such a variation in specific rotation for differences in concentration as dextrose. According to Tollens, this value ranges from 52·52 for a 1 per cent. solution to 54·73 for a 50 per cent. solution, which is about the limit of saturation at 20° C. The author considers that a value should be selected as expressing the normal weight, this being that weight of the pure sugar which, dissolved to 100 true c.c. and polarised at 20° C. in a 200 mm. tube, will give a constant reading of 100 on the saccharimeter scale. In the case of impure products, readings of less than 100 will be obtained, and the latter are corrected by a table giving the true percentage equivalent of each division of the saccharimeter scale. The author has converted the formula of Tollens ($[\alpha]_{D\ 20^\circ\ C.} = 52{\cdot}50 + 0{\cdot}018796p + 0{\cdot}00051683p^2$) from a percentage to a concentration basis, the latter form being more easily applied in the calculation of normal weights. The formula thus recalculated reads: $[\alpha]_{D\ 20^\circ\ C.} = 52{\cdot}50 + 0{\cdot}0227c + 0{\cdot}00022c^2$. According to this formula the specific rotation of a dextrose solution containing 32·5 grms. to 100 c.c. is 53·47. The specific rotation of sucrose being 66·5, and its normal weight (metric c.c. standard) 26·00 grms., 32·336 grms. of pure dextrose dissolved to 100 true c.c. will give a reading of 100 on the Ventzke scale. This value is still not absolutely correct, as there is a slight difference in the rotation dispersion of sucrose and dextrose as compared with quartz. The value of 1° Ventzke in angular degrees for dextrose is 0·3448, and the value of the 100 point of the Ventzke scale for dextrose may be taken, therefore, as 34·48 angular degrees. The specific rotation of a dextrose solution of 32·34 grms. concentration, according to the preceding formula, is 53·46. Substituting these values in the general concentration formula for specific rotation, $[\alpha]_{D\,20^\circ\,C.} = \frac{\alpha \cdot 100}{l.c.}$, in which a is the reading in angular degrees, l the dcm. length of the tube, and c the grms. of sugar dissolved to 100 c.c., we obtain for a 200 mm. tube the value: $c = \frac{34{\cdot}48 \times 100}{2 \times 53{\cdot}46} = 32{\cdot}248$ grms., as the correct normal weight of dextrose.

The correction to be added to any reading (s) of the saccharimeter scale is very approximately $+0{\cdot}02s - 0{\cdot}002s^2$. The percentage of dextrose (D) corresponding with any scale reading (s) is therefore expressed by the formula:

$$D = s + 0{\cdot}02s - 0{\cdot}0002s^2.$$

W. P. S.

Methods of Testing the (General) Stability of Explosives in Various Countries. (*Zeitsch. Schiess. u. Sprengstoffw.*, 1910, **5**, 10, 21, 72, 210, 432.)—This interim report of the Commission appointed by the Sixth Congress of Applied Chemistry to inquire into the methods of testing used in various countries, with a view to their unification, deals with the chemical stability, resistance to accidental explosion by shock, and other properties necessary for the safe manufacture, storage, transport, and use of blasting agents, propellants, and other explosives. The tests employed by the British, French, Dutch, Spanish, Italian, United States, and Belgian Governments are described. O. E. M.

Estimation of Phenol and *p*-Cresol in the Presence of Each Other. M. Siegfried and R. Zimmermann. (*Biochem. Zeitsch.*, 1910, **29**, 368-388.)—The method proposed depends on the estimation of the quantity of bromine required, under definite conditions, to convert the phenol into tribromophenol and the *p*-cresol into tribromocresol. It also depends on the estimation of the amount of bromine which is necessary, in the presence of potassium iodide, for the conversion of the two substances into tribromophenol and dibromo-*p*-cresol respectively. From the results of these estimations the quantities of phenol and *p*-cresol present may be calculated. The reagent solutions required are: (1) $\frac{N}{10}$ sodium thiosulphate solution; (2) potassium bromate-bromide solution, containing 0·834 grm. of potassium bromate and 2·97 grms. of potassium bromide per litre (the bromine titre of this solution is determined by titration); (3) a 5 per cent. potassium iodide solution; (4) dilute sulphuric acid (1 : 1); (5) 25 per cent. hydrochloric acid. One hundred c.c. of an aqueous solution containing the two phenols are placed in a 500-c.c. stoppered flask (if 100 c.c. of the solution are not available, water must be added to make up the volume), 30 c.c. of the dilute sulphuric acid are added, and the potassium bromate-bromide solution is run in from a burette until the precipitate which forms coagulates on shaking the mixture, and the solution is coloured distinctly yellow. A further quantity of the bromate solution is then added, so that at least 8 atoms of bromine are present for each molecule of phenol, and the whole is shaken frequently for one hour. After the lapse of this time the solution is filtered through glass-wool, and the filtrate is allowed to run into 30 c.c. of potassium iodide solution; water is added to the flask, shaken to dissolve bromine vapours, and then poured through the filter. The iodine liberated from the potassium iodide is then titrated. This estimation gives the quantity of bromine required to convert the phenol and *p*-cresol into their tribromo compounds. The quantity of bromine may be termed B_1. A second portion of 100 c.c. of the phenolic solution is now placed in a litre flask, 30 c.c. of hydrochloric acid are added, and the mixture is diluted with water to a volume of about 500 c.c. After the addition of the same volume of bromate solution as was employed in the first estimation, the flask is closed and the contents are mixed, but not shaken. At the end of fifteen minutes 30 c.c. of potassium iodide solution are added, the mixture is well shaken, and set aside in a dark place for one hour. The free iodine is then titrated. The amount of bromine necessary for the conversion of the phenols into tribromophenol and dibromo-*p*-cresol is thus obtained. Let it be called B_2, then the amount of *p*-cresol (x) in the solution is found from the equation $x = 0{\cdot}67605\,(B_1 - B_2)$, whilst the amount of phenol (y) is obtained from the equation $y = 0{\cdot}5884.B_2 - 0{\cdot}3923.B_1$. Results of experiments with solutions containing about 0·02 grm. of *p*-cresol and 0·03 grm. of phenol show that the process is trustworthy. W. P. S.

Volumetric Estimation of Quinones by Means of Titanium Trichloride. E. Knecht and E. Hibbert. (*Ber.*, 1910, **43**, 3455-3457.)—Titanium trichloride affords a ready and accurate means for the estimation of quinones, according to the equation—

$$C_6H_4O_2 + 2TiCl_3 + 2HCl = C_6H_6O_2 + 2TiCl_4.$$

The titration may be made either indirectly or directly. In the former case an excess of standardised titanium solution is added to the solution of the quinone in cold water, and the excess of titanium is titrated back by means of a standard solution of iron alum in presence of potassium thiocyanate as indicator. In the second case a trace of methylene blue is added to the quinone solution as indicator, and titration is made directly with the titanium solution. The titanium reacts selectively and quantitatively with the quinone before reducing and discharging the methylene blue. The quantity of the indicator taken should be such that it is decolorised by a single drop of the titanium solution. Results showing 99·7 to 99·8 per cent. of the theoretical values are cited for benzo-, toluo- and *α*-naphtho-quinones; the last, on account of its sparing solubility in water, should first be dissolved in glacial acetic acid and then poured into water. J. F. B.

Estimation of Sulphur in Organic Compounds. T. S. Warunis. (*Chem. Zeit.*, 1910, **34**, 1285-1286.)—The substance (0·2 to 0·4 grm.) is mixed with 10 grms. powdered potassium hydroxide and 5 grms. sodium peroxide in a large crucible of silver or nickel. The crucible, provided with a cover, is placed for about fifteen minutes in an oven maintained at 75° to 85° C., care being taken that the latter temperature is not exceeded at this stage. On removal from the oven the contents of the crucible will be found sintered together, and the crucible is next heated over a small flame, which is gradually increased until complete fusion occurs. It is maintained in this condition for some minutes and then allowed to cool, when the contents are much more easily dissolved by water than is the case when the fusion is made in the ordinary way with soda and peroxide. The aqueous solution of the melt is treated with hydrochloric acid containing bromine, and the sulphur is finally weighed as barium sulphate. G. C. J.

Estimation of Sulphur and Phosphorus in Organic Substances. C. G. L. Wolf and E. Osterberg. (*Biochem. Zeitsch.*, 1910, **29**, 429-438.)—In the method proposed the oxidation is carried out with nitric acid, and subsequently with a mixture of copper nitrate and potassium chlorate. A portion of the substance under examination (urine, etc.) is placed in a flask, and heated with 20 c.c. of fuming nitric acid, until, in the case of solid substances, complete solution is obtained, and nitrous fumes are no longer evolved. Further quantities of nitric acid may be added, if required. The solution is then rinsed into a porcelain basin, 20 c.c. of a solution containing 200 grms. of crystallised copper nitrate and 50 grms. of potassium chlorate per litre of water are added, the mixture is evaporated to dryness, and the residue is ignited at a dull red heat. After cooling, the residue is dissolved in 25 c.c. of boiling dilute hydrochloric acid (1 : 4), the solution is transferred to a flask, 150 c.c. of water are added, the mixture is boiled for fifteen minutes, cooled, and placed aside overnight. The next day the solution is filtered, and the sulphuric acid in the filtrate is precipitated by the addition of barium chloride. The filtrate from the barium sulphate precipitate is then treated with sulphuric acid, the excess of barium is removed by sulphuric acid from the filtrate, and the phosphoric acid is estimated by means of the molybdate method.

The method of oxidising the substance with copper nitrate and potassium chlorate was first recommended by S. R. Benedict (*J. Biol. Chem.*, 1909, **6**, 363), but the authors find that a preliminary treatment with fuming nitric acid is necessary to insure complete oxidation. W. P. S.

Estimation of Total Tartaric Acid by Goldenberg's Method. C. Ordonneau. (*Bull. Soc. Chim.*, 1910 [iv.], **7**, 1034-1041.)—Goldenberg's method (ANALYST, 1908, **33**, 200), which was adopted by one of the sections of the International Congress of Applied Chemistry in 1909, is subjected to criticism as follows: In presence of such proportions of calcium tartrate as occur in crude tartar, the method gives results which are about 2·2 to 2·4 per cent. too low. Salts of aluminium and iron depress the results even more than calcium tartrate, whilst phosphates, except those of aluminium and iron, lead to small positive errors. All these errors can be approximately halved by substituting phenolphthaleïn for litmus as indicator, and it is suggested that phenolphthaleïn should be adopted as indicator in analytical practice connected with the purchase of argol, as it is already used in all works for controlling manufacturing processes. The solution after boiling should be cooled down to 50° C. before commencing the titration, as at this temperature alumina interferes less with the indicator than it does in cold or boiling solution. It is also shown that no purpose is served by adding the acid solution to the potassium tartrate instead of *vice versa*, as recommended by Goldenberg and others. Identical results are obtained when the potassium tartrate solution is added to the acid solution. G. C. J.

INORGANIC ANALYSIS.

Estimation of Acidity in Hydrogen Peroxide Solutions. L. Wöhler and W. Frey. (*Zeitsch. angew. Chem.*, 1910, 23, 2353-2354.)—Endemann has asserted (Analyst, 1909, **34**, 290) that the acidity of hydrogen peroxide solutions is underestimated by almost exactly 50 per cent. when these are directly titrated in the cold with caustic alkali, using phenolphthaleïn as indicator. It is now shown that, with weak solutions of hydrogen peroxide (up to 3 per cent.), direct titration, using phenolphthaleïn as indicator, gives results which are very near the truth (see also Brown, Analyst, 1910, **35**, 497). So far from being low, the results are always a little above the truth, this being due to dissolved carbon dioxide, and, with increasing concentration of hydrogen peroxide, to an acid function of the peroxide. If in titrating weak solutions (up to 3 per cent. hydrogen peroxide) 0·3 c.c. be deducted from the volume of $\frac{N}{10}$ caustic alkali required by 25 c.c., the error of the corrected result will not exceed ±0·1 c.c. $\frac{N}{10}$ acid. Endemann's conclusions were based on a comparison of the direct method with the method in which the peroxide solution is decomposed by prolonged boiling with excess of standard caustic alkali, followed by titration of the excess of caustic alkali, using phenolphthaleïn as indicator. It is shown that this latter method may lead to high results, unless special precautions be taken to protect the boiling solution from the action of carbon dioxide; and it is suggested that Endemann overlooked this fact. In explanation of the alleged anomalous results obtained by direct titration, Endemann (*loc. cit.*) suggested that sodium perhydroxide was neutral to phenolphthaleïn. Were this the fact, it would afford an explanation of unduly high results, but not of the low results of Endemann; but Tafel has shown (*Ber.*, 1894, **27**, 2302) that sodium perhydroxide can be titrated accurately, using phenolphthaleïn as indicator.

If it is required to determine with exactitude the acidity of solutions of hydrogen peroxide of high strength, the hydrogen peroxide must first be destroyed by boiling in platinum, after addition of excess of caustic soda, since the direct method gives rise to errors in excess of 0·4 c.c. $\frac{N}{10}$ solution, when as much as 6 per cent. hydrogen peroxide is present. In such cases methyl orange should be given the preference as indicator, if it is known that no organic and other weak acids are present which would escape measurement by the use of this indicator. If phenolphthaleïn must be used, then the solution must be protected from carbon dioxide during evaporation, or a control experiment must be made. The author does not agree with Schmatolla (*Pharm. Zeit.*, 1905, 641) that Congo red is preferable to methyl orange.

G. C. J.

Separation of Alumina from Ferric Oxide. P. Barbier. (*Bull. Soc. Chim.*, 1910 [iv.], 7, 1027-1028.)—To the solution of alumina and ferric oxide in hydrochloric acid a slight excess of sodium acetate is added, so that the solution assumes a red tint and all the mineral acid present is combined with soda. A 10 per cent. solution of sodium hydrosulphite is added in small portions at a time until the red colour of the ferric compounds disappears. On boiling, the whole of the alumina is precipitated as a dense powder, which is easily filtered and washed free from salts of iron. The filter paper is moistened with nitric acid, ashed, and the alumina added to the contents of the crucible and ignited. The iron is estimated in the filtrate in any convenient manner. No figures are given, but the separation is said to be perfect.

When glucinum is present, this is precipitated as hydroxide with the alumina. The two bases may be separated by prolonged digestion (thirty-six hours) in the cold, with a concentrated solution of ammonium carbonate, which dissolves the glucina. After filtering off the alumina, the glucina in the filtrate may be thrown out of solution by prolonged boiling. C. G. J.

Rapid Determinations and Separations by Means of the Mercury Cathode and Stationary Anode. R. C. Benner and M. L. Hartmann. (*J. Amer. Chem. Soc.*, 1910, **32**, 1628-1636.)—Further experiment has been made with the simple equipment already described by Benner (Analyst, 1910, **35**, 544). Comparison of the rates of deposition under like conditions of current, volume of solution, etc., shows that, although the rate of deposition with the rotating anode is greater than with the stationary anode, it is not sufficiently so to recommend the use of so much more complex a piece of apparatus. The results obtained by Benner's method are as accurate as those obtained by other mercury cathode methods, and with the different metals so far experimented with it is found possible to adopt almost the same conditions as would be chosen if a rotating anode were being used in conjunction with a mercury cathode—that is to say, conditions which determine speedy deposition. Particulars are given concerning more than a hundred experiments, which show that the method is applicable to the estimation of nickel and its separation from aluminium, titanium, and the rare earths, to the estimation of cobalt and zinc, and to the estimation of iron and its separation from aluminium, titanium, and the rare earths. The time required for the deposition of 0·2 to 0·4 grm. from 10 to 20 c.c. of solution varies from ten to twenty minutes, and the results are seldom in error by more than ±0·0005 grm. G. C. J.

Estimation of Chromium in Chrome Tungsten Steel. H. Wdowiszewski and P. Bogoluboff. (*Chem. Zeit.*, 1910, **34**, 1365.)—The method of v. Knorre (*Stahl u. Eisen*, 1907, **27**, 1251) is found to afford the most accurate means of estimating chromium in steels which also contain tungsten, but it is somewhat tedious, and calls for the continuous attention of an experienced operator. The following modification economises time and gives results which differ little from those yielded by the original method of v. Knorre. To 1 to 2 grms. of borings contained in a 500 to 600 Erlenmeyer flask, 10 to 15 c.c. of a 15 per cent. solution of sodium phosphate are added for each grm. of borings, 7 to 8 c.c. of sulphuric acid (sp. gr. 1·65) for each grm. of borings, and finally 5 c.c. water. The borings begin to dissolve at once, and decomposition is complete in fifteen minutes if the contents of the flask be kept moderately warm. The temperature is then raised and 2 c.c. of nitric acid added. The metallic tungsten which separates out at first is oxidised by the nitric acid, and in presence of the sodium phosphate it passes into solution as phosphotungstic acid. The clear solution is diluted with 300 to 500 c.c. of hot water, 3 to 5 grms. ammonium persulphate are added, and the solution boiled until the excess of oxygen is expelled and the whole of the persulphate decomposed. The solution is then cooled, a measured quantity of standard ferrous solution is added, more than is sufficient to reduce the whole of the chromic acid present, and the excess of ferrous salt is determined by titration with permanganate. The whole series of operations occupies less than two hours, and when v. Knorre's method shows 5 per cent. of chromium, the simplified method above described shows 5±0·03 per cent. The quantity of sulphuric acid present should not be less than, nor greatly in excess of, that stated. G. C. J.

Estimation of Hydrogen in Gas Mixtures. O. Brunck. (*Chem. Zeit.*, 1910, **34**, 1313-1314 and 1331-1332.)—The author has used the method of Paal and Hartmann (ANALYST, 1910, **35**, 139), and finds it accurate and convenient. The absorption of the hydrogen may be quickened by using a Hempel pipette similar to that used for phosphorus, but packed with solid glass balls, which are preferable to beads or glass tubing, which are apt to entangle gas bubbles. The regeneration of the palladium sol may be effected as follows: Dilute sulphuric acid is added, until the whole of the palladium, together with its protective colloid (sodium protalbinate), is precipitated. No great excess of acid must be used, or, under the influence of the oxygen of the air, palladium may pass into solution as sulphate. The precipitate, which contains some unchanged picric acid, together with the palladium sol, is washed with water, and then suspended in water, and sodium hydroxide cautiously added until the precipitate disappears and the solution appears homogeneous. Sufficient sodium picrate (the author recommends as much as 5 grms.) is added, and the mixture is again available as an absorbent of hydrogen. G. C. J.

Estimation of Nitrates by the Phenol-Sulphonic Acid Method. H. Caron and D. Raquet. (*Bull. Soc. Chim.*, 1910 [iv.], **7**, 1021-1025.)—Perrier and Farcy have recommended (ANALYST, 1909, **34**, 174) the addition to the standard solution of an amount of chloride equal to that in the water residue under examination. As an alternative means of correcting for the influence of chlorides on the intensity of the coloration produced, they provided a curve having quantities of chlorine as abscissæ, and as ordinates factors by which the apparent amount of nitric anhydride found colorimetrically should be multiplied to get the true amount present. It is now shown that this curve is valueless except for quantities of nitric anhydride closely approximating those employed by Perrier and Farcy in their experiments, since the percentage reduction in colour depends not only on the amount of chloride, but on the absolute amount of nitric anhydride present. A simpler way of overcoming the influence of chlorides is to use freshly-prepared reagent. To 1 c.c. of 90 per cent. phenol, 10 c.c. of sulphuric acid are added, and 1 c.c. of this mixture is used for the test. Chlorine up to 10 parts per 100,000 is then without effect. It is important that the residue from the water and that from the standard solution be treated alike. If the former be cooled in a desiccator, and the latter on the bench, nitric anhydride will be over-estimated; and if the procedure be reversed, it may be under-estimated by more than 50 per cent. G. C. J.

Estimation of Nitrates in Water by a Sulpho-Salicylic Reagent. H. Caron and D. Roquet. (*Bull. Soc. Chim.*, 1910 [iv.], 7, 1025-1027.)—A 1 per cent. solution of salicylic acid in sulphuric acid may with advantage replace the phenol-sulphonic acid of Grandval and Lajoux. The coloration is more intense than that yielded by the ordinary phenol-sulphonic reagent in the proportion of 17 to 10, and is independent of the age of the solution. It is, however, advisable to make use of a comparatively freshly prepared solution for the reasons stated in the preceding abstract. The presence of chlorides does not affect the results, provided the solution be less than five or six days old, whereas phenol-sulphonic acid only one day old gives results which are sensibly influenced by the presence of chlorides. A convenient procedure is to evaporate 10 c.c. of the water under examination with 1 c.c. of 1 per cent. sodium salicylate, to add 1 c.c. of sulphuric acid to the residue, and then, after some minutes, 10 c.c. of water and 10 c.c. of ammonia. G. C. J.

NOTE.—Caustic soda may advantageously replace the ammonia.

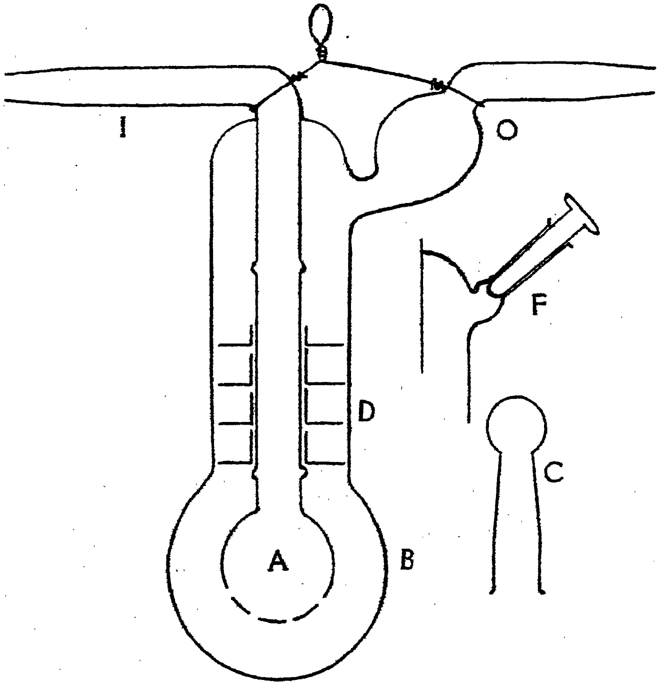
Characteristic Constituent of Natural Vichy Salts. A. Mallat. (*J. Pharm. Chim.*, 1910, **102**, 543-546.)—The mixture of salts obtained by the evaporation of Vichy mineral water, and known by the name of Natural Vichy Salts, always contain lithium salts. The detection of lithia, therefore, in a sample of the salts affords a means of ascertaining whether the salts have been obtained from Vichy water, or whether they consist of an artificially-prepared mixture consisting of sodium bicarbonate and other salts. According to the author's experience, these artificially-prepared mixtures never contain lithium salts. W. P. S.

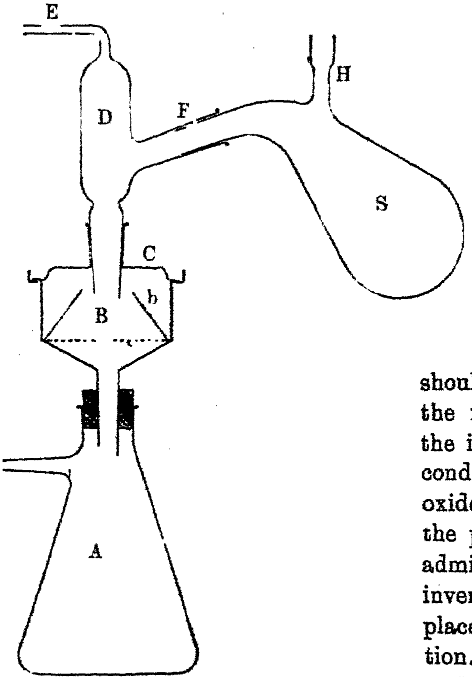
Determination of Hydrated Silicic Acid in Clay. F. K. Pence. (*Trans. Amer. Ceram. Soc.*, 1910, **12**, 43-53; through *J. Soc. Chem. Ind.*, 1910, **29**, 1308.)—Sjollema's diethylamine method (ANALYST, 1903, **28**, 123) and Herman's sodium paratungstate method (*Zeitsch. anal. Chem.*, **46**, 318) of separating amorphous from combined or crystalline silica are said to be too expensive for commercial analysis. The author therefore examined the older methods of separation by caustic soda or sodium carbonate. He finds that caustic soda is useless in this respect, as even a 1 per cent. solution will attack the combined silica. Sodium carbonate, however, gives better results, the method being as follows: Five grms. of the finely ground material are boiled with 120 c.c. of 5 per cent. sodium carbonate solution for ten minutes. After settling for a short time, the solution is decanted, and the sample treated twice more with the carbonate solution. The clay is then transferred to the filter-paper, washed with hot dilute sodium carbonate solution, and the silica in the combined filtrates determined in the usual way by acidification and evaporation to dryness. A control determination should be conducted at the same time, as the vessels usually yield a quantity of silica corresponding to about 0·2 per cent. on a

5 grm. sample. Should the amount of amorphous silica in a clay be unusually large —*i.e.*, more than 3 or 4 per cent.—a smaller sample should be used.

APPARATUS, ETC.

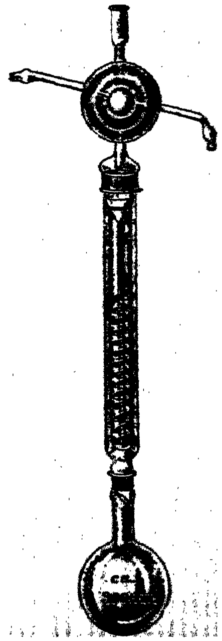
Potash Bulb. C. E. Waters. (*J. Amer. Chem. Soc.*, 1910, **32**, 1691-1693.)—The bulbed tubes A and B are made of very thin "condenser" tubing, the tubes I and O being of ordinary thickness. Around the cylindrical portion of A are four movable discs shown at D. These discs are made by abruptly flaring glass tubing of suitable bore and cutting off about 4 or 5 mm. from the end. Their extreme diameter should be quite 2 mm. less than the internal diameter of the cylindrical part of B, and they should move freely up and down the stem of A. They are prevented from falling below the cylindrical part of B, and from rising within 1 cm. of the outlet, by means of projections blown in the wall of A. The amount of potash solution to be used depends on the rate of flow of the gas, but enough to just reach the second disc is usually sufficient. The gas entering through I is first broken up into small bubbles on passing through the pinholes in the bulbed part of A. It is then trapped in succession by the discs, which, when working properly, alternately rise and fall, continually wetting the walls of B with fresh solution. F illustrates a stoppered side tube for filling the apparatus, to which it is affixed in a plane at right angles to that of the paper. C illustrates the caps which are placed on I and O when weighing. The apparatus is lighter and less fragile than that of Geissler, and has a smaller surface. When filled it weighs 35 to 40 grms. G. C. J.





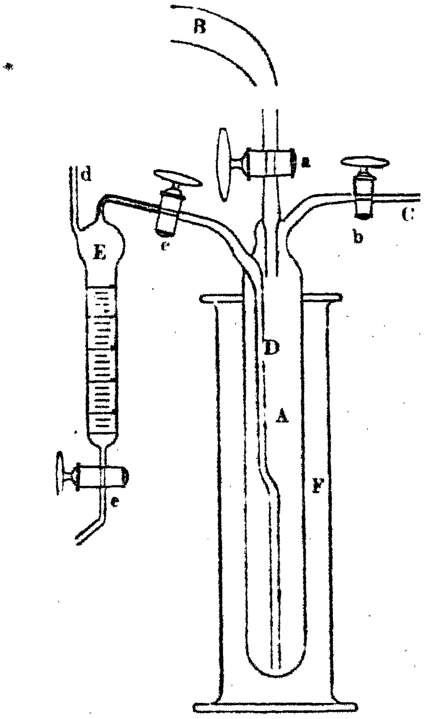
Apparatus for Filtering Hygroscopic Substances or those affected by Air. W. Steinkopf. (*Chem. Zeit.*, 1910, **34**, 1358.)—A suction flask, A, is fitted with a Buchner funnel, B, with an upper vertical extension, upon which rests a ground-glass lid with a central tube. Through this is fitted the ground-in tube of D, which has a side-attachment into which fits the reaction flask G. By turning this flask, the precipitate readily falls into the tube D, and thence on to the filter. The tube H, which should be represented on the nearest side of the flask, and not as shown here, serves for the introduction of a gas or to hold a reflux condenser. Tubes containing phosphorus pentoxide are placed between the suction flask and the pump, and at E, in order to prevent the admission of moisture to the apparatus. An inverted flask, J, with its stem cut off, may be placed upon the filter to keep the paper in position. When it is necessary to exclude all air, an indifferent gas is introduced through E. The apparatus is made by Bender and Hobein, Karlsruhe. C. A. M.

Automatic Extraction of Aqueous Liquids by Means of Specifically Lighter Solvents. R. Kempf. (*Chem. Zeit.*, 1910, **34**, 1365-1366.)—The flask, extraction apparatus, and ball condenser, are connected by means of ground-glass joints. Inside the external tube of the extraction apparatus is a long test-tube provided with glass points near the top and bottom, to insure its taking up an approximately central position within the wider tube. The inner tube, which serves to hold the aqueous liquid to be extracted, is also provided with two holes pierced in its side some way below the top. The only other part of the apparatus is the long funnel tube, around the lower part of which a glass spiral is wound. The operation of the apparatus is as follows: The flask is heated in any convenient manner, and the vapour of the ether or other solvent passes up the annular space surrounding the container of the aqueous liquid, which it maintains at a temperature near the boiling-point of the solvent. On reaching the condenser the vapours are condensed, and the liquid solvent falls into the funnel tube, from the bottom of which it escapes in small globules. These

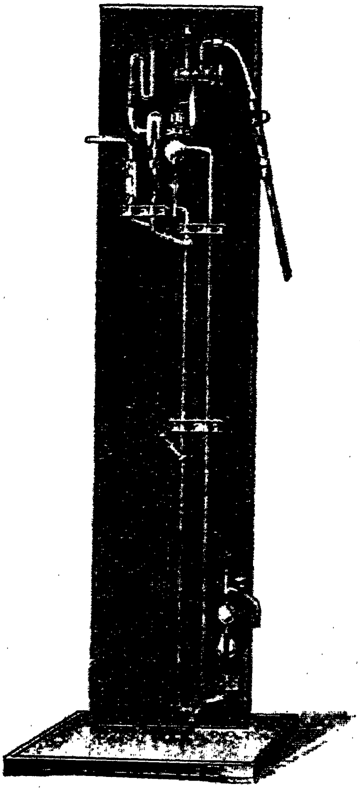


rise slowly through the aqueous liquid, and the glass spiral serves to prolong the period of contact between the immiscible solvents. Finally the ether overflows through the holes near the top of the inner tube, and flows back to the flask. The length of the funnel tube and the effective length of the inner tube (that is, its length from its bottom up to the level of the overflow holes) need to be chosen with due regard to the sp. gr. of the aqueous solution and the other solvent, and to the extent to which water and the other solvent dissolve each other. For ether and aqueous solutions of sp. gr. not far from unity, a funnel length of 52 cm. requires the effective length of the extraction tube to be kept as low as 34 cm. The apparatus is supplied by the makers, the Vereinigten Fabriken für Laboratoriums-bedarf, Berlin, with three inner tubes having effective lengths of 17, 26, and 34 cm., and the longest one serves for the extraction of about 175 c.c. of liquid. G. C. J.

Apparatus for Storing and Measuring Poisonous, Hygroscopic or Volatile Liquids. W. Steinkopf. (*Chem. Zeit.*, 1910, 34, 1319.)—For the storage and measurement of liquids which should not be exposed to the atmosphere, the author has devised the apparatus illustrated in the figure. It somewhat resembles the apparatus described by Falck for the storage of sterilised liquids. It consists of a cylindrical vessel, A, with fairly thick walls, connected with the adapter B by way of the cock *a*; another branch, C, is closed by the cock *b*, whilst a third branch, D, extends nearly to the bottom of the vessel, and is connected by way of the cock *c* with the burette E. This last branch is situated in a plane at right angles to that of the adapter B. The upper portion of the burette is protected by a potash tube which is connected with *d*. The vessel A is suspended in the stout glass cylinder F, in which it is held by a brass lid. The apparatus has been designed chiefly for use with anhydrous hydrocyanic acid. During the process of filling, the tap *c* is closed; *a* and *b* are open, and the open end of C is guarded with calcium chloride and potash tubes. The hydrocyanic acid enters through the adapter B which is connected with the condenser and solidifies in A under the action of an alcohol-carbon dioxide freezing mixture placed in F. After charging, the cocks *a* and *b* are closed, and the acid, if anhydrous, may be kept without change for weeks. For withdrawing a portion of the contents, the tube C is connected with a



calcium chloride tube and a rubber bellows, by which any desired quantity of liquid may be forced over into the burette. The same apparatus may be used with volatile liquids, such as methyl bromide or dry bromine. J. F. B.



Mercury Pump for Rapidly Obtaining a High Vacuum. A. Beutell. (*Chem. Zeit.*, 1910, 34, 1342-1344.)—The apparatus here shown has the advantages of using very little mercury, not being broken by the shock of the falling metal, and of being easily cleaned. The mercury is introduced into the small beaker-like receptacle at the bottom on the right, and this is closed by a stopper provided with a tap. The india-rubber tube at the top is connected with a water-pump, and the mercury is allowed to enter the pump. The tap is then turned to the point fixed by an asbestos stop, so as to allow the necessary amount of air to enter for the mercury to be raised. The mercury will then circulate uninterruptedly for days together through the two vertical columns. To stop the pump, first the lower and then the upper tap is turned 180°, so that air slowly enters, its speed being regulated by the asbestos stops to the taps. Any danger of fracturing the glass by the falling mercury is obviated by allowing a minute quantity of air to enter the pump through the pores of a sound cork fitted in the small tube to the left, so that there is always an air-cushion to protect the glass from the shock. This also prevents the production of electric sparks, and only the ordinary phenomena of the Geissler tube appear. With the most rapid type of the pump, a Röntgen vacuum can be obtained in a connected vessel within fifteen seconds, whilst with the slowest type a minute is required. The amount of mercury needed is from 8 to 20 c.c. The pump may be obtained from F. Hugershoff, Leipzig. C. A. M.

Thermostat for Refractometric Examinations. Poda. (*Chem. Zeit.*, 1910, 34, 1382.)—By means of the apparatus any required temperature may be maintained constant notwithstanding variations in the pressure of the water or gas supply. It consists essentially of a combination of a water-thermostat with a small centrifugal pump. A cylindrical copper vessel holding about 3 litres is nearly filled with water, which is heated by means of a Bunsen burner, controlled by a thermo-regulator. In the water is immersed a Luther's laboratory pump, worked by a water-turbine or an electric motor, so that the water is made to circulate through the prism chamber of the refractometer. The regulator is provided with a [illegible] graduated screw and millimetre scale, so that when once a definite temperature has been established it can rapidly be once more obtained. The copper vessel also contains a cooling coil, so that temperatures lower than that of the room may be obtained. The apparatus is made by K. Grass, Innsbruck. C. A. M.

Modified Separatory Funnel and Washer for Heavy Liquids. H. M. Atkinson. (*Chem. News*, 1910, **102**, 308.)—This is an ordinary pear-shaped separator with tap at the bottom, with the addition of a side-tube carrying a stopcock, about half-way up the side of the separator. It is useful for washing heavy liquids, such as aniline; and the wash-water, caustic soda solution, etc., can be readily run off through the side-tube without running out the main liquid in the funnel. The substance may also be dried with calcium chloride or other reagent without transference.

REPORTS.

Report of the Malt Analysis Committee (Coloured Malts and Caramel), 1910, to the Council of the Institute of Brewing. (*J. Inst. Brewing*, 1910, **16**, 529-533.)—The Committee consisted of Messrs. Julian L. Baker, L. Briant, A. J. Brown, A. Chaston Chapman, J. Heron, A. R. Ling, A. Gordon Salamon, and L. T. Thorne, assisted by a number of others connected with the brewing industry.

In the previous Report (*J. Inst. Brewing*, 1906, **12**, 1) it was recommended that the grinding of the malt for analysis should be done in a "Seck" mill set at 25°. For this is now substituted "Seck 0·5 mm.," this being the distance as measured with a feeler gauge between the rollers. The Committee recommend that this mill-setting be taken as applying also in their previous Report. Brown and crystal malts are to be ground in the "Seck" mill, but, owing to the possibility of roasted malts and barleys fouling the mill and colouring the subsequently ground pale malts, it is recommended that black grist be ground finely in a coffee-mill.

Brown and Crystal Malts—*Extract.*—Fifty grms. of the sample are ground in the "Seck" mill as above specified, and the grist mashed with 300 c.c. of distilled water at 158° F. and 100 c.c. of cold water malt extract previously heated to 150° F. This extract is prepared from a well-modified pale malt of diastatic power 30° to 40° (Lintner) by digestion with three times its weight of distilled water for one hour at 60° to 70° F., and subsequent filtration. The mixture is kept for one hour at a temperature of 150° F., then cooled to 60° F. and made up to 515 c.c., shaken, filtered, and the sp. gr. taken. The necessary correction for the cold water malt extract employed is obtained by diluting a volume of 100 c.c. of the malt extract with 300 c.c. of water, the mixture being kept at 150° F. for one hour. Subsequently it is cooled to 60° F., made up to 500 c.c. at 60° F., filtered, and its sp. gr. taken.

Colour.—A volume of 20 c.c. of the above extract, which must be brilliant, is diluted to 100 c.c., and the colour read in a 1-inch cell, using a Lovibond tintometer and glasses of the "52" series.

The colour due to the cold malt extract may be neglected.

BLACK BARLEYS AND MALTS—*Extract.*—A little over 50 grms. of the sample is finely ground in a coffee-mill, and of this exactly 50 grms. are extracted with about 350 c.c. of boiling distilled water, care being taken to avoid balling. The infusion is kept in a bath of boiling water for one hour, after which it is cooled, made up to a volume of 515 c.c. at 60° F., shaken, filtered, and the sp. gr. of the filtrate taken.

Colour.—A volume of 20 c.c. of the above extract, which, if not brilliant, must be refiltered, is diluted to 1,000 c.c., and the colour read in a 1-inch cell, using a Lovibond tintometer and glasses of the "52" series.

CARAMEL—*Colour.*—Ten grms. of the sample are dissolved in distilled water, and made up to 100 c.c. at 60° F. A volume of 10 c.c. of this solution is diluted to 1 litre filtered if necessary, and the colour read in a 1-inch cell, using a Lovibond tintometer and glasses of the "52" series.

STATEMENT OF RESULTS.—Results are expressed to the nearest first decimal place only, except in the case of tint, which is recorded to the nearest half-unit.

Brown and Crystal Malts.—Extract per standard quarter of 336 pounds. Colour: In a 1-inch cell, "52" series Lovibond (2 per cent. extract).

Black Barleys and Malts.—Extract per standard quarter of 336 pounds. Colour: In a 1-inch cell, "52" series Lovibond (0·2 per cent. extract).

Caramels.—Colour: In a 1-inch cell, "52" series Lovibond (0·1 per cent. solution).

Annual Report of the Dominion Laboratory, Wellington, New Zealand (1909). J. S. Maclaurin. (*Wellington, N.Z.*, 1910; pp. 76.)—The report gives, mainly in tabular form, the results of a large number of varied analyses, including analyses of coal, minerals, ores, rocks, gold and silver assays, water, soils, manures, explosives, milk, and other foods and beverages, etc. Amongst the mineral waters examined is one from the lake on White Island, the natural temperature of this water being 110° F. It is remarkable in containing, in addition to free hydrochloric acid (4·83 per cent.) and boron trioxide (0·031 per cent.), pentathionic acid, $H_2S_5O_6$, to the extent of 0·024 per cent.

The milk standard in the Dominion is fixed at 3·25 per cent. of fat and 8·5 per cent. of non-fatty solids, with not less than 12 per cent. of total solids; 1,598 samples were examined in the four worst months of the year to ascertain their quality. The results show that 3·88 per cent. of these samples fell below the standard for milk-fat, thirteen samples containing less than 3·0 per cent.; while 4·13 per cent. were below the standard for non-fatty solids, twenty-one containing less than 8·30 per cent.

REVIEW.

TECHNICAL MYCOLOGY. By DR. FRANZ LAFAR. Translated by CHARLES T. C. SALTER. Vol. II., "Eumycetic Fermentation." Part II. With 50 figures in the text. London: Charles Griffin and Co. 1910. Pp. ix, 191-748. Price 18s. net.

This long-expected volume brings to a close the English translation of this valuable work, of which the first volume was published in the original German in 1897. A regrettable delay has occurred in its production, as the corresponding chapters of the original were written in 1904-1906. The treatment of the subject-matter, therefore, is only brought down to a date now five or six years past, and no references later than 1905 seem to be included in the bibliography. How much the book suffers from this unfortunate circumstance is an indication of the rapid progress which is still being made in many branches of the subject. No attempt has been made to remedy this state of affairs, as might have been done by the addition of supplementary paragraphs giving the most recent views on many of the subjects discussed in the text, or even by the insertion of references to them, whereby the value of the book as a work of reference for present use would have been greatly increased.

This said, there is little to add but praise. The book is excellently produced, and editor, translator, and publisher are all to be congratulated on their share in this result. This part includes the bibliography and index to the entire work, together comprising about a quarter of the volume. A special feature of the bibliography, and one greatly to be recommended, is that reference is frequently made, not only to the original paper, but to the abstract in some one or more easily accessible journal, such as the *Chemisches Zentralblatt*, etc. The opportunity of making the bibliography serve also as an index of authors, by adding the number of the page on which each reference is to be found, has been missed, and the work is accordingly without this useful adjunct.

As in previous parts, each section is treated by an acknowledged authority on the subject, with the result that we are presented with a series of thoroughly well-informed monographs.

The range of subject is very wide, and comprises yeast nutrition and culture; the life-history and classification of the saccharomycetes and allied forms; the enzymes of yeast; the chemistry of alcoholic fermentation; and the morphology, classification, and chemical action of the technically important members of the higher groups of fungi, as well as of that lumber room of classification, the *fungi imperfecti*, including the group of Torulaceæ, at the moment of great interest to the English brewer.

One of the most interesting chapters of the book is the account of the life history, variability, and classification of the yeast organisms, in which the fundamental researches of Hansen on these important subjects are described. The present system of classification of the yeasts cannot, however, be regarded as at all satisfactory. This is at once evident from the facts that the Saccharomycetaceæ are defined as spore-producing fungi, the closely allied group of the Torulæ being thus excluded, and that Hansen succeeded by a simple process of cultivation in rendering many species of Saccharomyces permanently non-sporing, without altering any other of their characteristics. Much work is also still called for on the difficult subject of the differentiation of the very numerous species, varieties, and races of yeast.

Analytical methods do not bulk largely in this section of the work, but a considerable amount of information of the greatest possible value to analysts is scattered throughout its pages, particularly in those sections dealing with the mineral foodstuffs of yeast, the production of sulphites by the biochemical reduction of sulphates in fermented liquids, invertase, the by-products of alcoholic fermentation, the fermentation of dextrin by yeast, the autofermentation of yeast, etc.

This volume does not deal in detail with any of the technical processes of the fermentation industries, but it nevertheless provides an almost inexhaustible storehouse of facts bearing directly upon the nature of these processes, the organisms employed in them and the resulting products, and it forms therefore an invaluable weapon in the armoury of those whose fate it is to contend with the difficulties inherent in the employment of living organisms as chemical reagents. A. HARDEN.

NEW BOOK.

THE CHEMICAL TRADE DIRECTORY OF CHEMICAL MANUFACTURERS, MERCHANTS, BROKERS, AND AGENTS AND MAKERS OF CHEMICAL PLANT IN GREAT BRITAIN AND IRELAND. Fourth Edition. Davis Bros., 265, Strand, London, W.C. 1911. Price 10s.

An 8vo. volume, containing 454 pages of matter. The contents are in three sections. The first, an alphabetical list of names of chemical manufacturers, merchants, brokers and agents, and makers of chemical plant and materials in Great Britain and Ireland, with full addresses. The second, classified lists of chemical products, etc., with names and locations of the makers. The third section, a new one, contains information useful to those in the chemical trade, such as the text of the Alkali Act of 1906, and an abstract of the last report of the Chief Alkali Inspector. Then follow abstracts of legal decisions, the "Census of Production" returns for 1908, and a series of price diagrams, one showing the fluctuations in the price of coal-tar, etc. Tables are given showing exports and imports of chemicals, etc., for the years 1907-1909, the section closing with an abstract of the Factory and Workshop Act of 1901.

INSTITUTE OF CHEMISTRY.

PASS LIST.

FINAL EXAMINATION FOR THE ASSOCIATESHIP IN THE BRANCH OF BIOLOGICAL CHEMISTRY.—The following candidates for the Associateship passed: F. C. Dyche-Teague, H. F. E. Hulton and H. Shankster. H. Mansfield, A.I.C., presented himself for the Certificate, and passed.

JANUARY EXAMINATIONS, 1911.—Of nine candidates who presented themselves for the Intermediate Examination, six passed: J. Crawford, J. C. Earl, H. J. Evans, W. R. Pratt, D. C. Scott, and G. E. Slim. Of twenty-six candidates who presented themselves for the Final Examination, eighteen passed. In the branch of Mineral Chemistry: W. C. Davis, W. H. H. Norris, B.A. (Cantab.), B.Sc. (Lond.), and R. W. Pope; in the branch of Physical Chemistry: W. R. G. Atkins, B.A. (Dub.), and Bucchok Shen, B.Sc. (Birm.); in the branch of Organic Chemistry: W. Caw, J. C. Duff, B.Sc. (Manc.), A. Greeves, A.R.C.S. (Lond.), B.Sc. (Lond.), W. H. Nodder, B.Sc. (Lond.), T. A. Smith, and T. A. Wallace, B.A. (Dub.), in the branch of the Chemistry of Food and Drugs and of Water: W. H. Dickinson, M.B.Ch.B. (Edin.), Captain I.M.S., H. D. Elkington, R. H. Ellis, A. D. Heywood, and E. H. Shepherd, B.Sc. (Lond.); in the branch of Biological Chemistry: J. Crabtree, B.Sc. (Manc.). Captain Dickinson was examined for the Fellowship. One Fellow, R. W. Clarke, also obtained the Certificate in the Chemistry of Food and Drugs and of Water.

MARCH, 1911. Vol. XXXVI., No. 420.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The Annual General Meeting of the Society was held on Wednesday evening, February 1, in the Chemical Society's Rooms, Burlington House. The President, Mr. E. W. Voelcker, A.R.S.M., F.I.C., occupied the chair.

The minutes of the previous Annual General Meeting were read and confirmed.

The Hon. Treasurer presented the Accounts of the Society for the year 1910. These were adopted, and votes of thanks were passed to the Hon. Treasurer, Auditors, and Hon. Secretaries.

On the motion of the President, a vote of thanks was passed to the President and Council of the Chemical Society for their kindness in allowing the Society the use of their rooms at Burlington House during the past year.

The President delivered his Annual Address.

On the motion of Mr. Fairley, seconded by Mr. Smetham, a vote of thanks was by acclamation accorded to the President for his Address and for his services in the chair.

Mr. Thomas Macara, F.I.C., and Mr. Cecil Revis, A.C.G.I., were appointed Auditors of the Society's Accounts for the year 1911.

The election of Officers and Council for the ensuing year was postponed until Wednesday, March 1, to which date the meeting was adjourned.

The monthly ordinary meeting followed the annual general meeting, the President, Mr. E. W. Voelcker, occupying the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates in favour of Messrs. R. L. Collett, B.A., A.I.C., W. B. Cowie, F. Evershed, and G. Taylor, were read for the second time; and certificates in favour of Messrs. Joseph Clifford, A.R.C.S.I., assistant chemist in the Survey Department Laboratory, Public Works Ministry Gardens, Cairo; James Connah, B.Sc. (Lond.), F.I.C., Superintending Chemist, Custom House, London, E.C.; Harley F. Knight, "Ledbury," 64, Amhurst Park, Stamford Hill, N., assistant to Mr. Bertram Blount, F.I.C.; Charles H. LaWall, 39, South Tenth Street, Philadelphia, Pa., U.S.A., chemist to the Pennsylvania Food Commissioner (Philadelphia District) and to the Health Commissioner of Philadelphia; William Rest Mummery, F.I.C., 128, Devizes Road, Salisbury, chemist and bacteriologist to the Hygienic Dairy Society, Salisbury;

and W. Macro Seaber, B.Sc. (Lond.), F.I.C., 79, Mark Lane, London, E.C., analytical and consulting chemist, were read for the first time.

Messrs. C. L. L. Claremont, B.Sc., A.I.C., and H. D. Elkington, A.I.C., were elected members of the Society.

The following papers were read: "Note on the Detection and Estimation of Small Quantities of Antimony," by Philip Schidrowitz, Ph.D., and H. A. Goldsbrough; and "Commercial Analysis and Arithmetic," by Clarence A. Seyler, B.Sc., F.I.C.

* * * * *

ANNIVERSARY DINNER.

THE anniversary dinner of the Society took place on Tuesday evening, January 31, at the Trocadero Restaurant, under the chairmanship of the President, Mr. E. W. Voelcker, A.R.S.M., F.I.C. There were present about one hundred members and guests, among the latter being Sir Thomas Elliott, K.C.B., Secretary of the Board of Agriculture and Fisheries; Mr. W. Whitaker Thompson, LL.B., Chairman of the London County Council; Sir Edward Thorpe, C.B., F.R.S.; Dr. J. J. Dobbie, M.A., F.R.S., Principal Chemist of the Government Laboratory; Professor F. Gowland Hopkins, M.A., D.Sc., F.R.S.; Dr. Frank Clowes, Chemist to the London County Council; Dr. R. T. Glazebrook, M.A., F.R.S., Director of the National Physical Laboratory; Dr. A. T. Morton, Master of the Society of Apothecaries; Mr. Walter F. Reid, President of the Society of Chemical Industry; and Mr. James Swinburne, M.Inst.C.E., F.R.S., President of the Faraday Society.

After the loyal toasts had been duly honoured, the following toasts were proposed: "Government Departments," by Sir Edward Thorpe (responded to by Sir Thomas Elliott and Dr. J. J. Dobbie); "The Society of Public Analysts and Other Analytical Chemists," by Mr. W. Whitaker Thompson (responded to by the President); and "The Guests," by Mr. Otto Hehner (responded to by Mr. Walter F. Reid and Mr. James Swinburne).

* * * * *

A VOLUMETRIC METHOD FOR THE ESTIMATION OF TUNGSTEN.

BY EDMUND KNECHT AND EVA HIBBERT.

(*Read at the Meeting, December* 7, 1910.)

WHEN tungstic acid or its salts are reduced in strong hydrochloric acid solution by means of granulated zinc, the tungsten passes rapidly to the condition of the blue oxide, then becomes violet, and ultimately yields a brown solution of the tetrachloride. This latter is a powerful reducing agent, and is rapidly and completely brought back again to the condition of tungstic acid by oxidising agents. Otto von der Pfordten (*Ber.*, 1883, **17**, 508) has made use of these reactions for the volumetric estimation of tungsten, employing a standardised solution of potassium permanganate as the oxidising agent, in presence of manganous sulphate. The figures given by this author do not produce the impression that the method is very accurate showing as they do a maximum variation of about 2 per cent.

The new method which we propose is based upon similar principles to that of Otto von der Pfordten, the main differences being that in place of permanganate we use a standard solution of iron alum as oxidising agent (with potassium thiocyanate as indicator), and conduct the titration of the reduced tungsten solution in an atmosphere of carbon dioxide. Furthermore, the titration can be carried out in presence of ferrous iron, which is of course impossible with the permanganate titration. It is consequently not only available for the analysis of commercial tungstic acid (which is extensively used for preparing the metallic filaments in incandescent electric lamps) and tungstates, but also for the rapid and exact estimation of tungsten steels.

If tungstic acid is subjected to energetic reduction by zinc in presence of strong hydrochloric acid, the reaction may be considered as taking place according to the following equation:

$$WoO_3 + 4HCl + H_2 = WoCl_4 + 3H_2O\,;$$

and if the reduced solution be then treated with a ferric salt, reoxidation ensues, according to the equation

$$WoCl_4 + 2FeCl_3 = WoCl_6 + 2FeCl_2.$$

In order to prove this, experiments were first conducted with pure tungstic acid. The purity of the product was ascertained by reducing a known weight in a current of dry hydrogen at a temperature of about 600° C., and weighing the amount of metallic tungsten obtained.

0·5320 grm. of tungstic acid (dried at a red heat) yielded in this way 0·4220 grm. of metallic tungsten. The amount required by theory is 0·4219 grm.

In another experiment, 0·6790 grm. tungstic acid yielded after reduction 0·5385 grm. of metallic tungsten. The amount required by theory was 0·5385 grm. The tungsten obtained in this way when heated in the air to constant weight gave 0·6750 grm. tungstic acid. An accurately weighed quantity of this product was now dissolved in a small volume of ammonia, after which the solution was strongly acidulated with concentrated hydrochloric acid in a flask provided with a Bunsen valve. When reduction was complete, a current of carbon dioxide was passed into the flask, and the solution was titrated with standard iron alum after adding potassium thiocyanate as indicator. The titration gave 99·69 per cent. WoO_3.

The method was further tested on a pure sodium tungstate, with the following results: 0·25 grm. of this product, reduced and titrated in the way indicated, yielded 0·1760 grm. WoO_3. The amount required by theory is 0·1757 grm.

In the reduction of tungstic acid, the contents of the flask almost immediately become intensely blue, and this colour persists for some time. The liquid then assumes, for a very short period, the colour of permanganate, and ultimately yields a brown solution indicating the formation of $WoCl_4$. In titrating with iron alum the brown disappears, and gives place to blue, which persists until the whole of the tungsten is reconverted into tungstic acid. This blue colour may serve as indicator in place of the red of the thiocyanate, identical results being obtained in either case.

Tungsten and Iron.—In order to ascertain whether the estimations of tungsten by the new method were in any way affected by the presence of iron, known amounts of pure tungstate of soda were reduced as above in presence of weighed quantities of iron wire. The results given below are stated in terms of metallic tungsten:

	Taken: Grm.	Found: Grm.
Wo	0·0406	0·0404
Fe	0·9770	—
Wo	0·0203	0·0196-0·0197
Fe	1·0100	—
Wo	0·0944	0·0929
Fe	1·0200	—
Wo	0·1303	0·1292
Fe	1·0020	—

As will be seen, the results are slightly low in all cases.

Ferro-tungsten.—The alloy is ground in an agate mortar and sieved through calico. About 0·1 grm. is weighed in a porcelain crucible, and fused over a Bunsen with about 4 grms. of potassium persulphate until no more particles of metal are visible, which will require about 15 to 20 minutes. The melt is taken up in water, rendered alkaline with caustic soda, filtered from the ferric hydrate, and the tungsten estimated in the filtrate as described above. The iron can be estimated by dissolving the ferric hydrate in hydrochloric acid and titrating with titanous chloride, using potassium thiocyanate or methylene blue as indicator.

* * * * *

A NEW METHOD FOR THE VOLUMETRIC ESTIMATION OF MOLYBDENUM.

By EDMUND KNECHT and F. W. ATACK.

(*Read at the Meeting, December* 7, 1910.)

The method is based on the reduction of the molybdenum by zinc and strong hydrochloric acid, and the subsequent oxidation of the reduced solution in an atmosphere of carbon dioxide, with standard methylene blue.

Pisani (*Comp. rend.*, 1814, 59, 301) was the first to suggest the method of reducing the molybdenum with zinc and sulphuric acid, and then titrating the reduced solution with permanganate. Many formulæ of a complicated character have been advanced to represent the stage of reduction so obtained—*e.g.*, Mo_5O_7 (von der Pfordten, *Ber.*, 1882, 15, 1929) and $Mo_{12}O_{19}$ (Emmerton, *J. Iron and Steel Inst.*, 1886, 1018). Such formulæ were explained in a paper by Dudley (*Chem. News*, 1898, 77, 195), in which he points to the fact that Mo_2O_3 readily oxidises on exposure to air.

This reduction with zinc and sulphuric acid is very slow and tedious, and, using an atmosphere of carbon dioxide, one fails to obtain results which are in agreement.

Moreover, in all processes involving the use of permanganate, the iron has first to be precipitated if one wishes to estimate the molybdenum directly. Hence a rapid method was sought for the accurate estimation of molybdenum directly in presence of iron.

Energetic reduction with pure granulated zinc and strong hydrochloric acid results in the reduction of molybdenum to the condition of $MoCl_3$ if a current of carbon dioxide be maintained. The stages involved in this reduction are rendered visible by colour changes: the solution first becomes pale green, deepening to blue, then passes to orange, and, after gradually assuming the lighter shade of straw-yellow,* finally turns to a peculiar shade of pink (depending on the amount of molybdenum present), thus indicating the end of the reduction. This final yellowish-pink colour has not been obtained in presence of air, and is best shown if a large excess of strong hydrochloric acid is present.

The reduced solution may now be quantitatively oxidised by methylene blue solution containing 4 grms. per litre, standardised by the method described by Knecht (*J. Soc. Dyers and Col.*, 1905, 21, 9). During this oxidation the salmon-pink passes to a straw-yellow, then to a pale green (in absence of iron), which appears almost, often exactly, halfway through the titration; and, finally, one drop in excess gives the characteristic shade of methylene blue.

In this method of estimation, the oxidation of the $MoCl_3$ does not proceed as far as the stage represented by MoO_3, as is stated to be the case when permanganate is used. It has been shown that the final product is $MoCl_5$, the highest chloride known. Thus, as soon as the oxidation of the $MoCl_3$ is completed as far as $MoCl_4$, the $MoCl_5$ produced gives, in strong hydrochloric acid solution, the pale green colour mentioned above, the colour of the methylene blue appearing when a further volume of methylene blue, equal to that already added, has been run in from the burette. Thus the reaction occurs in two distinct stages—

$$2MoCl_3 + 2HCl + O = 2MoCl_4 + H_2O.$$
$$2MoCl_4 + 2HCl + O = 2MoCl_5 + H_2O.$$

The reduction is effected in an 8-ounce conical flask carrying a three-holed rubber stopper. One of these is fitted with a Bunsen valve, which is not closed as usual with a solid glass bead, but is fitted at the top with a glass tube, into which fits a small piece of indiarubber stopper. Through this passes a platinum wire, to which is attached a rod of pure zinc. Another hole carries a tube for the introduction of a stream of carbon dioxide; the remaining one carries the adapter for the burette. Having placed the molybdenum solution in the flask, 50 to 75 c.c. of strong hydrochloric acid are added, and then a few pieces of pure granulated zinc, the zinc rod being lifted well out of the solution. A violent reduction ensues, during which the stream of carbon dioxide is maintained. After this zinc has completely dissolved, the zinc rod is lowered into the solution for a few moments to insure complete reduction, being then removed, and washed with a little freshly boiled water carefully introduced down the valve from a wash-bottle. The warm solution is now titrated with standard methylene blue.

---

* Titration at this stage has shown the straw-yellow solution to approximate to Mo[illegible]O[illegible], which is very near the end of the reduction.

The method was tested on a pure ammonium molybdate, which was found by the gravimetric method (estimation as lead molybdate, $PbMoO_4$) to contain 54·4 per cent. Mo, the amount calculated for the formula $(NH_4)_6Mo_7O_{24}.4H_2O$ being 54·36 per cent. This formula also agrees with the amount of ammonia found—viz., 8·26 per cent. (calc. = 8·28 per cent.); and also with the amount of MoO_3 left on the careful ignition of the finely powdered salt—found, 81·56 per cent. MoO_3 (calc. = 81·53 per cent.).

These results agree exactly with those found, using a recrystallised sample of the ammonium molybdate used above, which had been carefully air-dried—found, 81·70 per cent. MoO_3. By direct titration with methylene blue the following figures were obtained in different estimations: 54·36, 54·43, 54·39, and 54·49 per cent. Mo. The method has also been tested on pure MoO_3 (prepared by the careful ignition of pure ammonium molybdate), which gave 66·60 per cent. Mo, as compared with 66·66 per cent. required by theory. The reduction and titration of molybdenum by this process should not require more than fifteen minutes if ferric iron be absent.

That it is essential to pass a current of carbon dioxide is shown by an experiment in which it was found that the percentage of Mo found by methylene blue was reduced from 54·42 to 44·30 by drawing air through the reduced solution for fifteen minutes. (The colour changes involved in the oxidation were readily followed.)

Molybdenum and Iron.—Ferrous chloride does not reduce methylene blue in hydrochloric acid solution, and hence the method may be used for the direct estimation of molybdenum in presence of iron, provided that all the iron has been reduced to the ferrous condition. The following results were obtained from mixtures of iron and molybdenum:

Molybdenum found: Grm.	Molybdenum taken: Grm.	Iron present: Grm.
0·0347	0·0348	0·0732
0·0368	0·0368	0·10 approx.
0·0367	0·0368	0·15 ,,
0·0368	0·0368	0·15 ,,
0·0449	0·0500	1·0 ,,

In using this method for the analysis of steel, it is to be noted that the salts of the lower oxides of titanium, tungsten, chromium, and vanadium, also exert a reducing action on methylene blue.

NOTE ON THE DETECTION AND ESTIMATION OF SMALL QUANTITIES OF ANTIMONY.

BY PHILIP SCHIDROWITZ, PH.D., AND H. A. GOLDSBROUGH, A.I.C.

(*Read at the Meeting, February* 1, 1911.)

IN connection with a recent piece of work having an important commercial bearing, it became necessary to work out a process for the determination of small quantities of antimony. By "small" we mean quantities such as $\frac{1}{50}$ or $\frac{1}{100}$ of a grain to the pound. We were not able in the literature on this subject to find any process which appeared likely to assist us under the conditions of our experiments. It did not appear to us that the Marsh process could give practical results, such as are obtained in the case of arsenic, because, as is well known, the deposit occurs on both sides of the flame, thus preventing the formation of a homogeneous mirror. The problem which confronted us was of a twofold nature: (1) The detection and determination of small quantities of antimony in colourless aqueous solutions, and (2) the detection and determination of antimony in certain classes of food-stuffs, such as preserved meats.

Detection and Determination in Clear Aqueous Solutions.—It occurred to us in the first place that it might be possible, in view of the very characteristic colour of the sulphide, to determine roughly the amount of antimony present by comparing the sulphide precipitate with precipitates obtained from solutions containing known quantities. Although relatively very small quantities of antimony may be detected in an aqueous solution in this manner, a few experiments sufficed to show that it was quite impossible to form even a rough opinion regarding quantity by this method. It then occurred to us that, as the antimony sulphide may be readily obtained in colloidal solution, it might be possible to obtain the compound directly in this form by employing a small quantity of a protective colloid. We anticipated that if this could be done we should obtain characteristically coloured solutions in which, by a colorimetric method, the amount of antimony might be readily determined. This we found to be the case. We found that 0·01 grm. of gum acacia in 10 c.c. total volume is sufficient to maintain 2 mgrms. of antimony in colloidal solution. Possibly the amount of antimony that may be held up in this way by this quantity of gum is much larger, but we did not experiment beyond the limit stated. We may add that the antimony employed throughout was in the form of tartar emetic, but that the quantities stated are actual amounts of Sb. The coloration obtained is characteristic and extremely delicate. With regard to the limits, we found that 0·005 mgrm. of Sb in 10 c.c. of liquid gave a distinct coloration—that is to say, it is possible to determine 1 part in 2,000,000. The coloration obtained by passing hydrogen sulphide into hot solutions is deeper than that obtained with cold solutions, and when very small quantities are in question we prefer the hot process. For quantities of 0·02 mgrm., however, the cold process is sufficiently delicate. The control solutions were made up as follows: Known quantities of antimony (in the form of tartar emetic) were made up to a total volume of 10 c.c. with distilled water, after adding

0·5 c.c. of strong HCl and 0·1 c.c. of a 10 per cent. gum acacia solution. It was found that the intensity of coloration was directly proportional to the quantity of antimony present. The experiments on which these statements are based were as follows: (*a*) Solutions containing 0·2 mgrm., 1 mgrm., and 2 mgrms., were directly compared with one another in the colorimeter; (*b*) solutions containing 0·01 mgrm. and 0·02 mgrm. were similarly compared; and (*c*) 0·05 mgrm. and 1 mgrm. were compared. In every case it was found that the heights of the columns of liquid at apparently equal colour intensity were inversely proportional to the amount of antimony present.

The method described presupposes the absence of other heavy metals of the second group which might form colloidal solutions, such as arsenic or mercury. It is also clear that in such cases the method would have to be modified according to circumstances, and that the same applies to cases in which organic matter is present. We have not made any experiments in regard to the separation of antimony from other heavy metals of the second group; but, under the ordinary practical conditions obtaining where food-stuffs are liable to be contaminated by antimony, mercury, lead, arsenic, and copper, are not likely to be present. We may add that arsenic and mercury readily yield colloidal solutions under the same conditions as we have described for antimony.

The Detection and Determination in Other than Clear Aqueous Media.—It is obvious that under certain conditions the method described above cannot be directly applied, and that some method of separating the antimony must be employed. It occurred to us that a convenient method might be that of Reinsch, and then separating the deposited antimony from the copper. It is well known that, in the presence of permanganate, dilute alkaline solutions will dissolve antimony which has been deposited on copper, and that in this way the separation from arsenic or organic matter may be effected. We are not aware, however, that this method has ever been suggested for quantitative work. It seemed to us, however, that under certain conditions the process might give useful results. It was obvious that it would be necessary to employ an excess of permanganate, and that this excess would have to be destroyed prior to passing sulphuretted hydrogen through the final solution. The method which we adopted, and which we found to work fairly well, was as follows: The copper with the Sb deposit was warmed to about 70° C. for a few minutes with 5 c.c. of a 5 per cent. KOH solution, 10 c.c. of distilled water, and an excess of permanganate. As a rule, 1 c.c. of a permanganate solution, of which 1 c.c. was equal to 0·01 grm. Fe, was sufficient. The solution was then poured off the copper, the latter washed with a little distilled water, and the solution then boiled for a few minutes, and subsequently filtered from the precipitated MnO_2. The excess of permanganate in the filtrate was then destroyed by adding a 1 per cent. solution of tartaric acid to the boiling liquid until the latter was colourless. The solution was then made up to a known volume, an appropriate aliquot part taken and made up to 10 c.c., after adding the requisite amount of gum solution and hydrochloric acid, after which the liquid was saturated with H_2S, as described above.

The amounts of antimony recovered in this manner we found to vary roughly between 70 to 80 per cent. of the original amount present. A number of experiments were made by two different observers, the amount actually present being unknown to the individual making the experiment. The following figures are fairly representative of the kind of results obtained:

Observer A. Antimony in Mgrms.		Observer B. Antimony in Mgrms.	
Found.	Present.	Found.	Present.
1·54	2·0	0·20	0·25
0·26	0·35		

These results are, of course, not entirely satisfactory, but they show that, under certain conditions of working, an approximate idea of the amount of antimony present may be obtained. We are doubtful whether any other method existing would give closer results for such small quantities of antimony.

We think the observations we have made might well form the basis of further work on this interesting subject.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Estimation of Formic Acid in Foods. H. Fincke. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 1-15.)—The author has investigated Auerbach and Pluddemann's method of estimating formic acid by means of mercuric chloride (*Zeitsch. Untersuch. Nahr. Genussm.*, 1909, **17**, 425), and describes processes for the removal of substances which interfere with the accuracy of the method should they occur in the solution in which the formic acid is to be estimated. When a series of estimations has to be made, it will be found most convenient to use the method volumetrically, the formic acid solution being neutralised and heated for two hours in a boiling water-bath with a definite quantity of standard mercuric chloride solution, sodium acetate being also added; after cooling, the excess of mercuric chloride is titrated with potassium iodide solution. The mercuric chloride solution used should contain 58·87 grms. of the salt and 15 grms. of sodium chloride per litre. For occasional estimations the method may be applied gravimetrically, in order to avoid the preparation of standard solutions. In this case the formic acid solution is boiled under a reflux apparatus with sodium acetate and an excess of mercuric chloride, and the precipitated mercurous chloride is collected on a filter and weighed, after having been washed successively with warm water, alcohol, and ether, and dried at a temperature of 100° C.

In separating formic acid from foods, it is necessary to acidify the portion of the sample used with tartaric acid, and to submit it to steam distillation until at least 1,500 c.c. of distillate have been collected. Mineral acids must not be employed, as they may cause any sugars present to caramelise and yield volatile products which reduce mercuric chloride. If formaldehyde or acetaldehyde be present in the food, a flask containing water and calcium carbonate must be placed between the distillation flask and the condenser; the steam and vapours from the distillation are passed through this flask, which is separately heated, and the formic acid is retained by the calcium carbonate, whilst the aldehydes pass over into the distillate. At the end of the distillation the contents of the calcium carbonate flask are filtered, and the formic acid is estimated in the filtrate. When sulphurous acid is present, the distillate (or the filtrate from the calcium carbonate flask, should the food also contain aldehydes) is neutralised, evaporated to a volume of about 100 c.c., and treated with sodium hydroxide and hydrogen peroxide. After standing for four hours at the ordinary temperature, the excess of hydrogen peroxide is destroyed by the addition of freshly precipitated mercuric oxide, and, after the lapse of thirty minutes, the mixture is filtered and the formic acid estimated in the filtrate. Salicylic acid yields an insoluble compound with mercuric chloride in the presence of sodium acetate, but the formation of the compound is prevented by the presence of sodium chloride. Generally, the amount of sodium chloride in the mercuric chloride reagent mentioned above is sufficient for this purpose, but with excessive quantities of salicylic acid it is advisable to concentrate the distillate containing the formic acid, and to add 1 grm. of sodium chloride, 2 grms. of sodium acetate, and 0·5 grm. of mercuric chloride, for every 50 c.c. of the concentrated solution. W. P. S.

Comparison of Meat and Yeast Extracts of Known Origin. F. C. Cook. (*Brewer and Maltster*, 1910, No. 11; through *Wochensch. Brau.*, 1911, **28**, 28.)—The author has submitted beef and yeast extracts to a comparative analytical investigation in order to establish on what points characteristic differences exist. The beef extracts were prepared by grinding lean meat, and extracting with water until the extracts showed no biuret reaction. The united filtrates were evaporated on the water-bath, with periodical removal of coagulated matters. The yeast extracts were prepared by heating well-washed beer yeast, and evaporating in a vacuum pan to a syrupy consistence; such extracts have the appearance and odour of meat extracts, but are somewhat paler in colour. The analytical results are tabulated below. From these it will be observed that, with one exception, the beef extracts are poorer in ash than the yeast extracts. The chlorine is practically constant, and the same is true for the phosphoric acid in the original extracts, but calculated on the dry fat-free solids the yeast extracts are richer in phosphoric acid than the meat extracts. The meat extracts are richer in fat (ethereal extract) and in nitrogen. The chief characteristic difference is the absence of creatine and creatinine from the yeast extracts, and the presence of considerable quantities of these bases in meat extract. This difference affords the best means for distinguishing between the two. Hehner (ANALYST, 1907, **32**, 292) gives the proportion of creatine and creatinine in meat extracts as 10 to 11 per cent.; the author found 8 per cent. as a maximum. No sugar could be detected in any of the extracts. In the ethereal extracts no cholesterol could be detected, and phosphoric acid was absent. Lactic acid could not be detected in the meat extracts, but the acidity of meat extract depends not only on the lactic acid, but also on the phosphates and proteins.

J. F. B.

Estimation of Citric Acid in Milk. E. Desmoulière. (*Bull. d. Sciences Pharmacol.*, 1910, **17**, 588-594; through *Chem. Zentralb.*, 1910, **2**, 1951-1952.)—The method of Denigès for the detection of citric acid by means of mercuric nitrate and permanganate cannot be made to serve for its quantitative estimation. Methods depending on the extraction of the dry solids of milk with ether after addition of sulphuric acid give low results, unless special precautions are taken, since the ether extracts not only citric and acetic acids, but phosphoric acid, which even at slightly elevated temperatures attacks citric acid. The following method is recommended:

Two hundred c.c. of milk are boiled for a short time under a reflux condenser with 100 c.c. of 2 per cent. acetic acid. When cold, the mixture is filtered, and 150 c.c. of the filtrate are taken down to a pasty consistency on the water-bath after addition of 2 to 3 grms. of kieselguhr. To the cooled residue, not more than 3 c.c. of dilute (1 : 5) sulphuric acid is added, and the mixture allowed to stand for two or three hours, with occasional stirring. A further 3 grms. of kieselguhr are then stirred in, and the mixture repeatedly extracted with cold ether which has been previously saturated with water. The ethereal extracts, measuring about 1,000 c.c. in all, are united, and the ether is distilled off at as low a temperature as possible. The residue is taken up with water, and the solution made up to a known volume. In one portion the total acidity is determined, in another the volatile acids (acetic acid), and in a third the small quantity of phosphoric acid which may possibly be present, even when the directions given are followed closely. The citric acid is found by difference.

In treating human milk, or the milk of goats, sheep, and asses, the amount of dilute sulphuric acid used may with advantage be reduced to 2·5 or even to 2 c.c., but cow's milk may require nearly the full 3 c.c. The following average percentages of citric acid in milk of various origin are given: Cow's milk, 0·21; goat's milk, 0·14; sheep's milk, 0·11; ass's milk, 0·10; and human milk, 0·08. G. C. J.

Estimation of Nicotine in Concentrated Tobacco-Juice. J. Schröder.

(*Chem. Zeit.*, 1911, **35**, 30.)—The concentrated tobacco-juice, now so extensively used for sheep-washes, is usually bought without reference to the proportion of nicotine it contains. Even in cases where a specified proportion of the alkaloid is guaranteed, there is but little agreement between the results obtained by the different published methods, and the author therefore urges that the method used ought always to be stated. Various German wholesale importers were anxious that their samples should be tested by the following method, stated to be due to Ulex: Ten grms. of the tobacco extract are triturated with 25 grms. of calcium oxide and 75 grms. of calcium sulphate, and the mass allowed to stand for three hours over sulphuric acid. The powder is then treated with 3 litres of water containing 25 grms. of sodium hydroxide, 2 litres of the liquid separated, 500 c.c. thereof distilled, and the nicotine in the distillate titrated with $\frac{N}{10}$ hydrochloric acid, with litmus as indicator. Two samples tested by this technical method and by other standard methods gave the following percentages of nicotine:

	Guaranteed Percentage.	Kissling's Method.	Heut's Modification of Kissling's Method.	Keller's Method.	Technical Method.
1 ...	8–9	6·24–6·41	6·45–6·60	6·93–6·69	9·59–9·36
2 ...	12–13	8·64–8·70	8·90–9·20	11·90–12·27	13·45–13·55

Even the method of Toth (ANALYST, 1902, **27**, 12), which Porchet and Régis (ANALYST, 1909, **34**, 534) recommended as sufficiently accurate for technical purposes, may show deviations of as much as 20 per cent. upon the proportion of nicotine present, and in the author's opinion it would be advisable to appoint a committee to work out a reliable method of estimation for international use. C. A. M.

Note.—Evidently the technical method estimates other basic substances besides nicotine.

Estimation of Cocoanut Oil in Lard by Means of the "Ethyl Ester Value." J. Hanuš and J. Thian.

(*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 745-749.)—Results of an investigation are recorded which show that the "ethyl ester value" (see ANALYST, 1907, **32**, 89; 1908, **33**, 281) of a sample of lard affords reliable evidence as to the presence or absence of cocoanut oil in the sample, and that the value gives approximately the quantity of this oil which is present. W. P. S.

Fatty Oil and Wax obtained from Coffee Berries. H. Meyer and A. Eckert.

(*Monatsh. Chem.*, 1910, **31**, 1227-1251.)—When unroasted coffee berries are extracted with benzene, they yield a mixture consisting of a fatty oil and a wax, and these two constituents may be separated from one another by treatment with petroleum spirit, in which solvent the wax is practically insoluble. The authors find that the oil has a saponification value of from 160 to 182, and an iodine value varying from 90·1 to 91·2. The fatty acids liberated from the oil were found to consist of carnaubic acid, 10 per cent.; daturic acid, 1 to 1·5 per cent.; palmitic acid, 25 to 28 per cent.; capric acid, 0·5 per cent.; oleic acid, 2 per cent.; and linolic acid, 50 per cent. The wax, when freed from fatty oil and caffeine, is a resin-like substance which may be powdered; it is readily soluble in hot alcohol, benzene, chloroform, glacial acetic acid, and acetone, slightly soluble in ether, and almost insoluble in petroleum spirit. It does not crystallize from its solutions. An investigation of the character of the wax showed that it contains carnaubic acid combined with a resin-alcohol (tannol). W. P. S.

Moroccan Olive Oil. A. Sasserath. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1910, **20**, 749-750.)—It is very probable that the oil known as Moroccan olive oil is not a true olive oil, but is obtained from the argan-tree (*Arganum sideroxylon*). This tree somewhat resembles the olive-tree, but the branches are covered with thorns; it yields a fruit similar to olive fruit, from the kernels of which the oil is obtained. A specimen of argan oil, extracted by means of ether from kernels of argan fruit, gave the following results on analysis: Sp. gr. at 15° C., 0·9188; iodine value, 95·94; acid value, 0·18; saponification value, 192·12; Reichert-Meissl value, 1·8; insoluble fatty acids, 95·6 per cent. The oil is golden-yellow in colour, tastes like earthnut oil, and gives a red coloration when shaken with concentrated nitric acid; it does not yield a coloration with either Halphen's or Baudouin's reagents. W. P. S.

Reaction of Turpentine Oil, Wood Turpentine Oil, and Rosin Essence. C. Grimaldi. (*Chem. Zeit.*, 1911, **35**, 52.)—These products may be distinguished from one another by their different behaviour with mercuric acetate solution and by the characteristics of the resulting precipitates. Thus, the precipitate given by turpentine oil is completely soluble in nitric acid, whereas those given by wood turpentine oil or rosin essence ("turpentine essence") are only partially soluble, this difference being probably due to the different terpenes of which the two latter oils almost exclusively consist. The reagent is prepared by mixing 27·5 grms. of mercuric acetate with sufficient water to make up 110 c.c., and filtering the liquid. In applying the test, 1·5 c.c. of the distilled oil are shaken at frequent intervals for some hours in a stoppered 200 c.c. flask with 100 c.c. of the reagent. After the flask has stood for forty-eight hours, 60 c.c. of nitric acid (3 parts by volume of acid of 1·40 sp. gr. to 1 part of water) are introduced, the shaking continued for some time, and the flask again allowed to stand. In the case of pure turpentine oil a clear solution is obtained, whilst wood turpentine oil and rosin essence give turbid liquids from which flocculent precipitates containing mercury slowly deposit. In doubtful cases the test is repeated upon larger quantities. The test may also be applied to mixtures of turpentine oil containing, *e.g.*, 25 per cent. of the other products. Thus, an unmistakable reaction was obtained by treating 8 c.c. of such a mixture with 400 c.c. of the mercuric reagent, and subsequently adding 320 c.c. of the dilute nitric acid (*cf.* ANALYST, 1910, **35**, 412). C. A. M.

Some Indian Oils and Fats. A. Kesava-Menon. (*J. Soc. Chem. Ind.*, 1910, **29**, 1428-1431.)—The author has examined the following authentic samples of Indian oils and fats:

GHI, the melted and clarified butter-fat, freed from water, of the milk of cows, buffaloes, etc. Ghi is much adulterated with the common vegetable oils. The following figures were observed (*cf.* Bolton and Revis, ANALYST, 1910, **35**, 343):

	Cow Ghi (from Milk of Two Cows).	Buffalo Ghi.

Note.—The buffalo ghi differs so much from the figures given by previous observers for the fat of buffalo milk that it is probable that, if not an adulterated sample, it is quite abnormal.

BASSIA OILS.—Oils from five trees of this family have been examined, and the following results obtained. The fats from these sources are sold under the names of illupi, ellupai, mowa, mowrah, etc. Arachidic acid is absent. The oil was extracted with petroleum ether, as the ether extract contains much resinous matter.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Estimation of the Enzymatic Activity of Nuclease. G. Pighini. (*Zeitsch. physiol. Chem.*, 1910, **70**, 85-93.)—The method proposed depends on the fact that the nuclease contained in blood-serum acts on nucleic acid, with the result that the optical rotation of the latter substance is gradually destroyed. Two c.c. of the serum are added to a quantity of nucleic acid solution sufficient to fill the polarimeter tube (say 22 c.c.), and the optical rotation of the mixture is observed; the mixture is then maintained at a temperature of 37° C., and the observations are repeated at intervals of an hour or so. For comparative estimations the proportion of the serum to the nucleic acid must be the same in each test, and it will be found most convenient to heat the mixtures in the polarimeter tubes, a number of the latter being employed. The nucleic acid solution is prepared by dissolving 1·60 grms. of nucleic acid in 100 c.c. of a 0·85 per cent. sodium chloride solution and adding 12 drops of ammonia. Results of experiments recorded show that the action of the nuclease is continuous, and that it proceeds most rapidly during the first hour; the rotation of the nucleic acid is destroyed completely in from twelve to twenty-four hours. After being heated to a temperature of 65° C., nuclease no longer possesses enzymatic properties.

W. P. S.

Method for Ascertaining whether a Liquid Contains One or More Enzymes. Achalme and Bresson. (*Comptes rend.*, 1910, **151**, 1369-1372.)—When a fermentative extract is obtained which acts on several substances, it is difficult sometimes to determine whether its multiple activity is to be ascribed to one and the same enzyme or to the presence of a plurality of enzymes in the same extract. The authors have devised a method for solving this question, which depends on the following hypothesis: If a limited quantity of a single enzyme be caused to act simultaneously on two different substrata, its action will be divided between the two. But if the liquid contain two enzymes, each will act on its own specific substratum independently of the other. Accordingly, the mode of procedure is as follows: Under identical conditions of temperature, concentration, acidity, or neutrality, a sufficiently small quantity of the active liquid to permit of the action being followed easily from hour to hour is caused to react upon solutions of each substance separately, and on a mixture of the two. If the action on the mixed substances represents approximately the sum of the action on the two separately, it is to be inferred that two distinct enzymes are concerned. If, on the other hand, the action on the mixed substances does not appreciably exceed that on the separate substances, only one enzyme is at work. Instead of estimating the quantity of substance modified in a given time, it may be convenient to determine the time necessary for complete hydrolysis. In the case of two enzymes this time will be practically the same for all three solutions, whereas in the case of a single enzyme the time is much longer in the liquid containing two substances to be converted. The authors have proved their hypothesis in the cases of emulsin and invertase.

J. F. B.

Method of Destroying Organic Matters in Testing for Mineral Poisons. E. Jungfleisch. (*Comptes rend.*, 1911, **152**, 199-200.)—The following process is recommended for completely destroying organic matters previous to testing for the presence of mineral poisons in animal organs, etc. About 300 grms. of the material are heated in a flask with about 300 c.c. of concentrated sulphuric acid while a current of nitrous vapours is passed through the mixture. The nitrous vapours are most conveniently obtained by passing a current of sulphur dioxide (from a siphon containing liquid sulphur dioxide) through a wash-bottle containing about 500 c.c. of concentrated nitric acid; a tube leading from the wash-bottle conducts the vapours to the bottom of the digestion flask. The nitrous vapours act catalytically in the destruction of the carbonaceous matters, and a perfectly colourless solution is obtained after about four hours' heating. The quantity of nitric acid mentioned is sufficient for the destruction of four or five quantities of 300 grms. of organic substance. W. P. S.

Physical Constants and Analyses of Certain Commercial Peptones. G. Pépin. (*Bull. d. Sciences Pharmacol.*, 1910, **17**, 594-599; through *Chem. Zentralbl.*, 1910, **2**, 1932-1933.)—The eleven preparations experimented with are classified in three groups according to their method of manufacture—(1) by the action of trypsin on flesh or fibrin, or by the action of pepsin on (2) flesh or fibrin or on (3) gelatine. The percentage of nitrogen when calculated to an ash-free basis lay between 12·6 and 17·6. The ratio of amino-nitrogen to total nitrogen varied between 1 : 4 and 1 : 36. The amino-nitrogen was much higher in the tryptic peptones than in the peptic peptones; and, of the latter, those derived from gelatine were poorer in amino-nitrogen than those derived from flesh or fibrin. The ash content was highest in the peptic peptones from flesh, in some as high as 20 per cent., and lowest in the tryptic products. The ash of the peptic products consists mainly of the chlorides of sodium and calcium, whilst carbonates are present in large amount in that of the tryptic peptones. The peptic peptones rarely contain phosphorus, magnesium, or iron, and then only in traces. The large quantities of calcium found in some of them was doubtless due to lime or chalk used for purposes of neutralisation.

For the purpose of determining the physical constants, solutions were made of such strength that each contained precisely 1 per cent. of nitrogen. The tryptic peptones had the greatest effect in depressing the freezing-point, the peptic peptones from gelatine having the least. The greatest optical activity is shown by the peptic peptones from gelatine, the least by the tryptic products. The electrical conductivity of the peptic products derived from flesh and fibrin was greater than that of the other preparations. G. C. J.

Microchemical Detection of Protein. T. Bokorny. (*Chem Zeit.*, 1911, **35**, 69-70.)—The author has based a microchemical method for the detection of protein on the coagulation phenomena and the formation of "proteosomes," observed when the subepidermal cells of certain plants of the order Crassulaceæ are treated with a solution of caffeine. The formation of these proteosomes is observed in the plasma of the cells in superficial sections of the leaf, generally in the form of closely crowded bodies of angular shape, or, if not so numerous, of a flattened, rounded shape. After contraction of the vacuole wall by the action of 10 per cent. nitric acid, or better of the caffeine solution itself, they are at liberty to assume a spherical form. The proteosomes are very lustrous and perfectly clear; their formation takes place distinctly in the plasma, and in many cases in the cell sap itself. Certain observers have mistaken them for a precipitate of caffeine tannate. The coagulation of the proteosomes may conveniently be studied with *Spirogyra*. The objects are treated with a 0·5 per cent. solution of caffeine, and the tube is suspended for a few minutes in a water-bath at 60° C. The coagulated proteosomes then appear very cloudy; on treatment with absolute alcohol they remain intact in the cells. The coagulation of the proteosomes prior to treatment with alcohol is recommended, because freshly-formed proteosomes are dehydrated so suddenly by alcohol that certain observers have stated that they are soluble. The proteosomes also undergo gradual coagulation on keeping for four days at the ordinary temperature in a saturated solution of caffeine. They may also be coagulated by chemical reagents—*e.g.*, a solution containing 8 per cent. of acetic acid, 4 per cent. of sodium chloride, and 0·5 per cent. of caffeine; the reagent acts very rapidly, the proteosomes lose their lustre and become opaque. J. F. B.

ORGANIC ANALYSIS.

Use of Calcium Carbide for Determining Moisture. I. Masson. (*Chem. News*, 1911, **103**, 37-38.)—The use of calcium carbide affords a reliable means for determining water in many substances, and especially in organic materials, and it is chiefly of value in those cases in which the material cannot be heated without giving off water of decomposition, or evolving vapours other than water-vapour, or without gaining weight by oxidation.

Calcium carbide in these cases, on being mixed with the substance, gives off acetylene readily, which may be measured. The method of Danne (1900) was to treat the powdered material in a test-tube with a layer of sand and an upper layer of carbide, and to heat the material, when the water-vapours acted on the carbide, with the evolution of acetylene, which was collected, the apparatus being standardised with known amounts of water. Dupré (ANALYST, 1906, **31**, 213) proposed a similar method for determining moisture in cordite and other explosives. It has been shown, however, that it is unnecessary to heat materials in this way, simple intimate admixture of the powdered carbide (in large excess) and the material being sufficient to bring about complete reaction. Such a method is now employed in Australia in estimating the moisture in sheep's wool (O. Masson, *Proc. Soc. Chem. Ind.* [Victoria], 1909). A known weight of wool clippings is introduced into a metal globe, which has a screw top and a tray in its interior, below the tray being the powdered carbide in considerable excess. A gas exit-tube is also provided. On shaking, the carbide falls on to the wool, and the reaction proceeds rapidly. The increased pressure obtained, the volume being kept constant, is observed by means of a mercury manometer suitably graduated.

The carbide method has been used by Roberts and Fraser (ANALYST, 1910, **35**, 217) in the case of hydrous petroleum products, these being rendered fluid, if necessary, by the addition of dry paraffin oil. The acetylene is measured by the quantity of brine displaced from a bottle, the necessary temperature correction being made.

With regard to the determination, by the carbide method, of water of crystallisation, the author finds (*J. Chem. Soc.*, 1910, **97**, 351) that hydrated salts may be divided into four classes, containing (1) those substances, like $Na_2CO_3.10H_2O$, which react completely; (2) those, like $BaCl_2.2H_2O$, which react only on heating; (3) substances which only react partially either in the cold or on heating ($CuSO_4.5H_2O$); (4) substances which are not affected by carbide even at 170° C.

The method used for wool is likely to be found useful in the case of materials like cotton, paper, fabrics, wood-pulp, tobacco, and flour. Modifications of the carbide method may also be employed for the examination of soils, minerals, guano, and coal. Substances like butter, cocoa, etc., may be mixed with a fat solvent like benzene to facilitate the action of the carbide. In all cases standardisation with known quantities of water is necessary; the yield of acetylene is found to be practically constant at 10·5 c.c., at 0° C. and 760 mm., for every 18·0 mgrms. of water (theory = 11·2 c.c.). A. R. T.

Direct Estimation of Caoutchouc in Vulcanised Rubber Articles. G. Hübener. (*Chem. Zeit.*, 1911, **35**, 113-115.)—Continuing the development of his bromination method (ANALYST, 1909, **34**, 170, 365; 1910, **35**, 266), the author has investigated further cases of admixtures which may possibly influence the validity of the results. In the present paper the effect of the presence of bituminous bodies, asphalt and "mineral rubber," has been dealt with, and it has been found that such bodies, under the prescribed conditions of bromination, yield insoluble bromo derivatives which vitiate the results by increasing the apparent percentage of caoutchouc. In presence of such admixtures a modification of the original method is necessary, which consists in eliminating the bituminous bromo derivatives by extraction, after bromination and before the titration of the combined bromine. The procedure is as follows: 0·1 grm. of the sample is brominated in the prescribed manner, and the mixed bromides are collected on a filter and washed with hot water. The funnel is then removed to another flask, and the precipitate is dehydrated by washing with absolute alcohol. It is then transferred to a beaker, in which it is digested at a moderate temperature with a mixture of equal parts of carbon tetrachloride and alcohol. The extract is decanted off, and the digestion is repeated until the liquid remains colourless. The precipitate is then filtered off, and the carbon tetrachloride is eliminated by washing with absolute alcohol. The filter and precipitate are placed in an Erlenmeyer flask with 20 c.c. of $\frac{N}{10}$ silver nitrate and 25 c.c. of strong nitric acid; the liquid is heated at first gently, until the violent reaction due to the presence of the alcohol has subsided, and is finally evaporated to a volume of about 15 c.c. The excess of silver is then titrated in the usual manner.

The author has proved, by the analysis of mixtures of known composition, that the bromides of bituminous matters are satisfactorily eliminated by the above treatment, whilst the caoutchouc bromide is quite unaffected. Further experiments have shown that when rubbers other than Para are present, containing resins soluble in acetone, the bromination method shows with satisfactory accuracy the percentage of ue caoutchouc, independent of the resins of the crude rubber. J. F. B.

New Test for Cupreïne. G. Denigès. (*Comptes rend.*, 1910, **151**, 1354-1355.)—Cupreïne occupies a position among the quino-cinchonine alkaloids analogous to that of morphine among the morpholic group—*i.e.*, it possesses a phenolic function.

It therefore yields a characteristic colour reaction with the same reagents as have been proposed by the author as a test for morphine. Ten c.c. of a 0·2 per cent. solution of cupreïne sulphate are placed in a test-tube, 1 c.c. of ammonia, and 1 c.c. of hydrogen peroxide (of a concentration not exceeding 1 volume), are added. After shaking, 0·1 c.c. of a 3 to 4 per cent. solution of copper sulphate is introduced. A fine blue coloration rapidly develops in the liquid, which gradually becomes darker and cloudy, holding in suspension greenish-blue corpuscles which ultimately settle to the bottom. The liquid becomes clear, with a fine emerald-green coloration, if it be mixed with an equal volume of alcohol, or if it be acidified with acetic or hydrochloric acid. The addition of a large excess of the latter acid or of sulphuric acid turns the colour to yellowish-red. The green solution shows an absorption band in the neighbourhood of the infra-red. The test is very delicate, and is perceptible with a solution containing 0·02 to 0·03 grm. of cupreïne sulphate per litre, if it be performed against a blank; no precipitate, however, is formed at that dilution. The test may be applied to the alkaloid *in situ*—*e.g.*, in the tissues of the plant—by moistening with a drop of a mixture of 1 c.c. of a 3 to 4 per cent. solution of copper sulphate, 5 c.c. of ammonia, and 10 c.c. of water, then touching the objects with a drop of hydrogen peroxide of not more than one-half volume strength. J. F. B.

Estimation of Formaldehyde. F. Herrmann. (*Chem. Zeit.*, 1911, **35**, 25-26.)—The method of estimating formaldehyde in the form of hexamethylenetetramine may be rendered accurate by causing the ammonia to be liberated from ammonium chloride within the liquid itself. Under these conditions the heat of the reaction causes the nascent ammonia to react instantaneously and quantitatively with the formaldehyde. From 4 to 4½ grms. of the formaldehyde solution are shaken with 3 grms. of pure powdered ammonium chloride in a stoppered flask, into which is subsequently introduced, as rapidly as possible and with constant shaking, 25 c.c. of 2N-sodium hydroxide solution. After the contents of the flask have cooled down to the ordinary temperature, they are diluted with 50 c.c. of water, and titrated with N-sulphuric acid, with methyl orange as indicator. The number of c.c. of N-sodium hydroxide solution consumed in the formation of the hexamethylenetetramine, multiplied by the factor 0·06 gives the amount of formaldehyde (in grms.) in the solution under examination. A correction must be applied for the amount of free acid usually present in commercial formaldehyde solutions. The results thus obtained in the duplicate estimation quoted were closely concordant.

C. A. M.

Separation of Liquid from Solid Fatty Acids—II. P. Falciola. (*Gazz. Chim. Ital.*, 1910, **40**, 425-435.)—Further experiments upon the method of separating liquid from solid fatty acids in natural fats by the method already described (ANALYST, 1911, 23) have shown that the solubility of ammonium stearate and palmitate in absolute alcohol is increased by the presence of ammonium oleate. The following results illustrate the degree of accuracy obtainable in the separation of these fatty acids from a larger quantity of oleic acid: A mixture of 5 grms. of oleic acid, 2·5 grms. of palmitic acid, and 2·5 grms. of stearic acid, was treated with the ammoniacal alcohol at 0° C., as previously described, and the separated oleate was found to contain 0·20 grm. of ammonium palmitate and 0·04 grm. of ammonium stearate. In the case of a mixture of the fatty acids melting at 48·2° C., and having an iodine value of 30·1, the solid fatty acids separated by this method melted at 54·5° to 56° C., and had an iodine value of 6·6 to 8. The method failed to give good results with certain oils, although in the case of sesame oil it effected a separation of the fatty acids into solid acids that did not give Baudouin's reaction, and liquid fatty acids which gave a pronounced reaction. Olive oil, however, left no insoluble ammonium salts upon the filter. Pure ammonium salts of other fatty acids were prepared, and their solubility in different solvents ascertained. *Ammonium linolate* is a soap-like salt which begins to melt at 57° to 58° C. It is readily soluble in methyl alcohol, and dissolves to the extent of 35 per cent. in ammoniacal absolute alcohol at 0° C. It is sparingly soluble in ether, but is soluble in hot benzene and acetone, and in cold carbon tetrachloride and chloroform. *Ammonium erucate* (melting-point 70° to 77° C.) is soluble in methyl and ethyl alcohols, sparingly soluble in ether, benzene, and chloroform, and nearly insoluble in cold acetone and carbon tetrachloride. *Ammonium laurate* (melting-point about 75° C.) is insoluble in cold water. Absolute alcohol at 7° C. dissolves about 4·8 per cent., whilst ammoniacal alcohol at the same temperature dissolves 3·5 per cent. It is soluble in methyl alcohol and in hot benzene, from which it crystallises on cooling, but is only sparingly soluble in ether and acetone. *Ammonium myristate* (melts imperfectly at 75° C.) is sparingly soluble in cold water, cold acetone and methyl alcohol, but is somewhat more soluble in alcohol. It is nearly insoluble in cold ether and carbon tetrachloride. *Ammonium caprylate* (melting-point 70° to 85° C.) forms a turbid solution in water. It is soluble in methyl and ethyl alcohol and in chloroform, and sparingly soluble in ether, carbon bisulphide, and chloroform. It may be obtained in crystalline form by cooling its solution in hot benzene. *Ammonium crotonate* forms white crystals melting at 105° to 115° C. It is readily soluble in cold water, methyl alcohol, and alcohol, and sparingly soluble in ether, carbon tetrachloride, benzene, and acetone. *Ammonium butyrate* is a deliquescent salt melting between 70° and 85° C. It is very soluble in alcohol, methyl alcohol, and chloroform, but is nearly insoluble in ether, acetone, or benzene. C. A. M.

Estimation of the Total Fatty Acids in Fat, Oils, and Soaps. P. Simmich. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 38-44.)—The author considers that the only accurate method of estimating the total fatty acids in oils, etc., consists in separating the fatty acids (liberated in the usual way from the saponified oil) by means of a mixture of ether and petroleum spirit, evaporating the solvent in a current of carbon dioxide, and exactly neutralising the residue of fatty acids by the addition of $\frac{N}{2}$ potassium hydroxide solution (alcoholic). The resulting soap is then dried, firstly in an atmosphere of hydrogen and then under reduced pressure at a temperature of 100° C., and weighed. The quantity of fatty acids is obtained by subtracting from the weight of the soap 0·01907 grm. for every c.c. of $\frac{N}{2}$ potassium hydroxide solution required for the neutralisation. Incorrect results are obtained if the fatty acids be dried in their free state before being weighed. W. P. S.

Characteristics of Neutralised Olive-Residuum Oils. L. Archbutt. (*J. Soc. Chem. Ind.*, 1911, **30**, 5-6.)—During the last few years products derived from the residual marc and the stones of the olives left after expression of ordinary olive oil have been sold for lubricating purposes under the name of "neutral" or "saponified" oils. The free acids which are originally present in these are removed by treatment with alkali and washing with water, so that a product with a guaranteed maximum acidity not exceeding 1 to 4 per cent. is obtained. These oils are usually turbid and often of a dark colour, and as a rule they contain moisture due to imperfect drying after the final washing. They frequently contain solid fat in sufficient quantity to cause them to give abnormally high results in Redwood's viscometer. They are also peculiar in their high proportion of unsaponifiable matter, which may exceed 3 per cent., and cause them to yield a precipitate in Bellier's test for arachis oil. Hence Renard's process should also be used before drawing a conclusion as to the presence of arachis oil. These oils also give an abnormal coloration (an immediate brown or greenish-brown emulsion) when shaken with an equal volume of nitric acid of sp. gr. 1·375, although the colour is quite distinct from that obtained with cottonseed oil. With Halphen's reagent no coloration is obtained. They oxidise more readily than neat's-foot oil or lard, but, in the author's opinion, are quite suitable for lubrication when used in admixture with a mineral lubricating oil. The following results were obtained with commercial samples:

Sp. gr. at 15·5° C. ...	0·9167	0·9165	0·9175	0·9186	0·9169	0·9175	0·9169

* Normal olive oil = about 435 to 446 seconds.

C. A. M.

Analysis of Gelatins. J. Herold jun. (*Chem. Zeit.*, 1911, **35**, 93-94.)—The difference between gelatin and glue may be said to lie in the relative proportions of glutin and glutose in each. Glutin is the gelatinising constituent of gelatin, and the best gelatin is that which contains the highest proportion of it. On the other hand, the presence of glutin in glue is actually a drawback to its adhesive power, and a high proportion of non-gelatinising glutose is the main desideratum. Glutose may be prepared from glutin by the regulated action of alkalies, or merely by prolonged heating with water. The best method of preparing glutose is by heating a solution of gelatin with strong ammonia in a sealed tube for two hours at 100° C., and removing the ammonia, after filtration, by evaporation. The author has previously described a method for the determination of the melting-points of gelatin jellies (ANALYST, 1910, **35**, 174). By mixing glutose and gelatin, he has observed that the melting-point of a 20 per cent. jelly is lowered in proportion to the amount of glutose present. For reasons explained (*loc. cit.*), the absolute melting-point of the jelly has no analytical significance, but the differences between the melting-points of jellies from the same gelatin at different concentrations may form the basis of a method of valuation. Preliminary observations with the purest form of gelatin procurable showed that the difference between the melting-points of 20 and 10 per cent. jellies was 1·2° C. This sample of gelatin contained 17 per cent. of moisture and 1 per cent. of ash; hence glutin = 82 per cent. by difference. If now the difference between the melting-points of 20 and 10 per cent. jellies of any other sample of gelatin be found to be $a°$ C., the percentage of glutin in the latter sample may be calculated by the expression, $\frac{a}{1{\cdot}2} = \frac{x}{82}$. The percentage of glutose will then be 100 – (water + ash + glutin).

This method gives results in complete accordance with the commercial valuation of the gelatin, but it requires the accurate determination of the melting-points to within 0·1° C., under strictly standard conditions. The author describes an apparatus for this purpose, consisting of a glass tube surrounding the lower part of the thermometer, leaving an annular space of 1 mm. The tube is closed at the bottom by a plug and a globule of mercury. When the jelly has been set around the thermometer (*e.g.*, at 19° C. for half an hour), the plug and mercury are removed; the temperature is slowly raised in a small glass air-bath surrounded by water at 5° C., and when the tube begins to slide down the thermometer the melting-point is observed. Since the difference in melting-point is strictly proportional to the concentration of the jelly, determinations may be made with 30 and 20 per cent. jellies if the sample be a very weak one. J. F. B.

Quantitative Estimation of Active Hydrogen in Organic Compounds by Means of Magnesium-Methyl Iodide. T. Zerewitinoff. (*Ber.*, 1910, **43**, 3590-3595.)—In previous papers (ANALYST, 1907, **32**, 299; 1908, **33**, 366) the author has described his gasometric method for the estimation of groups containing active hydrogen—*e.g.*, OH, SH, NH, and NH_2 groups—in organic compounds. This method has proved of service, even in the case of such complicated compounds as sugar and flavone, and sufficiently accurate results are generally obtained. In the present paper the author deals with the alkaloids—derivatives of tertiary amines. These react with magnesium-methyl iodide in pyridine solution if they contain hydroxyl groups, and the results at the ordinary temperature are practically identical with those obtained on heating to 85° C.; they therefore contain no amino group. The author has also studied certain tautomeric compounds, containing the group $CO.CH_2$, which is capable of assuming the form C(OH) : CH. These yield results somewhat below the theoretical value at the ordinary temperature, but give accurate values at 100° C. Similarly, primary and secondary nitro compounds of the aliphatic series are capable of assuming a pseudo-acid form, in which they form salts in virtue of the labile group $\mathrm{R.CH : N}\genfrac{}{}{0pt}{}{/\!\!/\mathrm{O}}{\backslash\mathrm{OH}}$, which reacts with magnesium-methyl iodide. These also give results somewhat lower than the theoretical at the ordinary temperature, but at 100° C. the values more nearly approach the theoretical, the conversion into the isomerides, however, never being quite complete. The author has investigated the applicability of other solvents than pyridine; these must be inactive towards the magnesium-methyl iodide, and preference is given to those of high boiling-point, for work at higher temperatures, and those having such a small vapour pressure that a correction is unnecessary. Suitable solvents are: Amyl ether (already proposed by Sudborough and Hibbert), anisol, and the hydrocarbons xylene and mesitylene. The three last solvents were distilled from sodium; the magnesium-methyl iodide was always prepared in amyl ether solution. These all gave satisfactory results with hydroxyl and amino groups. As a rule the amino groups only react with one hydrogen atom at the ordinary temperature, but on heating the mixture up to 85° C. in five minutes, the second hydrogen atom reacts quantitatively. J. F. B.

Estimation of Iodine in Organic Compounds and its Separation from other Halogens. A. F. Seeker and W. E. Mathewson. (*U.S. Dept. of Agric., Bureau of Chem.*, Circular No. 65, 1910, 1-5.)—The following process was found to yield reliable results when applied to the estimation of iodine in such compounds as erythrosine, iodoform, and phenyl iodide; it depends on the fact that the organic matter is completely oxidised when the substance is treated with potassium permanganate and nitric acid, the chlorine and bromine being converted into volatile products, whilst the iodine remains as iodic acid. A weighed quantity of about 0·4 grm. of the erythrosine is placed in a porcelain basin and dissolved in 5 c.c. of a 10 per cent. sodium hydroxide solution; 35 c.c. of a 7 per cent. potassium permanganate solution are then added, and, when the basin has been covered, 10 c.c. of nitric acid are introduced. The mixture is heated on a water-bath, the cover is removed when effervescence has ceased, and the solution is evaporated to dryness. A further quantity of 5 c.c. of concentrated nitric acid and 5 c.c. of the permanganate solution are added to the residue, and the evaporation is repeated. The residue is now taken up with 50 c.c. of water and 5 c.c. of nitric acid, 40 c.c. of a saturated sulphur dioxide solution are added, and, when the manganese hydroxide has dissolved, the iodine is precipitated by the addition of silver nitrate. After the mixture has been boiled to remove the excess of sulphur dioxide, the silver iodide is collected and weighed. In the case of volatile compounds like phenyl iodide the oxidation should be carried out in a flask attached to a reflux condenser. The Carius method was found to yield erratic and unreliable results when employed for the estimation of iodine in erythrosine. W. P. S.

Methyl Red as an Indicator compared with Methyl Orange. H. T. Tizard. (*J. Chem. Soc.*, 1910, **97**, 2477-2490.)—The methyl red of Rupp and Loose (*Ber.*, 1908, **41**, 3905), which has the constitution $NMe_2.C_6H_4.N:N.C_6H_4.CO_2H(o)$, is greatly superior to methyl orange as an indicator. The visible change, red to yellow, takes place between $10^{-5\cdot7}$ and 10^{-7}—that is, between H· concentrations $\frac{N}{200,000}$ and $\frac{N}{10,000,000}$. Not only, therefore, is the end-point very much sharper than when methyl orange is used, but the neutral point so found is very much nearer the theoretical neutral point. Methyl red is especially valuable for the exact titration of moderately weak bases, such as ammonia, by strong acids.

The following method of preparation is given: Five grms. of anthranilic acid are dissolved in 150 c.c. of water and 15 c.c. of concentrated hydrochloric acid. To this 2·5 grms. of solid sodium nitrite are added, and the solution kept for half an hour. It is then poured into a solution of 4·65 grms. dimethyl-aniline in a mixture of 5 c.c. of concentrated hydrochloric acid and 50 c.c. of water. Fifty grms. of sodium acetate are added, and the mixture is warmed to 40° C., when the red product begins to separate at once, though the reaction is not complete for some three hours. The substance is then collected, and can be recrystallised from glacial acetic acid. The yield is almost quantitative. Methyl red is very insoluble in water. Its saturated solution at ordinary temperature is only about $\frac{N}{100,000}$. It is, however, easily soluble both in acids and in alkalis. G. C. J.

Analytical Constants of Shellac, Lac-Resin, and Lac-Wax. Puran Singh. (*J. Soc. Chem. Ind.*, 1910, **29**, 1435-1436.)—The following constants were determined by the author on samples of pure shellac (free from orpiment and colophony) prepared by himself from three varieties of crude lac obtained from the Forest Department, Central Provinces, India. For comparison, the figures yielded by a factory sample are included, and this sample contained about 0·3 per cent. of "yellow arsenic" (orpiment). The constants of lac-wax and lac-resin were also determined:

Variety.	Moisture at 100° C.	Matter insoluble in Hot Alcohol.	Acid Number (A).	Saponification Number (B).	Ester Number (B-A).	Iodine Absorption (Hübl). 18 hours.	Endemann Number.
	Per Cent.	Per Cent.				Per Cent.	
Shellac from Kusum lac (from *Schleichera trijuga*)	2·7	0·7	61·1	201·0	139·9	9·6	8·4
Shellac from Palas lac (from *Butea frondosa*)	3·8	0·8	60·8	202·4	141·6	9·3	8·0
Shellac from block lac (*i.e.*, lac compressed during transit)	3·9	1·1	63·1	201·6	138·5	8·2	9·2
Mirzapur factory shellac ...	2·0	0·6	64·4	203·6	139·2	8·6	7·4
Lac-wax (melting-point 58°-59° C.)	—	—	21·1-24·3	79·2-85·0	57·1-60·7	8·8	—
Lac-resin (desiccator dry)	—	—	52·1-59·2	193·5-198·4	139·2-141·4	6·8-7·3	7·3-8·1
Lac-resin (melted)... ...	—	—	54·9	190·0	135·1	5·9	—

The three shellacs were prepared by extraction with wood-spirit, and not by repeated melting, so that they were free from the injurious effects of overheating. The "Endemann number," which is nearly constant for the best qualities of shellac at about 7 to 8 per cent., was proposed by Endemann in 1907 (*J. Franklin Inst.*, 1907, **164**, 285; 1908, **165**, 217; *cf.* ANALYST, 1907, **32**, 425) as a method for shellac examination, and consists in dehydrating 1·5 to 2 grms. of the sample by heating with 3 to 4 grms. of sand and strong hydrochloric acid. The author modifies the method by first heating the shellac for two hours at 100° to 105° C. with calcined precipitated silica, and then adding hydrochloric acid. The mixture is evaporated until thoroughly dry, and then extracted completely with alcohol. The proportion of non-condensible resin and fatty acids thus obtained is stated not to exceed 8 per cent. in genuine samples. A. R. T.

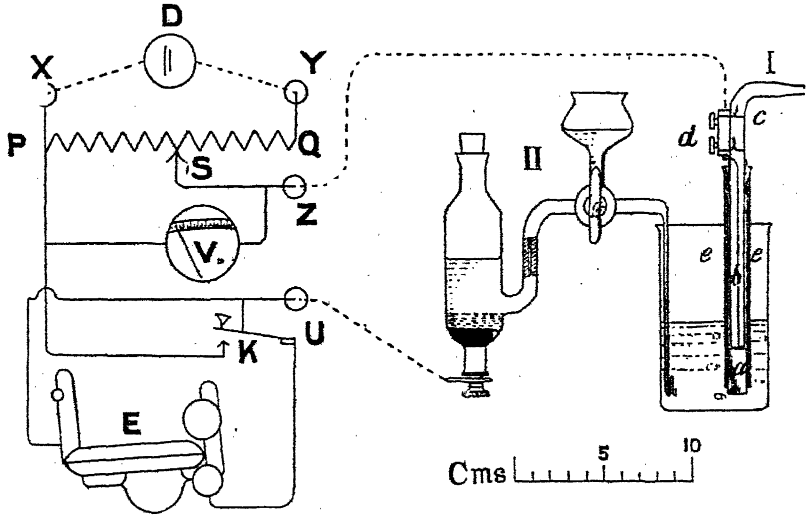
Note on the Composition of Soot. H. W. Harvey. (*J. Agric. Sci.*, 1910, **3**, 398-399.)—Samples of soot when analysed by Kjeldahl's method show from 0·5 to 11 per cent. of nitrogen, which is present mainly as ammonium chloride, though usually stated to exist as ammonium sulphate. The following table shows the relation between the nitrogen content and the weight per bushel:

Type of Soot.	Percentage of Nitrogen.	Pounds of Soot per Bushel loosely packed.	Pounds of Nitrogen per Bushel of Soot.
From kitchen chimney	11·0	9	1·0
" " "	5·4	23	1·2
From coal and wood fire	4·5	26	1·2
From dwelling houses (mixed)	3·6	29	1·0
" " " "	2·9	28	0·8
From 40-foot boiler shaft	0·5	47	0·23

The author concludes that soot should be bought by volume and not by weight, thus insuring an approximately constant quantity of nitrogen per bushel. Farmers generally are of opinion that a light soot is the best, and the figures quoted confirm this. There is some loss of nitrogen when soot is allowed to stand in a loose heap, as in the case of the mixed sample. H. F. E. H.

Determination of Sucrose in Beet Sugar Factory Products by Clerget's Process, using Invertase as Hydrolyst. J. P. Ogilvie. (*J. Soc. Chem. Ind.*, 1911, **30**, 62-64.)—In preparing the sugar solution for inversion by invertase, it is necessary to avoid the presence of acids, alkalis, or other reagents capable of inhibiting the action of the enzyme. In the case of highly-coloured sugar-factory products some special process of clarification must therefore be employed. The author describes the following method: Four times the normal weight of the sample (*e.g.*, molasses) are placed in a 200 c.c. flask, defecated with the minimum quantity of basic lead acetate and a little alumina cream, diluted to the mark, shaken and filtered. One hundred c.c. of the filtrate are treated with a current of sulphur dioxide gas until a faint odour persists. The liquid is transferred to a 200 c.c. flask, diluted to the mark, shaken and treated with a little dry chalk and kieselguhr before filtration. In this way a normal clarified solution is obtained which is neutral and free from lead. For the inversion, 50 c.c. are placed in a 100 c.c. flask and heated in a thermostat from 50° to 55° C.; 0·5 grm. of washed brewery yeast are added and 2 drops of acetic acid. The liquid is digested at the above temperature for four and a half to five hours, diluted to 100 c.c. with the addition of alumina and kieselguhr, filtered, and polarised. With pure sugar the Clerget constant obtained in this way was 131·6, as against 132 for the acid method of inversion. With beet molasses, however, the invertase method gave appreciably higher results than the acid method. This discrepancy was found to be due to observing the direct polarisation in alkaline solution and the polarisation after inversion in acid solution, when the ordinary acid method of inversion is used. The author has proved that if both polarisations be observed in acid solution, the acid method yields practically the same results as the invertase method. The most convenient modification of the acid method is that described by Pellet: The molasses solution is defecated by basic lead acetate and filtered. A portion of the filtrate is treated with a slight excess of sulphurous acid solution, to precipitate the lead, and filtered. The acid filtrate thus obtained is used for the direct polarisation and, with the addition of hydrochloric acid, for the inversion. J. F. B.

Electrometric Method for the Estimation of the Acidity of Tan Liquors. H. J. Sand and D. J. Law. (*J. Soc. Chem. Ind.*, 1911, **30**, 3-5.)—Owing to the difficulty of finding indicators that will give a sharp change of colour in dark tan liquors, the authors have devised an electrometric method of estimating the original hydrion concentration of the liquid, and the amount of alkali which must be added until there is reached a hydrion concentration corresponding to the change of colour with some indicator, such as phenolphthaleïn. In their opinion there is a relationship between the former and the swelling power of the liquid, and between the latter and its lime-solvent capacity. The method is based upon Böttger's observation (*Zeitsch. phys. Chem.*, 1897, **24**, 253) that when metals and also hydrogen absorbed by platinum black are brought in contact with solutions containing the same substances in the form of ions, a potential difference, depending upon the nature of the substances and the concentration of the ions, is established. The apparatus used by the authors for the titration of tan-liquors consists of the hydrogen electrode I. and the auxiliary electrode II., both of which dip into the liquid, and the potentiometer



box for the measurement of the difference of potential between them. These electrodes are represented on the right of the diagram, whilst the electrical apparatus is shown on the left. The hydrogen electrode I. consists of a thin platinum plate, *a*, attached to a long thin platinum wire, *b*, which is fitted into the glass tube *c*, and, passing through the sealed end of the tube, ends in the terminal *d*. A glass tube, *e*, connected with *c* by means of rubber, surrounds the plate *a* to within about 2 mm. from the bottom, and the plate itself is coated with platinum black. Hydrogen, purified by passage through permanganate solution, enters at the tube *c*, and escapes at the bottom, from twenty-five to thirty minutes being required to complete the saturation of the platinum black with the gas. Subsequently only about one minute's passage of hydrogen is required to repair the loss in saturation caused by the transference of the electrode from one liquid to the other before proceeding with the titration. The auxiliary electrode vessel II. has a normal calomel electrode, and the left limb of the capillary connection is filled from the funnel with N-potassium chloride solution, the other limb being charged with a $\frac{3}{5}$ N-solution of the same salt. The value 0·69 volt has been provisionally adopted as the end-voltage of the titration, this value having been obtained by titrating $\frac{N}{10}$ acetic acid solution with $\frac{N}{10}$ sodium hydroxide solution, with phenolphthaleïn as indicator; and this value also closely corresponds to a hydrion concentration equal to that of pure water. In measuring the difference of potential between the calomel and hydrogen electrodes, the two ends, P and Q, of a sliding rheostat are attached to the terminals of a dry cell, D, and the potential difference to be measured is balanced against the potential difference between one end, P, and the slider, S, by means of the capillary electrometer, E, the value being then read upon a sensitive voltmeter, V. The terminals, X and Y, are connected with a dry cell, and the terminals, Z and U, with the hydrogen and calomel electrodes. Hydrogen is first passed through the hydrogen electrode until the potential difference between it and the calomel electrode becomes constant. This potential difference is now measured by moving the slider up and down until, on depressing the key, K, no movement of mercury in the capillary electrometer is seen. The initial P.D. is then read on the voltmeter scale, which ranges from 0 to 1·5 volt. Alkali is now run in from a burette until, after establishment of equilibrium, a reading of 0·69 is shown on the voltmeter, it being then assumed that the liquid has been neutralised. The initial reading of the tan-liquors examined was usually about 0·54 volt. The following test estimations, in which known quantities of $\frac{N}{10}$ acetic, lactic, or butyric acid were added to a tan-liquor which had previously been titrated electrometrically, illustrate the accuracy of the method:

Acetic Acid.		Lactic Acid.		Butyric Acid.	
C.C. added.	C.C. found.	C.C. added.	C.C. found.	C.C. added.	C.C. found.
5	4·9	5	5·0	9·9	9·85
10	9·9, 10·0, 10·05	10	9·90, 9·95, 9·90	14·85	14·75
15	15·1	15	15·08, 15·05	—	—

Comparative estimations of the acidity of various samples by the electrometric method and by Procter's lime-water method gave the following results:

C.C. $\frac{N}{10}$ ALKALI SOLUTION REQUIRED TO NEUTRALISE 10 C.C. OF THE LIQUOR.

Electrometric method	7·0	9·1	10·0	10·6	10·3	10·45	10·65
Lime-water ,,	5·88	8·24	8·75	9·4	9·3	9·40	9·26

C. A. M.

Quantitative Estimation of Tannin by Means of Casein. M. Nierenstein. (*Chem. Zeit.*, 1911, **35**, 31.)—Experiments upon the estimation of tannin in barks and fruits by absorption with casein gave results from 1 to 1·5 per cent. higher than those obtained by the hide-powder method. The presence of alumina in decolorised tannin extracts caused the non-tannin substances to be too high. On the other hand, absorption by casein may prove of use in the analysis of tannin solutions in the dyeing and textile industries, and experiments are described which show that casein precipitates pure tannin quantitatively from [illegible] solutions, but does not form an insoluble compound with gallic acid or dextrose, both of which are frequently found associated with tannin. C. A. M.

INORGANIC ANALYSIS.

Estimation of Aluminium and Chromium in Ferro-Vanadium. W. Trautmann. (*Stahl u. Eisen*, 1910, **30**, 1802-1803; through *Chem. Zentralb.*, 1910, **2**, 1947-1948.)—The powdered alloy is fused in a nickel crucible, with equal parts of carbonate and peroxide of sodium, the melt is dissolved in hot water, and the diluted solution filtered into a beaker containing hydrochloric acid. Excess of ammonia and a little hydrogen peroxide are added to the acid solution, and the precipitate of alumina, which is contaminated by vanadium, is filtered off. The precipitate is freed from most of the vanadium by washing with an ammoniacal solution of ammonium nitrate containing some hydrogen peroxide. To remove the last traces of vanadium, the precipitate is redissolved in hydrochloric acid, and, after addition of ammonium nitrate and hydrogen peroxide, is reprecipitated by ammonia. The alumina is washed free from chloride by means of a hot ammoniacal solution of ammonium nitrate. Finally, the ignited alumina is freed from co-precipitated silica by means of hydrogen fluoride or by fusing with pyrosulphate.

To separate chromium from vanadium, the filtrate from the peroxide fusion is acidified with sulphuric acid, reduced by sulphur dioxide whilst boiling, and the chromium precipitated by ammonia. On redissolving the precipitate in dilute sulphuric acid, and again precipitating with ammonia, the chromium hydroxide is obtained quite free from vanadium. G. C. J.

Analysis of Bog-Iron Ores. A. Kaysser. (*Chem. Zeit.*, 1911, **35**, 94.)—The analysis of bog-iron ores presents many unsatisfactory features, especially as no confirmatory check can be applied to control the accuracy of the results. The sampling gives no difficulty, since the ore is easily pounded; but, in grinding the sample for analysis, the grains of free silica present tend to work to the top, and the composition of the portion taken for analysis is apt to vary with every movement of the bottle. The grinding must therefore be as fine as possible, and is best performed by a mechanical ore-grinder. The sample should then be dried for at least five hours at 100° C., taking into account the fact that at higher temperatures water of constitution is expelled and organic matter is lost. The dried sample is very hygroscopic, and must be weighed rapidly. In order to cope with the above difficulties, it is recommended that, in performing the assays in duplicate, one portion of 2·5 grms. should be weighed out air-dry, and another portion of 1 grm. after drying at 100° C. The sample should be weighed in a porcelain crucible and then roasted, to destroy organic matter. This should be done in a muffle, first heating the sample carefully, and then placing it in the red-hot furnace; otherwise the ore will decrepitate, on account of the large proportion of moisture present. In order to avoid roasting, the ore may be dissolved in hydrochloric acid, and the organic matter destroyed by a concentrated solution of permanganate. The large quantity of chlorine thus produced may be entirely eliminated by means of the stannous chloride employed for reducing the solution according to Reinhardt's method. In the titration it is desirable to colour the liquid in the basin before titrating with permanganate. A check on the results may be obtained by roasting the 2·5 grms. portion and treating the 1 grm. sample with permanganate, and averaging the results.

J. F. B.

Analysis of Ferro-Zircon. W. Trautmann. (*Zeitsch. angew. Chem.*, 1911, 24, 62.)—For alloys containing less than 20 per cent. of zirconium, the following methods are recommended:

If the alloy is to be opened up by a fusion, it is advisable to roast it first, and then to treat with soda and a little nitre. The alloy oxidises on roasting far more readily than does pure zirconium. On taking up the melt with water, a difficultly soluble compound of zirconium and potassium separates, but may be brought into solution by addition of a few drops of hydrochloric acid. Silica is separated by repeated evaporation with hydrochloric acid, and, when ignited and weighed, is fused with potassium bisulphate, and the melt treated with water and a little hydrochloric acid. The filtrate from the silica, thus purified, contains as a rule from 1 to 3 per cent. of the total zirconium present. For separating the zirconium from the united filtrates, precipitation by means of thiosulphate is preferred. The solution is nearly neutralised, sufficient sodium thiosulphate is added, and when the colour of the solution has been discharged the mixture is heated to boiling, when the whole of the zirconium falls out of solution, together with much sulphur, any aluminium which may be present, and always some iron. The iron is eliminated from the precipitate, after filtration and ignition, by means of a bisulphate fusion, followed by reprecipitation of the zirconium (and any aluminium) by means of thiosulphate. Finally, any aluminium present is separated by means of a peroxide fusion, the aluminium being precipitated from the aqueous extract of the melt by acidifying this with hydrochloric acid, and then adding ammonia. The alumina is weighed, and the zirconium dioxide in the precipitate subjected to fusion with peroxide is determined by difference.

If the alloy is to be decomposed by means of hydrofluoric acid, preliminary roasting is again recommended, especially if the alloy is one containing much carbon. After warming with hydrofluoric and sulphuric acids in a covered crucible until decomposition is complete, the heat is increased, and continued until fumes of sulphuric acid are given off. After the contents of the crucible have been brought into solution in water, with the addition of a few drops of hydrochloric acid if necessary, the zirconium can be estimated in any convenient manner. Duplicate determinations made by the two methods described agree within 0·1 per cent.

For the estimation of carbon in such alloys, direct combustion in a current of oxygen is recommended, the use of lead peroxide being unnecessary. G. C. J.

Analysis of Ferro-Uranium. W. Trautmann. (*Zeitsch. angew. Chem.*, 1911, **24**, 61-62.)—The powdered alloy is treated with hot aqua regia, if necessary for three hours, though a much shorter time suffices for its complete disintegration unless it contains much carbon or silicon. Disregarding any silica which may separate, the solution is diluted and, when cool, solid ammonium carbonate is added in quantity more than sufficient to neutralise the acid present. After allowing to stand for twenty-four hours, with frequent stirring, the precipitate, which contains the whole of the iron, aluminium, and silica, is separated by filtration, and the filtrate boiled for some time to decompose the ammonium carbonate. The greater part of the uranium separates out under these conditions, the solution at the same time acquiring a weak acid reaction. Addition of a few drops of ammonia changes the reaction and determines the quantitative precipitation of the uranium. The precipitate is washed with a weakly ammoniacal solution of ammonium nitrate, transferred to a porcelain crucible, ignited, and weighed as U_3O_8.

Carbon in such alloys is best determined by direct combustion, silicon by repeated evaporation with hydrochloric acid, after opening up with aqua regia. Aluminium, a common impurity, is most conveniently determined after a peroxide fusion. The filtrate from the aqueous extract of the melt is acidified with hydrochloric acid, the alumina precipitated by means of ammonia, and separated from the associated silica by treatment with hydrofluoric acid, or by means of a bisulphate fusion.

G. C. J.

Testing of Incandescent Mantles. J. H. Coste and W. E. F. Powney. (*J. Soc. Chem. Ind.*, 1911, **30**, 65-67.)—In the testing of incandescent mantles, the durability tests precede the photometric tests, since the latter occupy some considerable time, and should only be conducted on those batches which have passed the former test. For the durability test the Woodall-Moon machine is employed. The mantle, having been burnt off and hardened, is subjected on its proper burner to a series of shocks, administered by a miniature stamp-mill operated by a water-motor. The impacts delivered on the lower part of the machine impart to the support and the suspended mantle vibrations similar to those of heavy traffic, and the number is registered by a counter. From each batch of twelve mantles three are tested; and if any fail to survive 1,000 shocks, another three are taken. For upright mantles a minimum of 1,000 shocks, at the rate of 300 per minute, using 2-ounce weights, is exacted; for inverted mantles, 3,000 shocks, at 600 per minute, with 3-ounce weights, constitute the minimum. The shocks are in no case continued beyond 1,200 and 3,600 respectively; this allows one mantle out of six to fail if the other five pass the maximum test. For the photometric tests three mantles are taken from each batch, and burnt on the standard burners for 100 hours. They are then tested photometrically against a ten-candle Harcourt pentane lamp, using a Leeson star disc as modified by Dibdin. Readings are taken at equal angular intervals round the burner, the gas being burnt at the rate of 3½ feet per hour. In interpreting the results it is not desirable to take the average values, since the variations from the average may be very large in the case of individual mantles. The mean variation, obtained by the method of mean squares, is therefore deducted from the average in arriving at the comparative figure of merit. J. F. B.

Reagent Paper for the Volumetric Estimation of Zinc. R. Kopenhague. (*Ann. Chim. anal. appl.*, 1911, **16**, 10-12.)—A paper impregnated with cadmium nitrate enables the end-point of the reaction in the titration of zinc with sodium sulphide to be ascertained much more exactly than is possible with the ordinary lead carbonate paper or the cobaltous chloride paper of Deus. The cadmium paper is prepared by immersing strips of filter-paper in 10 per cent. cadmium nitrate solution, and drying them at 80° to 90° C. It keeps well, and in spotting tests reacts with an excess of sodium sulphide in fifteen to twenty seconds.

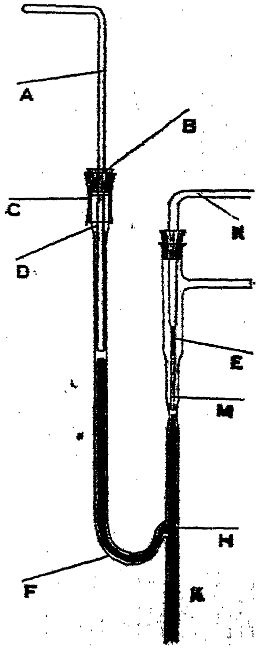
C. A. M.

Estimation of Tungsten. B. Mdivani. (*Bull. Soc. Chim. Belg.*, 1911, **25**, 41-42.)—The tungsten, which may be in solution as tungstate of ammonium or of a fixed alkali, is precipitated as W_2O_5 by addition of a freshly-prepared solution of stannous chloride containing 250 grms. of the crystallised salt in 1,000 c.c. of concentrated hydrochloric acid. About 20 c.c. of this solution are used for each decigram of tungstic acid supposed to be present. After boiling for one or two minutes, the precipitate is allowed to settle, which it does rapidly, and it is possible in a few minutes to wash it several times by decantation with hot water. If the supernatant liquor be decanted on to the filter each time whilst still quite hot, the precipitate remains flocculent, and no difficulty is experienced in filtration. The oxide thus precipitated and washed is finally brought on to the filter, dried, ignited, and weighed as WO_3. The error of the method is ± 0·5 mgrm. on 0·1 grm. WO_3, and the precipitate need never contain a detectable trace of tin. Ferric oxide up to ten times the amount of tungstic acid present does not interfere. G. C. J.

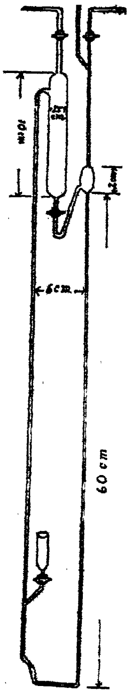
APPARATUS, ETC.

New Form of Constant Temperature Drying Oven. R. L. Siau. (*J. Soc. Chem. Ind.*, 1911, **30**, 61.)—The drying chamber consists of a long, narrow copper tube of round or square cross-section, closed at one end by a plate through which a small tube passes. It is wrapped round by a narrow copper tube of ⅛ to ¼ inch bore which enters the chamber at the end opposite to that closed by the plate and tubulure. A copper jacket of similar section to the oven fits loosely over the coil, the loose end of which passes through the jacket at any convenient point. This jacket is connected below with a boiling flask, and is provided at the top with a Soxhlet's ball condenser. The jacket covers the closed end of the drying chamber, the small tube passing through its wall; whilst at the other end the jacket is sealed off flush with the end of the drying tube by means of a stout plate, forming the entrance to the oven, which can be closed with a clamped door. When in use, the small tube at the farther end of the drying chamber is connected with a water-pump, and air is thereby aspirated through the copper coil, which is surrounded by the vapour in the jacketed space. This air enters at the front end of the oven, and passes over the substances contained therein. The air should be previously dried by suitable drying media, and the moisture expelled from the substance may be determined at the exit end by absorption. The dimensions of the oven are 18 inches in length, 3 inches in width, and 1½ inches in height inside; the boiling flask has a capacity of 250 c.c., and is half filled with water for a temperature of 100° C., or with toluene for 110° C. The moisture in a sample of barley or malt may thus be determined in one and a half to two hours at 100° C., as compared with four to six hours in the ordinary oven. J. F. B.

Gas Regulator for Thermostats. A. Slator. (*J. Soc. Chem. Ind.*, 1911, **30**, 61-62.)—The author describes the following modification of a toluene gas regulator as used on thermostats, which allows the amount of mercury to be decreased or increased according to whether a high or low temperature be desired. It consists of a side-piece, as illustrated in the accompanying figure (in which the toluene bulb is not shown). The glass rod plunger A passes through the rubber bung B, and forces the desired amount of mercury into the stem K of the apparatus. The cup D is filled, to the exclusion of all air, by a mixture of 2 parts of glycerol to 1 part of water. The bung B rests on the cup, and is held in position by the rubber tubing C, which overlaps the bung and cup. The bend F insures the mercury remaining in the side-piece even if the level in the stem falls below the joint H. By means of this arrangement the regulator can be adjusted accurately to any desired temperature over a wide range. It has also been found that the fragile end M of the tube N is better preserved from breakage if the two are connected by means of narrow rubber tubing, E, instead of being rigidly attached. J. F. B.



Freezing Mixtures. J. Duclaux. (*Comptes rend.*, 1910, **151**, 715-716.)—When acetone and carbon bisulphide are mixed, a considerable fall of temperature results. If each of these liquids is conducted separately, at the rate of 1 or 2 drops a second, through a long tube 1 mm. in diameter, to the bottom of a tube closed at its lower end, and wide enough to accommodate the two leading tubes, and if the liquids after mixing are allowed to ascend the outer tube throughout its length, thus cooling the entering currents, a temperature of −48° C. may be obtained. The author makes use of the principle as follows: The two liquids are introduced at the rate of 100 c.c. carbon bisulphide and 70 c.c. acetone per hour into the jacket of a jacketed vessel of silvered glass, the capacity of which, apart from the jacket, is 20 c.c. Once regulated, the temperature of the apparatus and of any substance placed in the vessel can be maintained for several hours at any temperature down to −43·5° without attention. The two liquids separate almost completely on adding to the mixture half its own volume of water. G. C. J.



Modified Boltwood Vacuum Pump. A. F. Odell.

(*J. Amer. Chem. Soc.*, 1911, **33**, 56.)—This modification of Boltwood's pump (*Amer. Chem. J.*, 1897, 76) occupies only one-third the space, and requires only one-tenth the amount of mercury, of the original form, and is equally effective. The pump shown in the figure requires 100 grms. of mercury, and within fifteen minutes a high vacuum can be obtained.

Considerable deviation exists in the manufactured forms of the Boltwood pump from the prescribed internal diameter (2·5 mm.) of the dropping-tube. According to the author, a slightly larger tube refuses to give low vacua, while a tube smaller in diameter than 2·5 mm. works so slowly as to be comparable with the older hand-lift varieties. A. R. T.

GOVERNMENT REPORTS.

On the Work of Inspectors of Foods. G. S. Buchanan.

(Appendix A, No. 10, from the Annual Report of the Medical Officer of the Local Government Board for 1909-10.)—The Report now submitted deals with work in special relation to the Public Health (Regulations as to Food) Act, 1907, local arrangements for meat and food inspection, work in special relation to the Sale of Food and Drugs Acts, and with foreign and colonial food legislation.

Since the issue of the report on the application of formaldehyde to meat (Analyst, 1909, **34**, 470), the quantity of formaldehyde in certain consignments of imported meat has shown a marked decrease; but there is still room for improvement, if this process is to continue to be applied.

Several inquiries were made as regards the local administration of the Sale of

Food and Drugs Acts. In one instance the attention of the County Council was directed to the undesirability of taking on one day the whole of the samples submitted for analysis during the quarter. In certain counties and boroughs the question of the selection of samples for analysis called for consideration. An inquiry was made regarding a process for reconstructing milk after separation and concentration; this process is carried out on a commercial scale at an establishment near London, and the concentrated separated milk and cream are despatched to London, where they are mixed with any desired proportion of boiled tap-water, and distributed in bulk or in bottles.* It is considered desirable that such reconstructed milk should be sold as prepared milk. The process does not destroy pathogenic organisms which may have been present in the original milk, neither is the reconstructed milk exceptionally free from bacteria.

Importers, rice millers, and other traders, have taken steps to minimise the quantity of steatite employed for "facing" rice since the issue of a Report dealing with the practice (ANALYST, 1909, **34**, 430). The question, however, appears to deserve the continued attention of local authorities, and it may be hoped that their action will restrain the extension of "facing" to other cereals, such as pearl barley.

During the year several public analysts reported on the presence of excessive quantities of tin in samples of canned fruits; many of the cans were badly soldered, and the tops and bottoms were put on so as to leave a raw edge of the metal plate exposed to the fruit-juices. It is desirable that all exposure of solder in the interior of the can should be avoided, and that the inside of the can should be lacquered. Fruits are often packed in glass, but it cannot always be assumed that this has been the original packing. An investigation of a series of bottled fruits for the detection of metallic impurity might be undertaken with advantage in districts where bottled fruit is largely sold.

The question of the issue of regulations regarding the practice of preserving cream by the addition of boric acid or other boron compounds is under the Board's consideration.

Inquiries are now in progress in regard to condensed milk, the composition of food for infants, and the chemical treatment of flour. The experimental work necessary in these inquiries has been facilitated by the provision of a chemical laboratory at the Board's offices. W. P. S.

On a Parasite Condition (Onchocerciasis) met with in Australian Beef. A. W. J. MacFadden and R. T. Leiper. (Local Government Board Food Reports, 1911, No. 11, 1-16, with three plates.)—Certain nodular masses observed in frozen quarters of meat arriving in this country from Australia were found to be due to the presence of long thread-like worms of the genus *Onchocerca.* The diseased condition is not peculiar to Australian cattle, but occurs also in other animals and in other parts of the world, including the United States of America. The parasites belong to a group of worms that require to be taken up by a biting insect, and to undergo a certain degree of development therein before they can be transmitted to another warm-blooded animal. They do not appear to be capable of surviving the death of the cattle for more than a few hours, and no evidence of vitality of the worm or its embryo has been met with in the case of Australian beef reaching this country. It follows that the direct development of the parasite in man, as a result of eating the affected meat, is impossible. The nodules are the product of changes taking place in the tissues as a result of some acrid toxin excreted by the worms, and the opinion is expressed that, for this reason, their presence in meat intended for human consumption is undesirable.

---

* This practice is now discontinued.

REVIEW.

A TEXTBOOK OF BOTANY AND PHARMACOGNOSY. By HENRY KRAEMER, Ph.B., Ph.D. Fourth revised and enlarged edition, 1910. Philadelphia and London: J. B. Lippincott and Co. Price 21s. net.

Previous notices of earlier editions of this work have appeared in our pages (*cf.* ANALYST, 1907, **32**, 311; 1909, **34**, 192). In the present edition the botanical part has been carefully revised by Dr. T. Holm. This portion of the work, which is admirably illustrated, is claimed to serve as a course of botany for students of pharmacy and pharmacognosy. The micro-analysis of the important plant constituents is treated in a short section, which contains a number of photographs of microscopic crystals. This work, which is admittedly a standard one, will be most useful to the analyst as a practical guide in the microscopical examination of vegetable drugs and allied products. An important feature of the book is the large number of illustrations—some 3,000 plates and 2,000 figures—which it contains. The plan of the work and the general make-up leave little to be desired.

APRIL, 1911. Vol. XXXVI., No. 4

IARI

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE Annual General Meeting of the Society, adjourned from February 1, was resume on Wednesday evening, March 1, in the Chemical Society's Rooms, Burlington House The President, Mr. E. W. Voelcker, A.R.S.M., F.I.C., occupied the chair.

The minutes of the meeting held on February 1 having been read and confirme the election of Officers and Council for 1911 was proceeded with, Messrs. C. A. H B.Sc., F.I.C., and L. Myddelton Nash, F.I.C., being appointed scrutators.

The scrutators having examined the ballot papers, and having reported t result of their examination,

The PRESIDENT announced the election of Officers and Council as follows:

President.—E. W. Voelcker, A.R.S.M., F.I.C.

Past-Presidents serving on the Council (limited by the Society's Articles Association to eight in number).—M. A. Adams, F.R.C.S., F.I.C.; Edward J. Bevar F.I.C.; Bernard Dyer, D.Sc., F.I.C.; Thomas Fairley, F.I.C.; W. W. Fisher, M.A. F.I.C.; Otto Hehner, F.I.C.; R. R. Tatlock, F.I.C.; J. Augustus Voelcker, M.A. B.Sc., Ph.D., F.I.C.

Vice-Presidents.—Arthur E. Ekins, F.I.C.; Arthur R. Ling, F.I.C.; John E. Stead, F.R.S., F.I.C.

Hon. Treasurer.—H. Droop Richmond, F.I.C.

Hon. Secretaries.—A. Chaston Chapman, F.I.C.; P. A. Ellis Richards, F.I.C.

Other Members of Council.—Horatio Ballantyne, F.I.C.; E. Richards Bolton; R. A. Cripps, F.I.C.; F. W. Harbord, A.R.S.M., F.I.C.; Charles A. Hill, B.Sc., F.I.C.; Edward Hinks, B.Sc., F.I.C.; G. N. Huntly, A.R.C.Sc., F.I.C.; F. R. O'Shaughnessy, F.I.C.; Edward Russell, B.Sc., F.I.C.; S. R. Trotman, M.A., F.I.C.; W. H. Willcox, M.D., B.Sc., F.I.C.; S. A. Woodhead, M.Sc., F.I.C.

The proceedings then terminated.

The ordinary monthly meeting followed, the President occupying the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. J. Clifford, A.R.C.S.I., J. Connah, B.Sc., F.I.C., H. F. Knight, C. H. LaWall, W. R. Mummery, F.I.C., and W. M. Seaber, B.Sc., F.I.C., were read for the second time; and certificates in favour of Messrs. Horace G. Battie, 24, Malvern Road, Beeston Hill, Leeds, senior research chemist to Messrs. B. R. Vickers and Son, Leeds;

eorge Davidson Elsdon, B.Sc. (Birm.), City Analyst's Laboratory, Council House, Birmingham, assistant to Mr. J. F. Liverseege, F.I.C.; Norman Evers, B.Sc. (Lond.), A.I.C., Bedcote House, Stourbridge, assistant to Mr. J. F. Liverseege, F.I.C.; and Arthur William Knapp, B.Sc. (Lond. and Birm.), F.I.C., 275, Birchfield Road, Birmingham, analytical chemist, were read for the first time.

Messrs. R. L. Collett, B.A., A.I.C., W. B. Cowie, F. Evershed, and G. Taylor, were elected members of the Society.

The following papers were read: "The Estimation of Iron by Permanganate in e Presence of Hydrochloric Acid," by Alexander Charles Cumming, D.Sc., and exander Gemmell; "Examination of the Process of Shrewsbury and Knapp for e Estimation of Cocoanut Oil," by Raymond Ross, F.I.C., Joseph Race, F.I.C., d Frank Maudsley, B.Sc., F.I.C.; "Note on Henry C. Frey's Method of Estimating etroleum in turpentine," by Herbert S. Shrewsbury, F.I.C.; "Notes on the Formaion of Hypoiodites and their Action on Sodium Thiosulphate—A Source of Error n Certain Iodine Titrations," by J. P. Batey; and "The Analysis of Sweetened ondensed Milk," by Arnold Backe, Ph.D.

A new form of specific gravity apparatus was shown by Dr. C. Butler Savory.

* * * * *

OTES ON THE FORMATION OF HYPOIODITES AND THEIR ACTION ON SODIUM THIOSULPHATE—A SOURCE OF ERROR IN CERTAIN IODINE TITRATIONS.

By J. P. BATEY, M.Sc.Tech.

(*Read at the Meeting, March* 1, 1911.)

In the course of some analyses of antimonious compounds by titration with iodine in presence of sodium bicarbonate, it was desired to make an indirect titration by adding an excess of the standard iodine solution to the mixture of the antimony and bicarbonate solutions, and then titrating back the excess of iodine by means of a standard solution of sodium thiosulphate. It was found that the results obtained by the indirect titration did not agree exactly with those obtained by direct titration with iodine.

As the indirect titration for antimony affords a much sharper end-reaction than the direct, and is more rapidly carried out, it was thought advisable to ascertain the cause of the observed discrepancy. This was all the more desirable because in a recent paper on the estimation of antimony by Beckett (*Chem. News*, 1910, **102**, 101; Analyst, 1910, **35**, 451) it is stated that both methods of carrying out the estimation yield the same results.

A number of experiments were therefore made, and these, while settling the original point in question, have led to some observations, which may be of interest, on the formation of salts of hypoiodous acid and their oxidising action on sodium thiosulphate.

1. *The Titration of Antimonious Salts with Iodine.*—In one experiment, 25 c of a solution of tartar emetic mixed with 25 c.c. of a saturated solution of sodiu bicarbonate required:

By direct titration ... ... 24·6 c.c. $\frac{N}{10}$ iodine solution.
By indirect titration ... ... 24·85 ,, ,,

In a second experiment, in which the amount of tartar emetic taken was the same, but in which 50 c.c. of the bicarbonate solution was used, the following results were obtained—

By direct titration ... ... 24·6 c.c. iodine solution.
By indirect titration ... . 25·5 ,, ,,

To make quite sure that the observed results were not due to the presence of norn sodium carbonate in the bicarbonate, the saturated solution of the latter was su jected to a current of carbon dioxide for some time. The resulting solution was use but it was still found that the amount of iodine used up in the indirect titration w excessive, although the error was less than before.

It was finally found that the double titration gave quantitative results if t amount of sodium bicarbonate used was reduced to a certain limit. Thus, in a la number of titrations, it has been found that if 1 to 1·5 grms. of bicarbonate (or 20 of a saturated solution) be employed for every 0·15 grm. of antimony present (25 c of an $\frac{N}{10}$ solution), exact results are obtained by the indirect titration; but if mo bicarbonate than this be used, an error is introduced.

It has further been found that Rochelle salt may be conveniently substituted for the bicarbonate in the indirect titration, and in this case the quantity used (provided it be sufficient) is of no consequence, since no error is introduced by using a large excess.

2. *The Titration of Iodine in Presence of Sodium Bicarbonate.*—The following experiments were carried out with the object of determining the cause of the error mentioned above: Standard iodine solution was mixed with sodium bicarbonate, and the iodine then titrated with sodium thiosulphate. A considerable loss of iodine took place, the extent of which is shown in the following table. Decinormal solutions of iodine and sodium thiosulphate were used, and in each case the bicarbonate was weighed out and shaken with sufficient cold water to dissolve it (about 15 c.c. to 1 grm.):

Weight of $NaHCO_3$.	Iodine Solution taken.	Thiosulphate Solution required.	Iodine lost per 1 Grm. of $NaHCO_3$.
grms.	c.c.	c.c.	c.c.
0·0	10	10·05	—
0·5	,,	9·3	1·4
1·0	,,	8·9	1·1
2·0	,,	8·5	0·75
4·0	,,	7·7	0·675

The loss of iodine under these conditions is considerable. A similar effect was observed by Puckner (*Chem. Centr.*, 1905, **1**, 1186).

I found that, if borax were used instead of sodium bicarbonate, a little iodine was absorbed, but not nearly to the same extent as with the bicarbonate. With Rochelle salt, on the other hand, no absorption of iodine could be detected.

It was thought that the loss of iodine might be due to the formation of iodates, and it was expected that, on acidifying the solutions which had been titrated with thiosulphate, the remainder of the iodine would be liberated. Excess of hydrochloric acid was therefore added to each of the solutions after titration with thiosulphate, but in no case was there the slightest trace of iodine liberated. If, therefore, an ate had been formed, the only possible explanation of its disappearance would be at it was reacting with sodium thiosulphate or with sodium tetrathionate. A few periments soon proved, however, that potassium iodate, either alone or in admixre with sodium bicarbonate and potassium iodide, had not the slightest oxidising tion either on sodium thiosulphate or on sodium tetrathionate.

The possibility of the formation of a hypoiodite was next considered, and it was ecided to study the action of sodium hypoiodite on sodium thiosulphate.

3. *The Action of Sodium Hypoiodite on Sodium Thiosulphate.*—R. L. Taylor J. *Chem. Soc.*, 1900, **77**, 725) has shown that, when excess of caustic soda solution is dded to a solution of iodine, the first products of the reaction are sodium hypoiodite nd sodium iodide. The hypoiodite is rapidly resolved into a mixture of iodate and dide. In such a solution an excess of a mineral acid will of course liberate a quanty of iodine equal to that originally taken.

The standard iodine solution was decinormal, and the solution of sodium hydroxide was of normal strength; about 15 c.c. of it were used for every 25 c.c. of iodine.

In studying the action of sodium hypoiodite on sodium thiosulphate, a measured volume of standard iodine was taken, made strongly alkaline with sodium hydroxide, and the desired amount of sodium thiosulphate at once run into the solution. The mixture was shaken and then acidified with hydrochloric acid, and any excess of iodine was titrated by means of sodium thiosulphate. It was at once apparent that when sodium thiosulphate reacts with sodium hypoiodite it uses up far more iodine than would be required to produce sodium tetrathionate.

In one experiment 30 c.c. of iodine was treated with sodium hydroxide, and 5 c.c. of thiosulphate then added. On acidifying, the liberated iodine required only 3·8 c.c. of the $\frac{N}{10}$ thiosulphate, so that in this case 26·2 c.c. of iodine had been used up by 5 c.c. of thiosulphate of the same equivalent strength. When the mixture of sodium hypoiodite and sodium thiosulphate was allowed to stand for a short time before acidifying, the oxidation proceeded still farther, provided of course that a sufficient excess of iodine was used. The limit of the reaction was reached when 1 c.c. of thiosulphate had used up 8 c.c. of iodine. It was found that sulphuric acid was produced, and the equation for the reaction may be represented as follows:

$$Na_2S_2O_3 + 4NaOI + 2NaOH = 2Na_2SO_4 + 4NaI + H_2O.^*$$

4NaOI is equivalent to $4I_2$.

---

* This equation of course only represents the ultimate effect of the oxidation. It is probable that several intermediate stages are passed through in the conversion of thiosulphate into sulphate.

In estimating the sulphuric acid produced, 5 c.c. of the $\frac{N}{10}$ sodium thiosulphate (equivalent to 0·233 grm. $BaSO_4$) was run into an excess of hypoiodite solution. After a short time the mixture was acidified with hydrochloric acid, and the sulphuric acid then estimated by the usual gravimetric method. The operation of precipitating and filtering off the barium sulphate was done in the cold. Several estimations of sulphate have been made with solutions which have been allowed to stand for different lengths of time before acidifying. From the amount of sulphuric acid produced in each case the amount of iodine required for the oxidation has been calculated (assuming that that portion of the thiosulphate which is not oxidised to sulphuric acid has been converted into tetrathionate on acidifying). The values thus calculated agree very closely with the loss of iodine actually found by titration.

Iodine used up, found by Titration.	Iodine required, calculated from the Amount of Sulphuric Acid produced.
c.c.	c.c.
22·5	22·30
28·8	28·40
33·6	33·40
34·9	35·30
39·0	38·95

There was still the possibility that potassium iodate in strongly alkaline solution might be capable of bringing about this oxidation of thiosulphate. The following experiments, however, prove that this is not the case, and they afford still further proof of the powerful oxidising action of the sodium hypoiodite.

Twenty c.c. of $\frac{N}{10}$ potassium iodate was mixed with an excess of potassium iodide solution and 20 c.c. of $\frac{N}{1}$ sodium hydroxide. To the mixture 3 c.c. of $\frac{N}{10}$ sodium thiosulphate was added; the solution was then acidified with hydrochloric acid, and the liberated iodine titrated. If no oxidation of thiosulphate had taken place, it was expected that the liberated iodine would require 17 c.c. $(20 - 3)$, but it was found, however, to require only 11·4 c.c. It was at once thought that the potassium iodate was exerting an oxidising action on the thiosulphate, and the experiment was repeated, the mixture being allowed to stand for some time before acidifying. It was expected that still less iodine would be obtained, but instead the titration required 13·9 c.c. of thiosulphate (*i.e.*, more than before).

These curious results were due to the fact that, when the strongly alkaline solution was being acidified with hydrochloric acid, iodine was liberated, which, reacting with local excess of caustic alkali, produced a momentary formation of hypoiodite. It is the hypoiodite alone which brings about the observed oxidation of the thiosulphate. This was shown to be the case by repeating the experiments, and running the alkaline solution from a fine jet, slowly, into a large excess of hydrochloric acid. In several titrations the iodine recovered varied from 16·0 to 16·4 c.c., thus showing that much less oxidation was taking place than before. By preventing all possibility of the formation of hypoiodite, it was possible to recover the total

17 c.c. of iodine, and this was done by first saturating the alkaline mixture with carbon dioxide, when all the alkali present would be converted into bicarbonate, and the solution at the same time saturated with free carbon dioxide. Directly this solution comes in contact with hydrochloric acid, so much carbon dioxide is liberated as to render the momentary formation of hypoiodates impossible.*

The oxidising action of sodium hypoiodite upon sodium tetrathionate† has also been studied, and for this purpose a standard solution of tetrathionate was made up of $\frac{N}{20}$ strength, by mixing equivalent quantities of $\frac{N}{10}$ iodine and $\frac{N}{10}$ thiosulphate.

As in the case of thiosulphate, the oxidation, on standing, was found to proceed to sulphuric acid, so that in this case one equivalent of the tetrathionate (2 c.c.) reacts with seven equivalents of iodine (7 c.c.). The reaction, however, is much slower with tetrathionate than with thiosulphate.

Taking 20 c.c. of iodine in the form of hypoiodite, and adding 6 c.c. of tetrathionate, it was possible, by acidifying the mixture quickly, to recover 19·6 c.c. of the iodine—*i.e.*, only 0·4 c.c. had been used up.

Working under similar conditions with an equivalent amount of thiosulphate (3 c.c.), the least amount of iodine which has so far been used up in any of a large number of experiments was 11·2 c.c. Even if we subtract from 11·2 the 3 c.c. which would be normally required to form tetrathionate, it will still be evident that the reaction between hypoiodite and thiosulphate proceeds under these conditions at something like twenty times the speed of that between hypoiodite and tetrathionate.

From the results of these experiments it would seem very improbable that, in the oxidation of thiosulphate by hypoiodite, the thiosulphate passes through the tetrathionate stage.

4. *The Action of Sodium Bicarbonate on Iodine.*—Returning now to the action of sodium bicarbonate on iodine, it would appear that some sodium hypoiodite is produced. From the researches of R. L. Taylor and others, however, it is evident that the quantity of hypoiodite formed will be diminished by the presence of free carbonic acid. This has been verified experimentally by taking a known weight of sodium bicarbonate and adding to it a known volume of $\frac{N}{1}$ sulphuric acid, thereby liberating some carbon dioxide, then adding iodine and titrating with thiosulphate.

The results are given in the following table:

Weight of Bicarbonate.	Weight of H_2SO_4.	Iodine.	Thiosulphate.
grms.	grm.	c.c.	c.c.
2	0·1	10	9·50
,,	0·2	,,	9·60
,,	0·4	,,	9·80
,,	0·6	,,	9·95

In the above experiments the acid was added very slowly, with the jet of the burette below the surface of the bicarbonate solution.

---

* Orton and Blackman (*J. Chem. Soc.*, 1900, 830) have shown that sodium arsensite is oxidised to arsenate by hypoiodites in alkaline solution, but that it is not oxidised by iodates.

† Gutmann (*Ber.*, 1907, **40**, 3614) found that sodium tetrathionate reacted with a hot solution of caustic soda (15 per cent.) to form sodium thiosulphate and sodium sulphite.

In the oxidation of antimonious compounds to antimonic compounds by iodine, ree hydriodic acid is produced, according to the equation:

$$Sb_2O_3 + 2I_2 + 2H_2O = Sb_2O_5 + 4HI.$$

The hydriodic acid reacts with the bicarbonate and liberates carbon dioxide; and if the ratio of free carbon dioxide to sodium bicarbonate is sufficiently great, the formation of hypoiodites is prevented, and therefore the thiosulphate is not oxidised too far. This, therefore, explains the fact observed above, that if the amount of bicarbonate used be reduced to a certain limit the indirect titration for antimony is accurate.

NOTE ON HENRY C. FREY'S METHOD OF ESTIMATING PETROLEUM IN TURPENTINE.

BY HERBERT S. SHREWSBURY, F.I.C.

(Read at the Meeting, March 1, 1911.)

IN Frey's method (*J. Amer. Chem. Soc.*, 1908, **30**, 420), 10 c.c. of the sample are mixed with 30 c.c of aniline, the mixture shaken vigorously for five minutes, and allowed to stand. The petroleum is then measured.

With a preliminary experiment the method appeared so satisfactory that I made the following test experiment with prepared mixtures of turpentine and petroleum:

Per Cent. by Volume of Kerosene.	Per Cent. of Kerosene measured after—		
	Five Minutes.	Thirty Minutes.	Forty Hours.
0	0	0	0
1	0	0	0
5	0	0	0
10	0	0	0
30	30	30	37
50	44	54	55
70	68	70	72
90	80	80	84
95	85	84	84
99	84	84	84

Apparently the method is only applicable when the percentage of kerosene is between 30 and 70, and the result then obtained is probably due to a happy compensation of errors.

Thirty minutes seems to be the maximum time necessary to leave the mixture to settle. The kerosene experimented with was the ordinary pitch oil used in Trinidad for illuminating purposes, with a Zeiss butyro-refractometer figure of 16 at 25° C., and an initial boiling-point of 160° C. The temperature at which the experiments were carried out was 28° C.

DISCUSSION.

Mr. L. M. NASH said that some time previously he tried this method—using, however, ordinary aniline, not anhydrous—but had obtained erratic results. Later on he had repeated his experiments, using anhydrous aniline as recommended by Frey, but had found that this made no difference. He noticed that Mr. Shrewsbury's experiments were made with kerosene, but kerosene was never used for adulterating turpentine. Petroleum spirit was what was used.

Mr. J. H. Coste wrote:

"A method based on the behaviour, when mixed, of three liquids of which only one is a chemical entity, the other two being mixtures of variable composition, does not appear hopeful.

"I think Mr. Shrewsbury has done useful work in showing the unsoundness of this method. It is much to be regretted that such enticingly simple processes based on very slender grounds, either *a priori* or empirical, should be brought forward only to mislead. I find that the method is inapplicable to ordinary turpentine substitutes."

ANALYSIS OF SWEETENED CONDENSED MILK.

BY ARNOLD BACKE (WITH A. WIBORG AND E. RÖER).

(Read at the Meeting, March 1, 1911.)

ANALYSES of sweetened condensed milk often show results which, even though correct analytical methods have been used, produce a somewhat erroneous impression of the composition of the product. For this reason we deem it useful to call the attention of analysts to certain important facts respecting the analysis of these preparations.

Formerly, when the determination of the fat was performed by extraction with ether after drying, one frequently came across analyses which showed too small a percentage of fat. With the adoption of the Gottlieb method, this difficulty has disappeared, and for the estimation of the other constituents no difficulty exists in arriving at figures sufficiently exact for practical purposes. As regards the determination of the sugar percentage, Kjeldahl's method of calculation must be followed (Report of the Carlsberg Laboratory, iv. 1) to obtain a reliable result.

But if the actual determination of the various constituents does not present any difficulty, other circumstances have to be considered which influence to a considerable extent the result of the analyses of condensed milk as a whole. It is natural that, in a tin of condensed milk which remains undisturbed for a long time, the fat should rise to the surface, and that the rapidity with which it thus rises should depend on the consistency of the milk. This movement being very slow, the separation of the fat produced in this way will not be counteracted in a short time if the tin be inverted. It can further be easily ascertained that a large part of the lactose is not in a state of solution in the condensed milk, but appears in the form of crystals. It frequently happens that condensed milks have a gritty taste, which is due to the presence of crystals of lactose. But even when no gritty sensation is perceived, the lactose is nevertheless separated in microscopic crystals. Whether the condensed milk is gritty or not depends on the size of the crystals. By thinning the milk with cold water and by centrifuging at once, it is possible to separate a large portion of the lactose. If a tin of condensed milk remains undisturbed for a certain time, these crystals sink towards the bottom of the tin. The speed of this downward movement is dependent on the size of the crystals and the consistency of the milk. Generally a little cane-sugar separates, but in much smaller quantities; and since it separates in larger crystals than lactose, they sink to the bottom more rapidly. In accordance with the way in which these various factors—size of the crystals, consistency of the milk, length of time during which the tin has stood—are combined, this separation into zones or layers of different composition in the condensed milk presents itself in various ways. Below follow some examples of milks, all of which are normal, but of different consistencies:

I. Milk Fifteen Days after Manufacture, fairly Thin, not Gritty.

(*a*) Analysis of the whole contents of the tin, well mixed:

Fat	11·40	11·45
Proteins (N × 6·37)	10·20	10·31
Lactose	14·13	14·20
Cane-sugar	37·48	37·52
Mineral matter	2·25	—
Water	24·98	24·90

(*b*) Analysis of the whole contents of the tin previously diluted with water:

Lactose	14·18
Cane-sugar	37·61

(*c*) Analysis by zones:

	1. Thin Layer on the Top of Tin.	2. Main Contents.	3. Thin Layer at Bottom.
Fat	12·09	11·84	11·53
Lactose	13·36	13·90	14·71
Cane-sugar	37·96	37·70	37·53
Water	24·73	24·85	24·85

The figures show that with milk of such a consistency the results obtained are sufficiently exact for practical purposes if the milk contained in the tin is well mixed. There is an appreciable difference between (*c*) and the other analyses. This difference will be alluded to later on.

II. Milk Two and a Half Months after Manufacture, fairly Thin, not Gritty.

(*a*) Analysis of the whole contents of the tin, well mixed:

	I.	II.
Fat	12·20	12·17
Lactose	14·19	14·18
Cane-sugar	35·89	35·95

(*b*) Analyses of zones: These have been chosen differently; the top zone comprises one quarter of the total contents of the tin, the next zone half the total contents, and the bottom zone a quarter:

	Top Zone.	Middle Zone.	Bottom Zone.
Fat	12·68	12·44	11·35
Proteins (N × 6·37)	10·29	10·05	10·03
Lactose	12·23	14·03	16·53
Cane-sugar	36·66	36·01	35·42
Mineral matter	2·14	2·14	2·15
Water	25·66	25·50	24·84

The average figures for the zones being—

Fat	12·23
Lactose	14·21
Cane-sugar	36·02

it can be seen that in this case also fairly exact results can be obtained, provided the milk is well mixed before being analysed.

III. Milk Four and a Half Months after Manufacture, rather Thick.

(*a*) Analysis of the whole contents of the tin, well mixed:

Fat	11·31	11·32
Proteins (N × 6·37)	9·62	—
Lactose	14·35	14·45
Cane-sugar	36·49	36·70
Mineral matter	2·13	—
Water	26·08	—

(*b*) The whole contents of a tin diluted with water:

Lactose	14·13
Cane-sugar	37·25

(*c*) Zones:

Top zone = one quarter of the total contents.
Middle zone = one half " "
Bottom zone = one quarter " "

	Top Zone.	Middle Zone.	Bottom Zone.
Fat	11·58	11·48	11·20
Proteins (N × 6·37)	9·74	9·68	9·59
Lactose	13·59	14·43	15·01
Cane-sugar	37·11	36·93	36·29
Mineral matter	2·15	2·13	2·16
Water	25·47	25·51	25·50

While the thicker consistency of the milk has rendered the separation of the various constituents less pronounced, it is more difficult to obtain a homogeneous sample by mixing.

IV. MILK OF MEDIUM CONSISTENCY, ONE AND A HALF MONTHS AFTER MANUFACTURE, NOT GRITTY.

The sample was divided into five equal zones.

	Top Zone.	Second Zone.	Third Zone.	Fourth Zone.	Fifth Zone (Bottom).
Lactose	13·02	13·45	13·48	13·64	14·54
Cane-sugar	40·20	40·00	40·20	40·07	39·50

V. THIN MILK, SEVEN MONTHS AFTER MANUFACTURE, NOT GRITTY, divided into five zones, the top one of which is one-tenth of the total contents of the tin; the second, third, and fourth, one-sixth; and the fifth, the remainder, or a little less than half the contents of the tin.

	Top Zone.	Second Zone.	Third Zone.	Fourth Zone.	Fifth Zone.
Fat	12·00	10·03	9·49	9·04	8·12
Proteins (Bordas' method)	8·83	8·73	8·54	8·49	8·70
Lactose	6·04	10·43	11·47	12·53	16·43
Cane-sugar	44·23	43·80	43·55	42·82	41·88

From this last sample it is seen what enormous differences may arise with thin milk if the tins remain undisturbed for a long time.

The fall in the percentage of cane-sugar is only apparent, and follows the fall in the percentage of water (not shown in the above table); the cane-sugar is separated only to a very small extent. The excess of lactose, in the later zones depresses the percentage of all the other constituents.

None of the various samples mentioned above were gritty milks. In gritty milks it is found that a deposit forms on the bottom of the tin to an extent depending on the consistency of the milk. If the milk is very thin, a more or less compact layer is formed in a short time at the bottom of the tin. In such a case the only means of obtaining a correct analysis of the milk is to dissolve the whole contents in water.

We have already mentioned that among the lactose crystals there are generally also some cane-sugar crystals. At times this latter sugar amounts to a considerable portion of the separated crystals, but as a rule its percentage is very small.

It is possible that the separation of the constituents which takes place in the tins occurs also during the process of manufacture of the condensed milk, although to a lesser degree, and only under certain conditions. That is why one finds now and again tins of the same manufacture whose contents have not exactly the same composition. This has certainly been the case in our sample No. 1, where *c* does not correspond entirely with the fresh milk from which it has been made.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Estimation of Aconitine by Silicotungstic Acid. H. Ribaut. (*Bull. Sci. Pharmac.*, 1910, **17**, 634-639; through *Chem. Zentralbl.*, 1911, **1**, 431.)—On an investigation of the method, the following points were established: The composition of the aconitine silicotungstate depends on that of the liquid in which the precipitate is formed. The latter contains more silicotungstic acid the greater the quantity of nitric or of silicotungstic acid present. These acids also increase the solubility of the aconitine silicotungstate, nitric acid having more effect than silicotungstic acid. Under the conditions prescribed in the French Codex—*i.e.*, in presence of a liquid containing 2·3 per cent. of nitric acid and 0·5 per cent. of free silicotungstic acid—Ecalle's factor, 0·793, gives satisfactory results. For practical purposes, under the prescribed conditions, a correction for the solubility of the precipitate may be dispensed with. The formula of aconitine silicotungstate in no way corresponds with Bertrand's general formula, $SiO_2.12WO_3.2H_2O.4Alkaloid + nH_2O$. The composition given by Ecalle, $SiO_2.12WO_3.2H_2O.3{\cdot}5Aconitine + nH_2O$, only holds good for a definite concentration of the liquid in nitric acid and silicotungstic acid. J. F. B.

Estimation of Atropine. Titration of the Alkaloids in Belladonna Extracts. M. Javillier. (*Bull. Sci. Pharmac.*, 1910, **17**, 629-634; through *Chem. Zentralbl.*, 1911, **1**, 430.)—The alkaloid solution should not be too dilute, since the atropine silicotungstate is not perfectly insoluble in water. The solution is acidified with hydrochloric acid until it contains 1 to 2 per cent. of the acid; a 10 per cent. solution of silicotungstic acid is then added drop by drop, with agitation, avoiding any considerable excess of the reagent. The liquid is allowed to stand for twenty-four hours, the precipitate is filtered or centrifuged off, washed with 1 per cent. hydrochloric acid, and incinerated. The atropine equivalent is found by multiplying the weight by 0·4064, and 0·0048 grm. per 100 c.c. is added to the result, to correct for the solubility of the silicotungstate, disregarding the volume of the washings. The precipitation may be effected either hot or cold, but prolonged boiling must be avoided. This process may be employed for the estimation of atropine in belladonna extracts. In this way the author found that certain commercial extracts showed as much as 55 per cent. less atropine than was found by the volumetric method of the French Pharmacopœia. Examination proved that the silicotungstate method gave the true quantity of atropine present. J. F. B.

Quantitative Estimation of Morphine. R. Gottlieb and O. Steppuhn. (*Arch. exp. Path. u. Pharmak.*, 1910, **64**, 54-66; through *Chem. Zentralbl.*, 1911, **1**, 430.)—The authors describe a method, originally indicated by Rübsamen, for the estimation of morphine. The morphine is extracted from the aqueous solution by means of chloroform, and is titrated according to Gordin's method. The morphine is dissolved in about 200 c.c. of water, and the liquid is made slightly alkaline to phenolphthaleïn; the extraction is then carried out by agitating five times with successive quantities of pure chloroform previously washed with water, 600 c.c. in all being used. If the alkaline reaction be strong, the extraction is less complete and less accurate, in consequence of the formation of acid decomposition products of the chloroform. The chloroform is distilled off from the extract, a measured quantity of $\frac{N}{10}$ sulphuric acid is added to the residue, the latter is dissolved in absolute alcohol, the solution is diluted to 100 c.c. with Wagner's reagent, filtered, and an aliquot portion of the filtrate is taken for titrating back the sulphuric acid in excess. One c.c. of $\frac{N}{10}$ sulphuric acid corresponds to 0·0285 grm. of morphine. Small quantities (0·05 to 0·1 grm.) of morphine may thus be estimated with an accuracy of about 96 per cent.

J. F. B.

Estimation of Nicotine in Concentrated Tobacco Juices. H. Ulex. (*Chem. Zeit.*, 1911, **35**, 121.)—The author describes a method which has been used by him for a number of years. Ten grms. of the sample are weighed out in a porcelain dish, and diluted with 1 to 3 c.c. of water, according to the consistence of the extract. A mixture of 1 part of soda-lime and 5 parts of calcined gypsum is then mixed with the liquid in sufficient quantity to produce a coarse powder. This is ground in a mortar with gentle pressure, and is passed through a hair sieve with about 220 meshes per square cm. The particles remaining on the sieve are again ground with a little more of the mixture, until the whole has been sifted. In mixing the liquid with the soda-lime, the quantity taken should be such that all tendency to heating is avoided. The total mixture will now amount to about 50 grms.; the ammonia will be volatilised, and the free nicotine remain behind. The elimination of the ammonia is completed by exposing the powder over sulphuric acid in a desiccator for about an hour. The nicotine is then distilled over in a current of steam. For the distillation, a tin can of about 3 litres' capacity is employed. This is charged with 1·5 litres of water heated almost to boiling; the dry powder is then introduced quickly, together with 3 to 4 grms. of sodium hydroxide and 4 grms. of paraffin wax to prevent frothing. The can is connected with the condenser, and 1 litre is rapidly distilled off. Distillation is then interrupted, and 1 litre of boiling water is added to the contents of the can, a second litre of distillate being collected in a separate vessel. The nicotine in the distillates is titrated with $\frac{N}{2}$ hydrochloric acid in presence of litmus. The method has been proved to give good results, and no evaporation of nicotine takes place during the elimination of the ammonia in the manner described. If this method appears to yield higher results than some of the methods depending on extraction, this is due to the incompleteness of the extraction, and not to a fault in the method described above (*cf.* ANALYST, 1911, **106**).

J. F. B.

Volumetric Estimation of Quinine in Drugs, etc. J. Katz. (*Ber. Deutsch. Pharm. Ges.*, 1910, **20**, 316-329; through *Chem. Zentralbl.*, 1911, **1**, 44-45.)—The process consists in evaporating an alcoholic solution of the alkaloid with hydrochloric acid, sodium chloride being added in order to expel the excess of the acid, and then titrating the quinine hydrochloride with potassium hydroxide solution, using Poirrier's blue as indicator. As applied to the estimation of quinine in cinchona bark, etc., the process is as follows: Six grms. of the dried and powdered bark are shaken with 15 grms. of chloroform and 5 grms. of a 5 per cent. sodium hydroxide solution for half an hour. Forty-five grms. of ether and about 1 grm. of magnesia are then added, and, after shaking, the liquid portion is passed through a filter. Forty grms. of the filtrate are evaporated to a volume of about 1 c.c., the residue is rinsed into a basin with 9 c.c. of alcohol, 10 drops of hydrochloric acid and 0.25 grm. of sodium chloride are added, and the mixture is evaporated to dryness. A further quantity of alcohol is added, and the evaporation is repeated, the residue being then dissolved in 25 c.c. of alcohol, and the solution titrated with $\frac{N}{10}$ alcoholic potassium hydroxide solution after the addition of 5 drops of a 0·2 per cent. Poirrier's blue solution. The number of c.c. of alkali required for the titration multiplied by 0·405 gives the percentage quantity of quinine in the bark. The addition of the magnesia is for the purpose of precipitating the colouring matters present in the bark.

W. P. S.

Colorimetric Estimation of Strychnine. E. Scandola. (*Boll. Soc. Med.-chirug. di Pavia*, 1910; through *Chem. Zentralbl.*, 1911, 1, 593-594.)—The method depends on the production of a red coloration when strychnine is treated with Mandelin's reagent (1 grm. of ammonium vanadate dissolved in 200 grms. of H_2SO_4,H_2O). The strychnine solution under examination is evaporated to dryness on a water-bath, and the residue is well mixed with 2 c.c. of the reagent. After the red coloration has developed, 10 c.c. of water are added, the solution is transferred to a graduated cylinder, and diluted to a volume of 100 c.c. The coloration is then compared with that produced by a known quantity of strychnine under similar conditions. Substances other than strychnine must not be present. The red coloration remains unaltered for several days; it then changes gradually to violet.

W. P. S.

Analysis and Composition of Jams. F. Hartel and J. Solling. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, 21, 168-196.)—In the analysis of jams estimations of the following constituents afford useful evidence as to the character and quality of the jam: Insoluble matter, soluble solids, total acidity, sugars before and after inversion, sugar-free extractives, starch syrup, mineral matters (total, soluble, and insoluble). The sample should also be tested for the presence of agar, dextrin, added colouring matter, and preservatives. Agar may be detected by boiling 30 grms. of the sample with 270 c.c. of water, filtering the solution, and cooling the filtrate; if agar is present, a precipitate forms within twenty-four hours. The precipitate may be collected, dissolved in a little hot water, and the solution cooled so as to form a jelly. A microscopical examination of the jam should also be made. The starch syrup, when present, was estimated as follows: A solution of the soluble constituents is prepared—100 grms. of the solution containing the soluble solids from 20 grms. of the jam; this solution is employed in the polarimetric determinations from the results of which the quantity of starch syrup present is calculated by means of the formulæ given below. E_D = the soluble solids as calculated from the sp. gr. of the solution; E_J = the soluble solids after inversion, calculated by Clerget's formula (100 grms. of sucrose yielding 105·265 grms. of invert sugar); $[\alpha]_{D20}E_{DV}$ = the specific rotation of E_D before inversion; $[\alpha]_{D20}E_{DN}$ = the specific rotation of E_D after inversion; $[\alpha]_{D20}E_J$ = the specific rotation of E_J; $+134{\cdot}1 = [\alpha]_{D20}$ of water-free starch syrup; $-20{\cdot}42 = [\alpha]_{D20}$ of invert sugar; $St.E_J$ = water-free starch syrup in E_J; St.M = water-free starch syrup in the jam; and w.St.M = the percentage quantity of ordinary starch syrup (containing 18 per cent. of water) in the jam.

$$E = \frac{[([\alpha]_{D20}E_{DV} - [\alpha]_{D20}E_{DN}) \times 1{\cdot}1365 \times 1{\cdot}05265] - [([\alpha]_{D20}E_{DV} - [\alpha]_{D20}E_{DN}) \times 1{\cdot}1365].E_D}{100} + E^D$$

$$[\alpha]_{D20}E_J = \frac{E_D \times [\alpha]_{D20}E_{DN}}{E_J},$$

$$St.E_J = \frac{(100.[\alpha]_{D20}E_J) - (100 \times -20{\cdot}42)}{+134{\cdot}1 - (-20{\cdot}42)},$$

$$St.M = \frac{St.E_J \times E_J}{100}$$

$$w.St.M \quad \frac{St.M \times 100}{82}.$$

Results of analyses of 128 samples of various jams are given, the analyses shown in the following table being selected from the figures recorded:

	Insoluble Matters.	Soluble Solids.	Acidity (as Malic Acid).	Invert Sugar.	Sucrose.	Sugar-free Extractives.	Mineral Matters.	Alkalinity of Mineral Matters.	
								Soluble.	Insoluble.
Raspberry ...	7·40	59·12	1·05	—	—	—	0·355	—	—
Raspberry ...	5·14	70·05	1·08	39·46	26·89	3·70	0·372	4·07	0·87
Raspberry (after removal of juice)	21·68	36·32	—	5·42	20·37	10·53	0·747	7·27	1·79
Apricot	1·90	80·66	1·87	52·53	21·38	6·75	0·567	—	—
Apricot (from dried fruit) ...	3·92	28·08	1·54	—	—	—	1·600	13·81	0·62
Strawberry ...	2·37	73·45	1·22	36·60	32·82	4·03	0·410	4·18	0·99

Orange	2·13	70·83	0·12	46·09	23·29	1·44	0·171	1·10	1·10
Quince	5·41	57·95	0·68	30·56	15·76	5·63	0·298	2·90	0·30
Quince jelly ...	0·03	73·20	1·06	54·14	12·58	6·48	0·576	—	—
Pumpkin ...	1·28	63·98	0·03	3·26	58·03	2·69	0·336	—	—
Gooseberry ...	2·74	57·98	1·12	46·90	5·24	5·84	0·270	2·00	0·50

The alkalinity is expressed in c.c. of $\frac{N}{1}$ acid per 100 grms. of jam. The above samples represent genuine jams, many of them having been prepared by the authors themselves. Of the whole number of samples examined, five contained agar, thirty-seven added colouring matters, and twenty starch syrup; many of the jams contained apple pulp, whilst one (a mixed jam) contained beetroot and another (also a mixed jam) rhubarb.

W. P. S.

Adulterant of African Sandal-Wood Oil. W. Lenz. (*Ber. Deutsch. Pharm. Ges.*, 1910, **20**, 351-358; through *Chem. Zentralbl.*, 1911, **1**, 23.)—The bark of the karambusi tree (*Warburgia Stuhlmanni Engl.* Order. *Winteranaceæ Canallaceæ*) is found in the Zanzibar markets along with sandal-wood; it yields an oil which is very similar to sandal-wood oil, and it is possible that it may be used to adulterate the latter oil. When distilled with steam, karambusi bark yields 0·6 per cent. of a viscous, yellowish-red oil, having an odour like that of sandal-wood oil. The oil has a sp. gr. of 0·9864 at 20° C., $[\alpha]_D = -41{\cdot}77$, and $[n]_D = 1{\cdot}51269$; it is soluble in its own volume of 90 per cent. alcohol, but is insoluble in 70 per cent. alcohol. The saponification value of the oil is 11·2, and the acetyl value 100·3. The residue remaining after the distillation of the bark yields mannitol, tannin, bitter substances, etc.

W. P. S.

Improvement in the Method of Malt Analysis. J. O'Sullivan. (*J. Fed. Inst. Brew.*, 1911, **17**, 35-48.)—The O'Sullivan method of estimating starch in malt involves the preliminary removal of the constituents other than starch by means of ether, alcohol, and water, after which the starch originally present is calculated from the maltose and dextrin obtained by treatment with diastase. The new method depends on the fact that extraction with water alone is all that is necessary. The author states that the standard method of analysing malts (*J. Fed. Inst. Brew.*, 1906, **12**, 1), while showing total brewers' extract, gives no information as to the composition of the transformation products, and he points out how this may be ascertained, and also how the transforming power (T.P.) of the malt can be expressed from the composition of the products of hydrolysis yielded by the "starch of the malt." By the following process the estimation of starch in malt can be deduced to within ± 2 per cent.:

Cold-Water Extract.—$\frac{N}{10}$ potassium hydroxide, in place of $\frac{N}{10}$ (*cf.* standard method, *loc. cit.*) ammonia is used. The sp. gr. of the solution is taken = (b). The cupric oxide reducing-power is determined gravimetrically on 20 c.c., and the result expressed as maltose per 100 c.c. (d).

Mash Extract.—Fifty grms. of the malt are warmed in the mashing flask to 60° to 61° C., and 360 c.c. water added at 68° C. The mashing is continued for one hour, and during the last ten minutes the temperature is raised to 75° C. The whole is made up to 515 c.c. at 60°, filtered, the sp. gr. (a) and cupric oxide reducing-power of 3 c.c. of the filtrate determined (c). Then $(a-b)$ = the sp. gr. and $(c-d)$ the grms. of maltose per 100 c.c. of the mash extract due to starch products, and $\frac{(a-b)}{4} - 0{\cdot}04$ = grms. of starch products per 100 c.c. (e) (this 0·04 is deducted for the increased amount of protein matter soluble in the hot mash). $\frac{(c-d)\times 100}{e}$ = percentage of maltose in starch products. The dextrin (f) is obtained from the formula $e-(c-d) = f$; and $\left\{f+\frac{c-d}{1{\cdot}055}\right\} \times 10$ = percentage of starch in the malt, where f = dextrin in grms. per 100 c.c. The transforming power (T.P.) of the malt is taken as the percentage of maltose produced from its own starch, and the percentage of starch in a malt so obtained agrees closely with that obtained by the original O'Sullivan method. All the fat is left in the grains in the new method; it is also shown that the cane-sugar in the malt is not inverted either in the cold or hot water extraction.

The following figures illustrate the nature of the results obtained:

Malt.	Grms. of Starch in 10 Grms. of Malt. Improved Method.	Diastatic Activity by— Improved Method. Per Cent. Maltose on Starch Products.	Diastatic Activity by— Improved Method. T.P. $\frac{\text{Grms. Maltose} \times 100}{\text{Grms. Starch.}}$	Lintner's Method. D.P.
1	4·240	84·05	87·9	51
4	3·532	89·33	93·6	40
7	4·629	87·10	91·2	49
11	4·515	79·10	82·0	58
12	4·506	79·10	82·0	44
18	4·384	58·40	60·2	13
19	4·925	78·90	82·3	26
20	4·890	85·68	89·7	31

The above figures indicate:

(1) In some cases the hydrolysis of the starch has gone beyond the so-called "resting stage," and exceeds 84·4 per cent. of maltose on the starch. (2) That there is no relationship between the D.P. Lintner and the maltose produced. (3) That the T.P. number shows the maltose obtained from the starch of the malt under standard conditions, and is an index of how the malt will behave in practice as regards its starch hydrolysis.

The distiller can calculate by this new method how much alcohol a given malt will produce. The cane-sugar in the cold-water extract of the malt must first be estimated by neutralising the alkaline cold-water extract, and digesting 10 c.c. with 0·01 grm. invertase for an hour at 55° C. The increase in the cupric reducing power as dextrose per 100 c.c., divided by 1·0526, gives the cane-sugar in 10 grms. of malt. The yield of alcohol from starch is 57 per cent.; cane-sugar, 53 per cent.; and approximately from the mixed sugars dextrose, levulose, and maltose, 52 per cent. If, therefore, the starch per cent. is multiplied by 0·57, the cane-sugar by 0·53, and the sugars as maltose by 0·52, the results when added give the theoretical yield of alcohol per cent. from the malt. In a malt 6·3 per cent. of alcohol was obtained from the cold-water extract, as compared with 6·4 calculated, and 28·7 per cent. from the fermentation of the unboiled hot mash, as compared with 28·6 calculated.

H. F. E. H.

New Constant in the Analysis of Pepper. C. Arragon. (*Schweiz. Wochenschr. Chem. Pharm.*, 1911, **49**, 46-47; through *Chem. Zentralbl.*, 1911, **1**, 593.)—A determination of the iodine value of a sample of pepper is recommended as affording a means of ascertaining the purity of the sample. If foreign starch be present, the iodine value gives, approximately, the quantity of the adulterant. Two grms. of the finely powdered sample are mixed with 15 c.c. of chloroform and 25 c.c. of Hübl's reagent, and, after four hours' contact, the excess of iodine is titrated with thiosulphate solution. During the titration the mixture must be shaken thoroughly, as the powder occludes unabsorbed iodine. Thirty samples of pure pepper yielded iodine values of from 16·1 to 18, whilst four samples, containing 60 per cent. of rice starch, gave iodine values of 7·5. There is advantage in determining the iodine value on the chloroform extract of the sample. W. P. S.

Estimation of Tartaric Acid. A. Heczko. (*Zeitsch. anal. Chem.*, 1911, **50**, 12-21.)—Though Goldenberg's method (ANALYST, 1908, **33**, 200) is in almost universal use, yet serious differences are occasionally recorded between the results obtained by different chemists, and it is shown that the method always tends to give low results (see also Ordonneau, ANALYST, 1911, 81). These low results, which in the most favourable circumstances are seldom less than 0·4 to 0·5 per cent. below the truth, are in the main due to the fact that potassium bitartrate is not wholly insoluble in alcohol, and to the action of neutral potassium tartrate on freshly precipitated calcium carbonate. The errors due to the former cause may be eliminated by treating the potassium bitartrate used for standardising the caustic alkali exactly as though it were a sample of argol to be analysed, instead of titrating it directly. It is also pointed out that, for material of high lime content, the amount of potassium carbonate specified by Goldenberg is insufficient, and in such cases the total tartaric acid may be seriously underestimated. The use of 15 c.c. instead of 10 c.c. of 66 per cent. potassium carbonate as a matter of routine would avoid this occasional source of error. Finally, it is suggested that some of the differences recorded between different workers' results may be due to mechanical loss during the evaporation to 15 c.c. before addition of acetic acid and alcohol. The author conducts this operation in a 300 c.c. Erlenmeyer flask set with its axis horizontal. G. C. J.

Estimation of Total Tartaric Acid. A. Heczko. (*Zeitsch. anal. Chem.*, 1911, **50**, 73-82.)—The results of an investigation of a process proposed by Moszczenski (*J. Soc. Chem. Ind.*, 1898, **17**, 215) are given. Whilst the method is more rapid than the Goldenberg process, and yields accurate results when applied to pure tartrates, in the case of crude tartrates it gives results which are from 1 to 2 per cent. too high. The details of the method are: Three grms. of the sample containing more than 45 per cent. of tartaric acid, or 6 grms. when the tartaric acid is less than 45 per cent., are boiled for two minutes with 20 c.c. of $\frac{N}{2}$ sulphuric acid; after cooling, the mixture is rinsed into a 200 c.c. flask with 93 per cent. alcohol, well shaken, and diluted with alcohol to the mark. When the precipitate has settled, the liquid portion is filtered, and 100 c.c. of the filtrate are transformed to a 300 c.c. Erlenmeyer flask. Three c.c. of glacial acetic acid and 10 drops of a saturated potassium chloride solution are added, and 16 c.c. of an alcoholic potassium acetate solution (20 grms. of the salt to 100 c.c. of alcohol) are run in drop by drop from a burette, with continual stirring. The mixture is stirred for a further five minutes, allowed to settle for thirty minutes, and the liquid portion is then passed through a filter. The precipitate is washed twice with 40 c.c. of 97 per cent. alcohol, brought on to the filter, and there washed with about 80 c.c. of alcohol. The precipitate is then dissolved in 200 c.c. of hot water, and the boiling solution is titrated with $\frac{N}{5}$ potassium hydroxide solution, using litmus-paper as indicator. The alkali solution is standardised on 1·5 grms. of pure potassium hydrogen tartrate after this has been submitted to the above treatment, but using only one half of the quantities of the reagents mentioned. W. P. S.

Estimation of Tin in Canned Foods. H. Schreiber and W. C. Taber. (*U.S. Department of Agriculture, Bureau of Chemistry, Circular No.* 67, February 8, 1911, pp. 1 to 9.)—The authors have critically examined several methods for determining tin in canned meats, fish, and vegetables, and, whilst agreeing that the method of Schryver (ANALYST, 1909, **34**, 121) by moist combustion with sulphuric acid is accurate, yet, they state, it is open to the objection that not more than 25 grms. of material can be digested in one flask, with a consequent large multiplication of any analytical error. The digestion is further stated to be accompanied by foaming of the material, and to require considerable experience. For these reasons the authors prefer their alkali-fusion method, except in the case of salted fish, etc., containing large amounts of salt, which prevents the ready burning off of the carbon after fusion.

The method is conducted as follows: Obtain a homogeneous sample by passing the material through a meat-grinding machine, and treat 100 grms. of the mixed sample with 10 grms. of magnesium oxide in an 8-ounce wrought-iron crucible. Stir thoroughly into the mixture 50 c.c. of an aqueous solution containing 150 grms. sodium hydroxide and 100 grms. sodium carbonate per litre, add 75 c.c. of alcohol (95 per cent.), and again stir. Evaporate the alcohol carefully on the steam-bath, with frequent stirring to avoid frothing and bumping, removing the crucible occasionally from the source of heat if necessary. After a time the material boils quietly. After about one hour's heating at 100° C., transfer the crucible to a hot-plate covered with a thin sheet of asbestos, and gradually evaporate to dryness, the temperature of the asbestos at first registering 130 to 160° C. Finally raise the temperature and boil down to dryness, this requiring about one and a half to two hours. Place the crucible in a cold muffle, heat gradually, finally burning off the carbon completely (two to three hours). When cold, cover the residue in the crucible with water, and, after standing a few minutes, transfer the contents to a beaker, add 40 c.c. of diluted sulphuric acid (1 : 1) to the latter, and wash out the crucible with water and 10 c.c. of this acid, scraping the sides of the crucible with an iron spatula. To the mixed solutions in the beaker now add 50 c.c. of strong sulphuric acid and 30 c.c. of strong nitric acid. Boil briskly on the hot-plate until fumes of sulphuric anhydride are evolved for ten minutes. Allow the liquid to cool, and when just cold (not solidified) carefully run in under the cover-glass small successive quantities of water until violent action is over. Then add 150 to 200 c.c. water, stir, and wash into a litre Erlenmeyer flask, the total volume of the liquid being 300 to 400 c.c. Next pass a stream of hydrogen sulphide gas for a few seconds into the cool liquid, shake the flask, and add ammonia slowly till the black ferrous sulphide just persists on shaking. Make acid with diluted sulphuric acid (1 : 1), adding 10 c.c. acid in excess. Dilute the liquid to 1 litre with boiling water, and continue a rapid stream of hydrogen sulphide for twenty-five minutes, and then cork the flask and allow to stand overnight. Heat the liquid next day at 100° C. for half an hour, with shaking, and after partial cooling filter the solution, washing the precipitate on the paper six times with a solution containing 50 c.c. of glacial acetic acid and 100 c.c. of saturated ammonium acetate solution per litre. Treat the washed precipitate, returned with the paper to the flask, with 100 c.c. of potassium hydroxide solution (20 per cent.), boiling for a few minutes till the solution is clear. Decant the solution through a double filter-paper, washing till the filtrate is colourless and measures about 200-300 c.c. Add 20 c.c. of strong hydrochloric acid to the filtrate, stir, and continue adding hydrochloric acid in presence of phenolphthaleïn till the liquid is just acid; then add 1 c.c. acid in excess, testing the acidity of the solution with litmus-paper. Stir well and heat at 100° C. for twenty minutes, and again leave overnight.

Test the reaction of the clear supernatant liquid with litmus-paper. If not acid, render acid with strong hydrochloric acid, and then add 1 c.c. in excess. If the liquid after standing overnight is acid and turbid, make alkaline with potash, and then acid with 1 c.c. excess. The liquid must not be alkaline nor too acid, or filtration will be difficult. Stir occasionally during half an hour's heating on the steam-bath. Filter, returning the filtrate to the paper again till perfectly clear. If the liquid is vigorously stirred, and then allowed to rest till the precipitate clots, filtration and washing are usually easy. Wash alternately with water and the ammonium acetate wash-water, till the filtrate is free from chlorides. Dry and ignite the precipitate with the paper in a porcelain crucible, cool, and weigh as stannic oxide.

The method gives good results, as shown by the following analyses in comparison with Schryver's method:

	Schryver's Method. Sn per cent.		Alkali-Fusion Method. Sn per cent.
Mushrooms	0·0385; 0·0366; 0·0355	...	0·0370

Fish	0·0338; 0·0386	...	0·0332

A. R. T.

Analysis of Oils of Turpentine. II. F. W. Richardson and J. E. F. Whitaker. (*J. Soc. Chem. Ind.*, 1911, **30**, 115-117.)—In reply to the criticisms of Coste (ANALYST, 1910, **35**, 112), the authors point out that Borneo petroleum (which is rich in aromatic hydrocarbons) differs widely from American petroleum, the products of which are principally used for the adulteration of turpentine. They have never yet met with any turpentine substitute or adulterant composed of Borneo petroleum spirit, and their information is that for a very long period no Borneo spirit has been imported into Europe. Samples of American and Borneo "daylight petroleum" gave the following results:

	Borneo.		American.
Sp. gr. at 15·5° C.	0·81364	...	0·80192
Refractive index at 15·5° C. ...	1·4549	...	1·44474
Iodine value (Hübl), sixteen hours	1·65	...	—

These differences were much accentuated in the fractions obtained on distillation:

Fraction at—	Volume per Cent.		Sp. Gr. at 15·5° C.		Refractive Index at 15·5° C.	
	Borneo.	American.	Borneo.	American.	Borneo.	American.
°C.						
1. 126-149	8·0	9·8	0·8090	0·7500	1·4533	1·4180
2. 149-154	21·2	3·6	0·8104	0·7548	1·4541	1·4211
3. 154-161	28·5	3·4	0·8114	0·7580	1·4545	1·4229
4. 161-165·5	13·4	3·0	0·8130	0·7618	1·4546	1·4255
5. 165·5-171	10·6	2·8	0·8134	0·7652	1·4547	1·4286
6. 171-177	8·2	2·4	0·8142	0·7713	1·4547	1·4286
Residue	10·1	75·0	0·8236	—	1·4586	—

The barium sulphate value estimated in the following manner showed that Borneo petroleum undoubtedly contains a large proportion of aromatic hydrocarbons. Five c.c. of the liquid were heated for an hour on a water-bath beneath a reflux condenser, with 8 c.c. of a mixture in equal parts of sulphuric acid (sp. gr. 1·82) and fuming sulphuric acid, the flask being shaken from time to time. The liquid was then cooled, diluted, and poured on to 30 grms. of barium carbonate in a large dish, the mixture made up to 500 c.c., and 100 c.c. (=1 c.c. of the original sample), separated by filtration, boiled to decomposed barium bicarbonate, and the barium estimated as sulphate in the filtrate. The number of mgrms. (less 5 mgrms., the correction for the barium sulphite produced by the reduction of the sulphuric acid to sulphurous acid) gives the barium sulphate coefficient. The following average figures were thus obtained: Benzene (commercial), 1083; Borneo petroleum, 523; American petroleum, 99; American motor spirit, 90; and American turpentine, 98. The barium sulphate value would thus detect benzene if used as an adulterant of turpentine oil; whilst if Borneo spirit were to be used for this purpose, the addition might be detected by this value and by the iodine value. Benzene may be separated from turpentine by distillation with the aid of a Young's still-head. Over 90 per cent. of commercial benzene passes over below 82° C., and the distillates show a uniform sp. gr. of 0·884, and a refractive index of 1·499 at 15·5° C. Morrell's modification of Armstrong's method (ANALYST, 1910, **35**, 218), in which the unpolymerised portions are not separated before distillation, does not give more accurate results than the original process of Armstrong. A mixture of unknown composition analysed by the authors' methods and by the method of Armstrong gave the following results:

Oil Constituents.	Present.	R. and W.'s Methods.	Errors.	Armstrong's Method.
	Per Cent.	Per Cent.		Per Cent.
Turpentine ...	47·6	49·9	+2·3	67·2 (diff.)
Petroleum ...	20·0	19·6	−0·4	32·8
Gasolene	21·65	21·0	−0·65	
Benzene	10·75	9·5	−1·25	

On the other hand, polymerisation with sulphuric acid by Armstrong's method is valuable as a qualitative test for detecting petroleum products in turpentine oil. Thus, a sample of turpentine (sp. gr. at 15·5° C., 0·84292; refractive index at 15·5° C., 1·4630; and iodine value, 257) was found by the authors' distillation process to contain 19·6 per cent. of petroleum products. A sample of genuine turpentine and of this suspected sample examined by Armstrong's method yielded small amounts of unpolymerised liquids with the following characteristics:

	Genuine Turpentine.	Suspected Sample.
Sp. gr. at 15·5° C.	0·8594	0·7994
Refractive index at 15·5° C. ...	1·4760	1·4482

Samples of different kinds of turpentine recently examined have given the following results:

	American.	French.	Russian.	Swedish.
Sp. gr. at 15·5° C.	0·86864 to 0·87224	0·86908 and 0·86805	0·36608	0·8650 and 0·86776
Refractive index at 15·5° C.	1·4695 to 1·4722	1·4705 and 1·4706	1·4710	1·4740 and 1·4772
Iodine value (Hübl), sixteen hours ...	353 to 440	402, 402	276	315 and 255
Barium sulphate factor	90 and 98	103 and 113	139	140
Polarimeter reading $[\alpha]_D$	+78°	−32·3° and −31·5°	+12·6°	+12·75°

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Modification of Heller's Ring Test for the Detection of Albumin in Urine, etc. F. Michel. (*Chem. Zeit.*, 1911, **35**, 183.)—Heller's ring test for albumin is rendered less liable to error by increasing the sp. gr. of the nitric acid by dissolving in it an inert substance, and especially ammonium nitrate. About 2 c.c. of the reagent thus prepared are placed in a test-tube, and 1 c.c. of the urine, or other solution under examination, added drop by drop with the aid of a pipette. In the case of a large amount of albumin being present, a sharply-defined ring is immediately produced, whilst when only traces are present it appears after a short time. On shaking the tube the two layers slowly mix. In the presence of albumin the upper layer becomes turbid, whereas when ordinary nitric acid is used in the test the turbidity first produced on mixing the two liquids speedily dissolves. On heating the turbid solution with continual shaking it becomes clear; but when the tube is again cooled, the albumin once more separates as a more or less pronounced turbidity. In the test with ordinary nitric acid, the albumin is immediately decomposed in the cold, and the solution cannot again be made turbid. If water is added to the upper turbid layer, there is a still more pronounced turbidity. The albumin deposit may be dissolved somewhat more rapidly by adding a large amount of acetic acid before heating. On then cooling the liquid there is only a relatively small turbidity produced, though it becomes more pronounced on adding a large quantity of water. C. A. M.

Colorimetric Detection of Oxidising Substances in Animal Organs. W. Loele. (*Munch. med. Wochenschr.*, 1910, **57**, 2414-2416; through *Chem. Zentralbl.*, 1911, **1**, 38.)—Certain cells, such as leucocytes, epithelium cells from the mouth, etc., yield coloured compounds when treated with an alkaline phenol solution; as this reaction takes place only in the presence of an oxidising agent, it appears that these cells contain an oxydase together with an amino base. A solution containing formaldehyde and naphthol absorbs oxygen from the atmosphere and becomes coloured first green, then blue, and finally grey-black; the colour is changed to red by acids and is soluble in chloroform. The addition of blood-serum, peptone, meat extract, or bile, accelerates the formation of the colour, whilst boiled meat extract is without influence. It is probable that this action of blood-serum, etc., is due to the presence of an oxidising enzyme. W. P. S.

Detection of Salvarsan, and its Differentiation from Inorganic Arsenic in Forensic Cases. G. O. Gaebel. (*Arch. Pharm.*, 1911, **249**, 49-56.)—Salvarsan (containing about 34 per cent. of arsenic) is now injected in doses of 0·6 to 1 grm. in syphilitic cases. Within half an hour of its introduction into the system, excretion by way of the kidneys begins, but several weeks later arsenic can still be detected in the urine, and even after tests fail to detect it there it can still be found in the body for another month. Salvarsan gives Reinsch's, Marsh's, and Gutzeit's tests for arsenic, and may be detected by the biological test with *Penicillium glaucum.* It may be distinguished from mineral arsenic by Bettendorf's reagent, which gives with it a yellow amorphous precipitate remaining unaltered for days. The precipitate dissolves on heating to form a clear solution, which when boiled gradually darkens, but does not give the typical arsenic reactions with hydrogen sulphide, etc. The readiness with which the organic complex in the molecule can be oxidised may be made the basis of several reactions. Thus, iron chloride gives an intense coloration from green to red, perceptible in a dilution of 1 : 15,000. Gold chloride gives a deep red colour; platinum chloride is slowly reduced in the cold; and Nessler's reagent is instantly reduced. The presence of the aromatic amino group in salvarsan may be detected by an azo reaction. Thus, if the solution is acidified with a few drops of hydrochloric acid, cooled to about 0° C., treated with sodium nitrite solution in slight excess (the excess being subsequently removed by the addition of urea till potassium iodide starch paper no longer turns blue), and then with a saturated solution of α-naphthylamine acidified with hydrochloric acid, there is gradually produced a red to violet-red colour, which becomes more intense on standing. In a solution of 1 : 15,000 the coloration does not appear for some hours in the cold, but its appearance is accelerated by heat. The reaction is characteristic of salvarsan when arsenic is detected in the azo colouring matter. To isolate the latter, the solution is saturated with sodium chloride and, after shaking for some minutes and standing for a few hours, is filtered from the precipitate. The contents of the filter are washed with sodium chloride solution, and dissolved in hot dilute hydrochloric acid, and the solution tested for arsenic by Reinsch's or Gutzeit's test. Atoxyl also forms a red azo colouring matter with α-naphthylamine under these conditions, but the coloration is immediately produced. The two compounds may be distinguished by the fact that β-naphthylamine gives no coloration with diazotised salvarsan, whereas in the case of atoxyl there is produced an immediate onion-red azo colouring matter. To the presence of the amino group must also be ascribed the blue coloration obtained when salvarsan solutions are treated as in the indophenol reaction

Concentrated hydrochloric acid gives a precipitate (salting out) with even very dilute solutions of salvarsan, and a nearly insoluble precipitate is produced with mercuric chloride. For the detection of salvarsan in organic material, the latter is digested for some hours at a gentle heat with several times its volume of 96 per cent. alcohol acidified with a few drops of hydrochloric acid. The liquid is then filtered, evaporated to a syrup at a moderate heat, and gradually treated with absolute alcohol until the precipitate ceases to increase, after which it is filtered and the filtrate freed from alcohol. The residue is taken up with water and filtered, and the united yellow-coloured filtrates are tested as described above. In all cases the author has succeeded in identifying the unaltered salvarsan. Experiments upon the quantitative estimation of the arsenic, in which the organic complex of the compound was destroyed by means of potassium chlorate and hydrochloric acid and the liquid distilled in a current of chlorine in the presence of iron chloride, gave fairly concordant results (*e.g.*, 29 and 29·5 per cent.), but deviating too far from the theoretical quantity (34·2 per cent.). The same result was obtained when a mixture of nitric and sulphuric acids was used to destroy the organic matter. A method in which the slightly acidified solution of salvarsan is titrated with $\frac{N}{10}$ iodine solution, with starch solution as indicator, has given promising results, the end-point of the reaction being quite sharp.

C. A. M.

Composition of the Gases of the Blood in Chloroform Anæsthesia. Estimation of the Chloroform. G. A. Buckmaster and J. A. Gardner. (*J. Physiol.*, 1910, **41**, 246-262; through *Chem. Zentralbl.*, 1911, **1**, 343.)—The dark colour of the blood during chloroform anæsthesia is due to the partial saturation with oxygen of the hæmoglobin, which in cases of profound narcosis is reduced to as low as 60 per cent. of the normal quantity. A chart of the respiration movements shows that this partial saturation does not depend upon a retardation of respiration, but, rather, is due to a combination of the chloroform with the blood-corpuscles, which deprives them of their power of conveying oxygen. For the estimation of chloroform in the gases of the blood, the best method was found to be combustion, in the presence of an excess of oxygen and water, by means of a glowing platinum spiral in a vessel closed with mercury. The reaction is as follows:

$$CHCl_3 + 2Hg + O_2 = CO_2 + 2HgCl + HCl.$$

This requires a diminution in volume equal to that of the volume of chloroform and of the carbon dioxide formed therefrom and absorbed by the water. The mean experimental results confirmed this assumption.

C. A. M.

Changes which Mercury Compounds undergo when in Contact with Organic Matters. W. Brunetti. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 92-94.)—When mercury is detected during the course of a toxicological analysis, the question may arise as to the form in which the metal is present in the animal organs under examination. With the object of ascertaining what changes, if any, take place in the composition of various mercury compounds when these have been for some time in contact with organic substances, the author has carried out a number of experiments, the results of which are given below. The various mercury compounds employed were mixed in quantities of about 0·2 grm. with portions of meat-juice prepared by extracting meat with cold water. After ten days' contact at the ordinary temperatures, the mixtures were acidified with tartaric acid and submitted to steam distillation for three hours. The metallic mercury or mercury compound passing over into the distillate was collected and weighed. This procedure showed that certain mercury compounds are decomposed by organic matter, and yield metallic mercury in the distillate, whilst others, though not decomposed, are themselves volatile. For instance, metallic mercury, mercuric sulphide, and mercuric cyanide are not altered by contact with organic matter, nor do they volatilise with steam; yellow mercuric iodide, although not reduced, is slightly volatile in steam, about 1 per cent. of the quantity present being found as such in the distillate. Red mercuric iodide is also volatile in steam, but it is found in the distillate as yellow iodide; about 18 per cent. of the red iodide is thus volatilised. Mercury ointment also yields mercury in the distillate, but the quantity found depends on the fineness of the particles of the metal in the ointment. The other mercury compounds used in the experiments were all reduced, and yielded distillates containing mercury. These compounds included mercuric peptonate (39·15), mercuric albuminate (32·45), mercuric chloride (30·68), mercurous chloride (19·11), mercurous nitrate (15·26), ammonium mercury chloride (15·01), mercuric acetate (11·34), mercuric oxide (8·73), and mercuric nucleinate (trace). The figures in parentheses indicate the quantities of volatile mercury in each case, calculated in percentages of the total amounts present. (*Cf.* Lecco, ANALYST, 1910, **35**, 259.) W. P. S.

Comparative Studies on the Valuation of Pepsin according to the Directions of Various Pharmacopœia. E. Hercod and T. Maben. (*Schweiz. Wochenschr. Chem. Pharm.*, 1911, **49**, 17-23; through *Chem. Zentralbl.*, 1911, **1**, 590-591.) —The experiments were carried out according to the directions prescribed by different Pharmacopœia. When pepsin is allowed to act on albumin or fibrin in the presence of an acid, and the mixture is analysed from time to time, the results obtained show that the amount of syntonin and proteoses diminishes, whilst the quantity of peptone gradually increases, the rate at which these changes take place depending on the proportion of acid to pepsin. As the quantities of acid and pepsin, the temperature and duration of the digestion, and the preparation of the albumin, vary with each Pharmacopœia, one and the same sample of pepsin may show different digestive powers according to the method by which it has been tested. This is seen from the results given in the following table:

Pharmacopœia.	Acidity of Solution, Per Cent. HCl.	Ratio of Acid to Pepsin.	Temperature of Digestion.	Duration of Digestion (Hours).	Time the Albumin is Boiled (Minutes).	Time the Albumin is Dried (Minutes).	Activity of Pepsin (Pepsin : Albumin).
Belgian	0·25	250 : 100	40° C.	1	10	10	1 : 100
British	0·20	5000 : 100	40·5° C.	6	15	12	1 : 2500
German	0·125	125 : 100	45° C.	1	10	10	1 : 100
Italian	0·09	90 : 100	38° to 40° C.	1 to 2	—	—	1 : 100
Swiss	0·20	200 : 100	40° C.	1 to 2	5	15	1 : 100
American	0·30	3500 : 100	52° C.	2½	15	16	1 : 3000
French	0·25	150 : 100	50° C.	6	—	—	1 : 25 (fibrin)

The authors suggest that the test should be carried out under the following conditions, etc., in order that uniform results may be obtained: Acidity of solution 0·25 per cent. hydrochloric acid, ratio of acid to pepsin 250 : 100, temperature of digestion 52° C., time of digestion 2 hours, time the albumin is boiled 10 minutes, time the albumin is dried 15 minutes, ratio of pepsin to albumin 1 : 2000.

W. P. S.

Analysis of Zygadenus Intermedius ("Death Camas"). F. W. Heyl and L. C. Raiford. (*J. Amer. Chem. Soc.*, 1911, **33**, 206-211.)—The several species of *Zygadenus* are the cause of heavy stock losses, particularly amongst sheep, which have occurred in Montana, Wyoming, and other of the North-Western States of America. The animals appear to suffer most during early spring when the plant is in flower, and after rains. The plant, which contains one or more poisonous principles, has a relatively high food-value as a whole, and the bulb contains a large percentage of sugar. From a chemical examination, Slade (*Amer. J. Pharm.*, 1905, **77**, 262) concluded that the poisonous alkaloids sabadine, sabadinine, and veratralbine were present.

During grinding of the dry plants, it was noticed that the "dust" was extremely irritating (possibly due to veratralbine). The following figures were obtained on analysis of the various parts of the plant:

	Leaf.	Flower.	Bulb.	Root.
Moisture	6·91	6·13	7·50	7·56
Starch (diastase method) ...	none	none	23·53	none

Volatile ether extract	1·33	1·07	1·30	0·80
Alcohol extract	35·12	46·27	39·60	—
Analysis of Alcohol Extract:				
Resin	5·03	—	2·58	5·00
Sucrose	5·60	—	18·44	1·02
Reducing sugar (calculated as invert sugar)	5·89	—	6·69	2·45

By using a modified process, similar to the U.S.P. method for the assay of belladonna leaves, the authors obtained the following amounts of crystalline alkaloidal residues: Leaf, (*a*) 0·41 per cent.; (*b*) 0·28 per cent.; (*c*) 0·26 per cent.; bulb, 0·39 per cent. and 0·24 per cent. The investigation is being continued.

A. R. T.

ORGANIC ANALYSIS.

Quantitative Estimation of Acetaldehyde by Means of Pyrrol, and the Application of this Method to the Estimation of Lactic Acid. W. Sobolewa and J. Zaleski. (*Zeitsch. physiol. Chem.*, 1910, **69**, 441-451; through *Chem. Zentralbl.*, 1911, **1**, 509-510.)—An alcoholic solution of pyrrol slightly acidified with hydrochloric acid gives a red coloration with aldehydes. In presence of less than 0·1 per cent. of aldehyde a white turbidity is formed, which may be developed more conveniently by using an aqueous solution of pyrrol, and heating on the water-bath. Pyrrol which has become somewhat yellow by the action of air during storage is better suited for this reaction than the freshly rectified product. By this means a quantity of 0·2 to 0·3 mgrm. of acetaldehyde or formaldehyde may be detected. The test is less sensitive with the higher aldehydes and those of the aromatic series. Ketones yield the same reaction. The test may be employed for quantitative purposes in the following manner: A series of tubes are charged each with 15 c.c. of a solution containing 5 to 10 mgrms. of pyrrol and 1 to 2 per cent. of free hydrochloric acid, and increasing quantities of the aldehyde solution are added to the tubes from a burette. The tubes are shaken, and after standing for half an hour, the tube showing a turbidity with the smallest quantity of aldehyde is observed. This quantity represents the aldehyde equivalent of the pyrrol solution, which is a constant within the limits of 0·035 and 0·015 per cent. concentration of aldehyde, the aldehyde solution having been brought within these limits before making the test. The constant must be established, for the pyrrol solution used, by means of an aldehyde solution of known strength. This solution is standardised by testing it first against the pyrrol solution, then oxidising a portion of the aldehyde by means of a restricted quantity of standard bichromate solution, distilling off the residual aldehyde and testing the distillate again with the pyrrol solution. The difference between the two tests is then calculated in terms of the quantity of aldehyde equivalent to the quantity of bichromate used. In the estimation of lactic acid by Jerusalem's method the authors have applied their pyrrol test for the estimation of the aldehyde produced. Jerusalem's method always yields results which are considerably too low, but its use is recommended on account of its simplicity. J. F. B.

Carbonylferrocyanides: Their Extraction and Analysis. E. Lecocq. (*Bull. Soc. Chim. Belg.*, 1911, **25**, 72-80.)—Carbonylferrocyanides may be obtained, during the course of the manufacture of potassium ferrocyanide, by evaporating the filtrate from the insoluble potassium calcium ferrocyanide. When the liquid is concentrated to a sp. gr. of about 30° Bé., a precipitate is formed, consisting of calcium sulphate, potassium calcium ferrocyanide, and potassium calcium carbonylferrocyanide. Whilst the latter salt is soluble in water, it is insoluble in solutions containing large quantities of calcium salts, such as the concentrated liquid mentioned. On separating the precipitate and washing it with water, the carbonylferrocyanide goes into solution, and can be separated by concentrating the solution and allowing the salt to crystallise. It has the formula, $CaKFeCO(CN)_5,5H_2O$. The quantity of carbonylferrocyanides in crude materials, etc., may be estimated by thoroughly mixing 100 grms. of the sample with 10 grms. of powdered calcium oxide. After four or five hours' contact, the mixture is washed into a flask with 300 c.c. of water, shaken occasionally for several hours, and filtered. After washing the residue with water, the filtrate and washings are evaporated to a volume of about 100 c.c., and 35 grms. of calcium chloride and 3 grms. of potassium chloride are added to the concentrated liquid. The precipitate which forms is collected on a filter when the solution is cold; the filtrate is rejected and the precipitate is extracted with warm water. The solution of the carbonylferrocyanides thus obtained is concentrated to a volume of 25 c.c. in order to precipitate the last traces of the double ferrocyanide which remain in the solution, and the latter is then treated with 10 c.c. of a 10 per cent. potassium hydroxide solution, and 2 c.c. of a 10 per cent. potassium carbonate solution. The precipitated calcium carbonate is removed by filtration, the filtrate, diluted to 100 c.c., and acidified with 5 c.c. of 20 per cent. sulphuric acid, is titrated with a copper sulphate solution which has been standardised by titration against a quantity of pure potassium calcium carbonylferrocyanide prepared as described above; paper impregnated with an iron salt is used as the indicator in the titrations. The result obtained will be in terms of potassium calcium carbonylferrocyanide, but may be expressed as ferric carbonylferrocyanide or violet (in which state the substance exists in the crude materials), by multiplying the result by 0·706. Ferric carbonylferrocyanide, or violet, may be used as a pigment in inks, paints, etc.

W. P. S.

Critical Investigation of the Analytical Methods for the Estimation of Caoutchouc. O. Korneck. (*Gummi Zeit.*, 1910, **25**, 4-9, 42-46, 78-88; through *Chem. Zentralbl.*, 1911, **1**, 511-513.)—The methods according to which the caoutchouc is estimated by difference should only be employed with the greatest caution. Of the processes depending on direct precipitation, Spence's process (ANALYST, 1907, **32**, 424) is the best. Fendler's alcohol precipitation method is not very well suited for African varieties. Investigations of the methods depending on the preparation of derivatives showed that Budde's bromination method gave low results, particularly with respect to the fraction termed "insoluble caoutchouc substance," consisting of pure caoutchouc and proteins, in which the pure caoutchouc largely resisted bromination. As the result of his studies on the nitrosite method, the author has evolved the following modified procedure: One grm. of technically pure caoutchouc, or the material left after extraction of the resins, is finely ground and swollen in 75 c.c. of benzene in a covered beaker at the ordinary temperature, with frequent stirring. As soon as the maximum degree of liquefaction is reached (varying from a few hours to some days), nitrous fumes, prepared from nitric acid, sp. gr. 1·3 and arsenious acid and dried over phosphoric anhydride until dark green in colour, are passed in, whilst the contents of the beaker are stirred with the gas-leading tube, and any lumps of nitrosite which may form are broken down. After treatment, the liquid is allowed to stand for a short time, and the green solution is decanted off through a Gooch crucible containing asbestos. The nitrosite is well washed with benzene, and is again treated with nitrous fumes in presence of 75 c.c. of benzene. The beaker is then covered, and allowed to stand for twenty-four hours. Next, the nitrosite is well broken up by pressing it against the sides of the vessel with the gas-leading tube, the clear liquid is again decanted off through the crucible, and the kneading is continued with fresh benzene until the washings remain colourless. The nitrosite is collected in the crucible, and washed with absolute ether until it becomes a pulverulent yellow mass. The crucible, nitrosite, empty beaker, and gas tube are then dried to a constant weight at 80° C., and weighed. The nitrosite adhering to the utensils is next dissolved in 50 c.c. of warm acetone, which is poured through the filter, and the whole is washed with acetone until free from nitrosite. The same utensils are dried and weighed again. The weight of nitrosite so found is multiplied by $\frac{136}{289}$ for the calculation of pure caoutchouc. This method gives good results with crude caoutchouc.

The author describes a method for the precipitation of the caoutchouc resins in the form of ozonides. When ozone is passed through a solution of crude rubber in carbon tetrachloride, the ozonides of the resins are precipitated at the surface of the solvent, whilst the caoutchouc ozonide remains in solution. On treatment with a current of steam, the resin ozonides are converted into solid decomposition products, which are easily separated from the other constituents, dried, and weighed. The method is obviously not exact, the results being probably too high, but they agree fairly well with results obtained by other methods. J. F. B.

Estimation of Caoutchouc as Tetrabromide. T. Budde. (*Gummi Zeit.*, 1910, **25**, 269-270; through *Chem. Zentralbl.*, 1911, 1, 513-514.)—In the original description of the volumetric modification of the tetrabromide method, the quantity of $\frac{N}{5}$ silver nitrate (25 c.c.) prescribed is not a sufficient excess when 0·15 to 0·20 grm. of crude rubber is taken for treatment. The author assumed that this error on his part would be self evident, but apparently Korneck (see preceding abstract) has overlooked this point, and the low results recorded by him are in part attributable to this cause. Further, the presence of moisture appears to have an unfavourable influence on the results of the tetrabromide method as compared with those of the nitrosite method, since the concordance between the two is almost exact when dry materials are used in bromination. The author has studied the influence of protein on the results of the tetrabromide method, and finds that 100 grms. of protein may combine with 4·6 grms. of bromine, equivalent to 1·95 grm. of caoutchouc. If the quantity of protein in crude rubber may in certain cases amount to 8 to 10 per cent., the error introduced by its combination with bromine would be only 0·195 per cent. The statement that the "insoluble proteins" in rubber do not combine with bromine in the tetrabromide process must therefore be modified, since the proteins do unite with bromine; but the error thereby introduced is negligible (*cf.* ANALYST, 1910, **35**, 267). J. F. B.

Analysis of Crude Caoutchouc. G. Fendler. (*Gummi Zeit.*, 1910, **25**, 311-316, 351-357; through *Chem. Zentralbl.*, 1911, **1**, 514-515.)—In carrying out the nitrosite method, nitrosites of the proteins are formed which are soluble in benzene but not in light petroleum spirit. The author contends that if the criticisms of Korneck (see above) against the use of petroleum spirit be justified in this connection, the error involved is only small. On the other hand, Korneck states that the preparation of the nitrosite may, if desired, be undertaken without previous removal of the resins soluble in acetone. The error introduced by omission to remove the resins is far more considerable than that caused by the presence of the nitrosites of the proteins. In the tetrabromide process, Budde's volumetric modification is not capable, in its present form, of taking the place of the gravimetric procedure. Further, it is essential in this method also to remove the resins before bromination. According to the author, it is possible in nearly all cases to filter the toluene solution of the rubber through paper before proceeding to brominate. From 100 c.c. of the solution it is possible to obtain 10 c.c. of filtrate in quite a short time; this quantity is then available for bromination free from insoluble proteins and other impurities. The author disagrees with Korneck's view as to the value of Spence's method of direct precipitation, the range of application of which must be very restricted. In his view it should be possible to devise a direct method to be applied to the toluene solution prepared as for the tetrabromide method. The only doubt is whether it would be possible to drive off the toluene quantitatively from the filtered solution. By centrifuging the unfiltered toluene solution, it might be possible to estimate accurately the insoluble impurities.

J. F. B.

Rubber of Mascarenhasia Elastica. (*Bull. Imp. Institute*, 1910, **8**, 346-352).—This new species of *Mascarenhasia*, yielding the rubber known in East Africa as "M'goa" or "Goa" rubber, grows in German and Portuguese East Africa, the East Africa Protectorate, and Pemba Island. The raw, moist rubber has the following composition:

	East Africa Protectorate.	Pemba.	Portuguese East Africa.	
			Ball Rubber.	Smoked Sheet Rubber.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Moisture	10·0	15·8	1·4	8·4
Caoutchouc	69·0	71·7	90·8	74·2
Resin	6·1	7·6	4·5	6·9
Proteins	3·5	3·1	2·4	3·5
Insoluble matter	11·4	1·8	0·9	7·0
Ash, per cent.	2·29	1·09	1·90	1·80
Physical properties... ...	Fairly satisfactory.	Good.	Good.	Good.

The high proportion of insoluble matter in certain of the samples is chiefly due to the presence of vegetable impurities, the result of careless collection.

A. R. T.

Modification of the Furfural Method for the Estimation of Pentosans. K. H. Böddener and B. Tollens. (*J. für Landw.*, 1910, **58**, 232-237; through *Chem. Zentralbl.*, 1911, **1**, 427-428.)—After the distillation with hydrochloric acid, the estimation of the furfural may be considerably accelerated by precipitating the phloroglucide hot instead of in the cold. The reaction then proceeds approximately, according to the equation $C_5H_4O_2 + C_6H_6O_3 = C_{11}H_4O_2 + 3H_2O$. The procedure is as follows: Three hundred c.c. of hydrochloric acid, sp. gr. 1·06, are mixed with the acid furfural distillate in a beaker, and double the calculated quantity of phloroglucin, *plus* 0·15 grm., previously dissolved in hydrochloric acid, sp. gr. 1·06, is added. The total volume is then made up to 400 c.c. by means of the same acid. The mixture is heated to 80° to 85° C., and allowed to stand for one and a half to two hours at the ordinary temperature. The precipitate is collected in a Gooch crucible, washed with 150 c.c. of water, dried for four hours at 95° to 98° C., and weighed in a stoppered bottle. A correction of 1 mgrm. is added to the weight of the phloroglucide to compensate for its solubility, and the weight of furfural is calculated by the factor 0·571. Very good results are obtained with pure furfural; but when methyl furfural, derived from materials containing methyl pentosans, is present, the usual Kröber method of cold precipitation is preferred. J. F. B.

Estimation of Pentosans with the Aid of Fehling's Solution. J. T. Flohil. (*Chem. Weekblad*, 1910, **7**, 1057-1063.)—The author has determined the conditions under which Fehling's solution is reduced by furfural in direct proportion to the quantity present, and he makes use of the data in the estimation of pentoses and pentosans. The details of the method are briefly as follows:

The substance to be analysed is distilled with dilute acid, the distillate made up to 400 c.c., and 50 c.c. withdrawn. This is neutralised, 20 c.c. of Fehling's solution added, the liquid made up to 100 c.c. and boiled for thirty-five minutes under a reflux condenser. The reduced cuprous oxide is then estimated gravimetrically, or the unreduced cupric salt is titrated iodometrically. It is necessary to carry out a blank experiment in which the same quantity of salt is present.

Under these conditions it is found that 1 c.c. of $\frac{N}{10}$ sodium thiosulphate solution corresponds with 0·0063 grm. of copper or with 0·0024 grm. of furfural. The weight of metallic copper multiplied by the factor 0·3775 is stated to give the weight of furfural. Estimations of pentosans in such substances as cocoa are cited both by the phloroyhicide method and the new method, and the agreement is excellent.

NOTE.—This paper is written in a somewhat loose manner. Thus the particular acid used for the decomposition of the pentosan is not stated, nor is the dilution of the acid given. Further, although the author directs that the distillate should be made up to 400 c.c., he does not state what the approximate volume of the distillate should be. It is doubtful whether with some substances the whole of the furfural would have passed over when the distillate measured 400 c.c. The factor given by the author, 0·3775, for calculating the weight of furfural from that of the copper, should, according to his other data, be 0·3809. A. R. L.

Pentosans of Certain Wood Fungi. J. L. Wichers and B. Tollens. (*J. für Landw.*, 1910, **58**, 238-242; through *Chem. Zentralbl.* 1911, **1**, 428.)—The method described by Böddener and Tollens (p. 161) for the precipitation of furfural phloroglucide was used side by side with Kröber's method of cold precipitation for the estimation of the pentosans in various wood fungi. The results with the two methods were fairly concordant, but those afforded by Kröber's method were slightly higher and, in the author's opinion, more reliable. The percentage of pentosans ranged, according to the species, from 1·21 per cent. (for *Fomes polymorpha*) to 6·73 (for *Lenzites flaccida*). The tinder fungus (*Fomes fomentarius*) showed 3·34 per cent. of pentosans, the precipitate containing some methylfurfural derivative. By the hydrolysis of this fungus, dextrose and pentoses—probably also some mannose groups —were detected, but no galactose groups. J. F. B.

Gums from Northern Nigeria. (*Bull. Imp. Institute*, 1910, **8**, 352-365.)—Investigations made show that the gum-trees of Northern Nigeria, in the Bornu and Yola Provinces, are principally *Acacia Senegal*, *A. Seyal*, and *A. Sieberiana*—the species which yield the important commercial gums of the Sudan and Senegal. The following table summarises the results obtained by the examination of gums from different species:

Source of Gum.	Moisture.	Ash.	Matter Insoluble in Water.	Strength as Measured by Viscosity.	Colour of Mucilage.
	Per Cent.	Per Cent.	Per Cent.		
BORNU PROVINCE:					
Acacia Senegal	10·24 to 11·48	2·87 to 3·17	1·20 to 1·94	5·36 to 6·66	Almost colourless to pale brown
Acacia Seyal ...	11·19 to 11·42	2·50 to 2·66	0·84 to 1·41	5·86 to 6·66	Brown
YOLA PROVINCE:					
Acacia Suma ...	13·32 to 13·56	2·00 to 2·36	4·10 to 4·50	14·1 to 16·70	Colourless to brown
Acacia Sieberiana	13·63	2·65	0·76	13·30	Pale coloured
SOKOTO PROVINCE:					
Combretum sp. ...	12·90	2·00	1·20	7·80	Dark brown

The methods of examination employed for these gums are those described in Part II., "Selected Reports Imp. Institute" (Colonial Reports, Miscellaneous, No. 63, Cd. 4,971, pp. 140-142). A. R. T.

Estimation of Hordenine in Germinating Barley. T. Torquati. (*Arch. Farmacol. sperim.*, 1910, **10**, 62-71; through *Chem. Zentralbl.*, 1911, **1**, 166.)—The author describes the following method employed by him in investigations on the formation of hordenine in germinating barley: The material is macerated for twelve hours with a dilute solution of tartaric acid, heated for three hours, and then filtered hot. The dried tartaric acid extract is triturated with freshly-ground gypsum, and extracted with alcohol. The alcohol is evaporated, and the residual extract is dissolved in water; the solution is freed from colouring matters and fat by means of ether, it is then made alkaline with potassium carbonate, and is exhausted by shaking with ether. The hordenine is extracted from the concentrated ethereal solution by means of dilute sulphuric acid, and the solution of the sulphate is again made alkaline and extracted with ether. Pure hordenine is obtained by evaporation of the ether. J. F. B.

Estimation of Hydroquinone. J. Pinnow. (*Zeitsch. anal. Chem.*, 1911, **50**, 154-155.)—The estimation of hydroquinone by means of Fehling's solution, with the aid of tables empirically prepared, as in the case of sugars, is only possible in rare cases. The cupric reducing power of the hydroquinone rises and falls, in a series of comparative experiments, with increasing concentration; the cause of the irregularities apparently lies in chemical-kinetic processes. The oxidation equivalents of hydroquinone and of the potassium salt of hydroquinonesulphonic acid are almost identical: 1 molecule of the substance requires 3 atoms of oxygen. The reducing power of hydroquinone towards Fehling's solution is considerably increased by the presence of sulphites (as in photographic developers). With a sufficient quantity of sulphite, the cupric reducing power of hydroquinone is increased one and a half times, and that of the sulphonate is increased one and a quarter times, with the formation of a combined product of oxidation. On the other hand, the estimation of hydroquinone may be carried out with satisfactory results by extraction for three-quarters of an hour with ether in Partheil's apparatus (*Ber.*, 1901, **34**, 3611), and subsequent drying of the extract in the water-oven. Hydroquinone exists in ethereal solution in double molecules; its dissociation coefficient and the coefficient of distribution for the single molecules, between ether and water at 15° C., have been determined by the author. J. F. B.

Quantitative Estimation of Nitric Acid in Vegetable Products. K. Krog and J. Sebelien. (*Chem. Zeit.*, 1911, **35**, 145-146.)—Estimation of the nitric acid in vegetable products rich in sugar (*e.g.*, beetroot) by Tiemann's modification of Schloesing's method gives inaccurate results, owing to the reducing influence of the carbohydrates. Although cane-sugar might be removed by precipitation as barium sucrate, yet the invert sugar present in old beetroots cannot be eliminated in this way. The author has therefore tested the applicability of Busch's method of precipitating the nitric acid with *nitron* (ANALYST, 1905, **30**, 256) from aqueous and alcoholic extracts of the dried and finely divided substance, the latter being obtained by digesting about 10 grms. for three hours in a shaking apparatus with a mixture of 300 c.c. of 96 per cent. alcohol and 200 c.c. of water, and then diluting the liquid to 500 c.c. An aliquot portion (250 c.c.) was then evaporated to a small volume to expel all alcohol (in which the nitrate precipitate is soluble), and then treated with the reagent. On concentrating the extracts (whether aqueous or alcoholic) a persistent turbidity was produced, and to remove this a treatment with animal charcoal, followed by filtration, was necessary. In parallel experiments the method gave 1·63 per cent. of nitric acid (N_2O_5) in the case of an aqueous extract, and 1·65 per cent. with an alcoholic extract, whilst by the method of Schloesing and Tiemann only 1·38 per cent. was obtained. For products such as dried beetroot the method of extraction with dilute alcohol is preferable to extraction with water, since a purer solution is obtained, and it is not necessary to remove proteins by precipitation with copper sulphate. Occasionally an amorphous greyish-white precipitate (quite distinct in appearance from the crystalline *nitron* nitrate precipitate) is produced on adding the reagent to an aqueous extract; and, although this may be prevented by the addition of sulphuric acid, the other precipitate is then more difficult to separate. On the other hand, such amorphous precipitates are not given by alcoholic extracts. When the amount of nitrate is very small concentration of the volume to 80 c.c., as recommended by Busch, is insufficient, and to obtain complete precipitation it is necessary to reduce the volume to 20 to 30 c.c. before adding the *nitron*, and to keep the mixture in ice-water for one to two hours (*cf.* ANALYST, 1907, **32**, 349).

C. A. M.

Analysis of Fats and Oils. American Chemical Society. (*J. Ind. Eng. Chem.*, 1911, **3**, 50-52.)—The Committee on Uniformity of Methods of Analysis puts forward the following methods tentatively, and invites criticism:

MOISTURE AND VOLATILE MATTER—*Weighing Out.*—The sample is softened by heat, but not melted, and is emulsified (*e.g.*, by means of an egg-beaker). The necessary quantity for the determination is weighed out into a watch-glass or shallow glass dish, the sides of which are not more than 1 cm. high.

Method No. 1.—From 5 to 10 grms. are heated to constant weight at 110° C., the weight being considered constant when successive weighings thirty minutes apart do not differ by more than 0·05 per cent.

Method No. 2.—From 5 to 10 grms. are heated for four hours at 50° C. in a vacuum oven under a pressure not exceeding 30 mm. of mercury.

Routine Method.—The sample is heated in an aluminium beaker placed on an asbestos board over a burner, the temperature not being allowed to exceed 130° C. The beaker is rotated to avoid spluttering, and the operation considered at an end by the discontinuance of rising bubbles of steam or by other signs known to users of the method.

MOISTURE.—Ubbelohde's method is recommended. A mixture of 100 grms. of the sample with 100 c.c. of xylene is distilled slowly, and the first 50 c.c. of the distillate collected in a tube graduated in tenths of a cubic centimetre. The percentage of water is read off directly and corrected for the solubility of water in xylene, as to which the committee has an investigation in hand.

SUSPENDED IMPURITIES.—From 5 to 20 grms. are dried in a beaker over asbestos board (the residue from a moisture and volatile matter determination may be taken), and is dissolved in hot petroleum ether (b.p., 50° to 70° C.) by gentle boiling on the water-bath. The undissolved matter is filtered off in a Gooch or porous crucible, washed with boiling petroleum ether, and dried to constant weight.

FREE FATTY ACIDS.—From 5 to 15 grms. are weighed into a 100 c.c. Erlenmeyer flask, and melted if a solid fat. Hot neutral alcohol (100 c.c.) is added, and the mixture titrated with $\frac{N}{10}$ or $\frac{N}{2}$ caustic alkali, using phenolphthaleïn as indicator.

Acid number to be reported as mg. KOH required to neutralise 1 grm. Where the fat is known to have a mean molecular weight of 282 or thereabouts, that figure is to be used in calculating the percentage of free fatty acids, which is to be based on the sample freed from moisture and volatile matter.

The neutral alcohol required is prepared by boiling 1,000 c.c. of 95 per cent. alcohol with 50 grms. caustic soda for six hours under a reflux condenser, allowing to stand twenty-four hours, and distilling.

TITER (*Melting-Point*).—The fat (75 grms.) is saponified by mixing with 60 c.c. of 30 per cent. caustic soda and 75 c.c. of 95 per cent. alcohol (or 120 c.c. water) in an iron or porcelain dish, and boiling down to dryness over a low flame, with constant stirring to prevent scorching. The soap is dissolved in a litre of boiling water and, if alcohol has been used, boiled for forty minutes to remove it, maintaining the volume of the liquid by occasional additions of water. To the soap solution, freed from alcohol, and contained in a porcelain vessel, 100 c.c. of 30 per cent. sulphuric acid are added, and the mixture boiled until the fatty acids form a transparent layer. The fatty acids are collected in a small beaker, placed on the steam bath until the water has settled, decanted into a dry beaker, filtered with the use of a hot-water funnel, and dried for twenty minutes at 105° C. The dried fatty acids are then cooled to within 15° or 20° C. of the expected titer and transferred to a tube 4″ × 1″ and 1 mm. thick in the wall. This tube is placed in a bottle about 6″ × 3″, which is fitted with a cork to hold the tube rigidly. The thermometer, graduated to 0·1° C., is suspended so that it can be used as a stirrer, and the mass is stirred slowly until the mercury remains stationary for thirty seconds. The thermometer is then allowed to hang quietly, with the bulb in the centre of the mass, and the highest point to which the mercury rises is taken as the titer of the fatty acids. The room temperature should be reported.

The fatty acids are tested for complete saponification by boiling 3 c.c. with 15 c.c. of 95 per cent. alcohol in a test-tube, and adding an equal volume of ammonia (sp. gr., 0·96). No turbidity should appear.

UNSAPONIFIABLE MATTER—*Definition*.—The non-fatty constituents of fats and fatty oils, soluble in petroleum ether (b.p., 35° to 50° C.).

Wet Method.—The fat (3 grms.), free from moisture and volatile matter, is weighed into a 150 c.c. flask, and a 30 per cent. excess of strong, nearly colourless, alcoholic potash is added. The mixture is boiled for an hour under a reflux condenser and then transferred to a 100 c.c. stoppered cylinder, made up to 50 c.c. with cold water, and shaken with 30 c.c. petroleum ether. The petroleum ether layer is syphoned off, and the extraction repeated with five separate portions of petroleum ether. The united petroleum ether extracts are washed three times with 20 c.c. of 50 per cent. alcohol, poured into a tared flask, the greater part of the petroleum ether removed by distillation, and the residue dried on the water-bath, and finally in an oven at 105° C.

Dry Method—The fat (5 grms.) is saponified in a 200 c.c. flask by boiling under a reflux condenser with a 30 per cent. excess of alcoholic soda for thirty to sixty minutes, or until saponification is complete. The solution is transferred to a 4-inch basin and dried on a water-bath, and then in an oven for one to two hours at 120° C.

The dried soap is ground up in an agate mortar with 10 to 15 grms. granular anhydrous sodium carbonate, placed in a 33 × 80 mm. extraction thimble, covered with a plug of cotton wool, and redried for an hour at 110° to 120° C. The thimble is then transferred to a Soxhlet extractor and extracted for about ten hours (fifty or more syphonings) with petroleum ether, access of moisture being excluded by attaching a calcium chloride tube to the top of the condenser. The extract is transferred to a tared beaker, the solvent evaporated on the water-bath, and the residue dried in an oven to constant weight. The residue should be tested for complete solubility in petroleum ether.

METALLIC SOAPS.—*Definition.*—Fatty acid compounds with bases other than alkalies. Insoluble in water.

Method No. 1.—The filtrate and washings from the determination of suspended impurities are evaporated to about 200 c.c., and allowed to stand at least twelve hours in a cool place (18° to 20° C.). The separated insoluble metallic soaps are then filtered off on a Gooch crucible, washed with cold petroleum ether (b.p., 35° to 50° C.), dried, and weighed.

Method No. 2.—The filtrate from the determination of suspended impurities is evaporated, burned, and ignited to constant weight. The weight of the ash from metallic soaps thus obtained is to be reported (1) as such, and, considering the ash to consist entirely of lime, it is calculated to normal soap, using 281 as molecular weight of fatty acid, and reported (2) as lime soap.

Criticisms and suggestions should be addressed to W. D. Richardson, 4215, Prairie Avenue, Chicago. G. C. J.

Interpolation Method of Oil Analysis. J. J. Kessler and G. K. Mathiason.

(*J. Ind. Eng. Chem.*, 1911, **3**, 66-72.)—This paper contains a study of the degree of accuracy obtainable in the method of calculating the percentage composition of a mixture of oils from certain physical constants of the mixture. The results obtained with experimental mixtures are given in tabular form and plotted as curves, and it is shown that certain values such as the viscosity, flash-point, and ignition point (fire-test) and possibly other physical constants do not show an additive relationship, and that considerable errors may result from drawing deductions from interpolation of data thus obtained. This also applies to the Maumené test, and the figures indicate that, as at present applied, the results obtained by that test are incapable of enabling a quantitative estimation of the composition of a mixture to be made, as in the method recommended by Stillman (*Engineering Chemistry*, 1900). In the case of the saponification value, however, the relationship is additive, and holds good even for small proportions of one oil in the presence of another. C. A. M.

Estimation of Lecithin in Oil. W. Fresenius and L. Grünhut.

(*Zeitsch. anal. Chem.*, 1911, **50**, 90-106.)—The following process is recommended for the estimation of lecithin in fixed oils and fats, and is based on the extraction of the lecithin by means of alcohol, the quantity of lecithin being calculated from the amount of alcohol-soluble-phosphoric acid obtained. As lecithin is soluble in both oil and alcohol, the quantity extracted from the oil is proportional to the solubility of lecithin in the two liquids; repeated extraction with fresh quantities of alcohol results in practically the whole of the oil being dissolved by the alcohol, and the authors, therefore, extract the oil twice with successive quantities of cold alcohol, the total quantity of lecithin present being calculated from the amount dissolved by alcohol according to the formula:

$$x = \frac{p_1 a_1 o_1 + p_1 v_2 (o_1 a_2 - a_2 a_1)}{v(p_1 o_1 - p_2 o_2).}$$

Fifty grms. of the oil are weighed into a 200 c.c. graduated cylinder and shaken for twenty minutes with 100 c.c. of absolute alcohol. After standing for one hour, the volumes of the oily layer (o_1) and of the alcoholic layer (a_1) are noted. Seventy-five c.c. (v) of the alcoholic layer are now removed by means of a pipette for the first phosphoric acid estimation (p_1); the pipette is then washed with absolute alcohol, the washing being added to the cylinder, and the contents of the latter are diluted with absolute alcohol to the original total volume. The contents of the cylinder are then shaken as before, the volumes of the two layers (o_2 and a_2) are read off, and a further 75 c.c. of the alcoholic layer are drawn off for the second phosphoric acid estimation (p_2). The two quantities of alcohol are evaporated separately in platinum basins, and the dry residues are fused with a mixture of sodium carbonate and sodium nitrate. The phosphoric acid in the fused masses is then precipitated by means of molybdic acid in the usual manner, and the yellow precipitate is ignited, and weighed. The ignited precipitate has the formula, $P_2O_5.24MoO_3$, and the quantity of phosphoric acid is calculated accordingly. Lecithin contains an average of 9·02 per cent. of phosphoric acid (P_2O_5). Two preparations of lecithin in oil examined, contained 3·11 and 7·80 per cent. of lecithin, respectively. W. P. S.

Determination of Origin of Mineral Oils and their Products. N. Chercheffsky. (*Ann. Chim. anal.*, 1911, **16**, 45-50.)—The author has fractionated numerous samples of American, Russian, Roumanian, Galician, and shale oils, and for the fractions having sp. gr. of 0·75, 0·78, 0·80, and 0·82, has determined the mean boiling-point, refractive index, index of solubility (Riche and Halphen), critical temperature of solution, cloud temperature, and iodine number. By fractionating a sample of unknown origin and examining the fraction in a similar manner and comparing them with his tabulated results, it should be possible to fix the origin of the sample. As it is inconvenient to try to collect fractions of predetermined sp. gr., it is suggested that fractions be collected, each representing a range of boiling-point of 20° from, say, 100° C. to 300° C., and that curves be drawn on squared paper through a series of points, each of which has the mean boiling-point of one fraction for abscissa and its sp. gr. for ordinate. The results of the other tests are plotted on the same paper, and the refractive index, etc., for the fraction of sp. gr. 0·75, etc., may then be seen by inspection. The following tables are given:

I. Boiling-Points °C.

Sp. Gr. at 15°/15° C. of Distillate.	American.	Russian.	Roumanian.	Galician.	Shale Oil.
0·75	141	109	108	113	127
0·78	191	159	153	166	168
0·80	227	182	179	202	198
0·82	266	220	208	242	228

II. Refractive Indices at 15° C.

Sp. Gr. at 15°/15° C. of Distillate.	American.	Russian.	Roumanian.	Galician.	Shale Oil.
0·75	1·4182	1·4143	1·4160	1·4174	1·4219
0·78	1·4345	1·4309	1·4334	1·4356	1·4373
0·80	1·4453	1·4419	1·4458	1·4466	1·4469
0·82	1·4564	1·4533	1·4572	1·4586	1·4568

III. Index of Solubility (Riche and Halphen).

Sp. Gr. at 15°/15° C. of Distillate.	American.	Russian.	Roumanian.	Galician.	Shale Oil.
0·75	70	70	68	68	66
0·78	93	75	73	74	74
0·80	117	85	80	94	93
0·82	154	92	91	126	109

IV. Critical Temperature of Solution °C.

Sp. Gr. at 15°/15° C. of Distillate.	American.	Russian.	Roumanian.	Galician.	Shale Oil.
0·75	20	—	—	—	—
0·78	50	36	—	31	31
0·80	69	48	30	53	43
0·82	87	60	42	73	54

V. Cloud Test °C.

Sp. Gr. at 15°/15° C. of Distillate.	American.	Russian.	Roumanian.	Galician.	Shale Oil.
0·75	61	55	52	49	44
0·78	79	66	53	60	55
0·80	91	72	57	76	63
0·82	105	80	64	90	71

The index of solubility is the number of c.c. of a mixture of equal parts of chloroform and 93 per cent. alcohol which just suffice to dissolve 100 c.c. of the fraction under examination. The critical temperature is determined by heating some of the oil with an equal volume of 96·5 per cent. alcohol in a sealed tube until the mixture is just clear, and noting the temperature at which the first sign of cloudiness appears on slow cooling. The cloud test is made in a similar manner, but in an open tube and with acetic anhydride as solvent. It is said that the iodine number of normal petroleum products varies from 0 to 7, whilst that of some American refined products resulting from "cracking" may be as high as 20 to 25. The iodine number of shale products varies with the density of the oil, that of ordinary burning oil being 65·75, whilst the lighter fractions may have values up to 110. G. C. J.

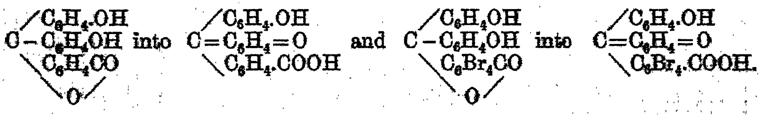
Estimation of Unsaponifiable Matter in Wool Oils. A. H. Gill and A. E. Shippee. (*J. Ind. Eng. Chem.*, 1911, **3**, 72-73.)—The method of extraction with petroleum spirit has the drawbacks that the extraction may be incomplete, that the soap is soluble in the solvent, and that the complete removal of the solvent is difficult, and involves the loss of volatile constituents in the unsaponifiable matter. The other method in common use is based upon an estimation of the free acids in the oil (as oleic acid), followed by an estimation of the combined fatty acids (calculated into olein). The sum of these two values deducted from 100 gives the amount of unsaponifiable matter. The following table gives the results thus obtained by the two methods in the examination of typical samples of wool oils:

Oil.	Sp. Gr. at 15° C.	Unsaponifiable Matter.		Saponification Value.	Free Acids as Oleic Acid.
		Extraction Method.	Differential Method.		
		Per Cent.	Per Cent.		Per Cent.
Scotch wool	0·908	65·7	65·4	73	12·8
Wool oil	0·908	91·7	90·9	17	3·3
Oleine, 42% saponifiable	0·911	58·5	56·6	88	41·3
English oleine, 42% saponifiable ...	0·911	59·4	59·2	80	40·7
Wool oleine, 95% „ ...	0·910	31·2	31·0	140	65·2
Wool oleine, 35% „ ...	0·910	65·2	65·3	69	32·6

Notwithstanding the possible errors due to assuming that the whole of the fatty acids in the oil consist of oleic acid, the results show that for technical purposes the differential method is sufficiently accurate. In fact, with the exception of oil No. 3, the differences between the results of duplicate estimations by either method were greater than the average differences in the results given by the two methods.

C. A. M.

Phenolphthaleïn Derivatives and their Properties as Indicators. E. Rupp. (*Arch. Pharm.*, 1911, **249**, 56-68.)—The halogen derivatives of phenolphthaleïn, such as tetrabromophenol-phthaleïn, in which the halogen enters only into the phenol ring, give only diffused gradual changes of colour, both with ammonia, and with very dilute fixed alkali solutions. On the other hand, derivatives in which the substitution occurs in the phthalic nucleus show a sharp change of colour both with fixed alkalis and ammonia, although this change does not coincide with the saturation-point, but with a minimum of hydroxyl ions which is constant for each particular substitution compound. The explanation of this is given by the chromophore theory of indicators, according to which the formation of coloured salts from colourless acid compounds must be attributed to an intramolecular transformation, the pseudo form of the free phenolphthaleïn being converted into the quinonoid form in the coloured salts—*e.g.*,



$$C\begin{cases}C_6H_4.OH\\ -C_6H_4OH\\ C_6H_4CO\diagdown O\diagup\end{cases}\text{ into }C\begin{cases}C_6H_4.OH\\ =C_6H_4=O\\ C_6H_4.COOH\end{cases}\text{ and }C\begin{cases}C_6H_4OH\\ -C_6H_4OH\\ C_6Br_4CO\diagdown O\diagup\end{cases}\text{ into }C\begin{cases}C_6H_4.OH\\ =C_6H_4=O\\ C_6Br_4.COOH.\end{cases}$$

Since a rapid velocity of isomerisation is essential to the utility of a compound as an indicator, it might be anticipated that octobromophenolphthaleïn would be less suitable for the purpose than tetrabromophenolphthaleïn, and this is borne out by the results of titrations. The fact that phthaleïn derivatives with closed hydroxyl groups, such as diacetylphenolphthaleïn, dibenzoylphenolphthaleïn, and dibenzenesulphophenolphthaleïn, cannot be used as indicators is due to an inhibition of the formation of the colour-producing quinonoid group. Tetrachlorotetrabromophenolphthaleïn gave accurate results as an indicator in the titration of ammonia, quinine, and sodium carbonate, but with this exception only the nitro- and nitrobromo derivatives proved serviceable. In the case of these derivatives, which could also be used with weak bases and with morphine and quinine, the change of colour (yellow instead of red) showed that the property was no longer bound up with the phthaleïn complex, but had passed to the nitro-oxyphenyl group. This was confirmed by a comparative series of titrations of morphine and quinine with *p*-nitrophenol as indicator, the results being in exact agreement with those obtained with these indicators. With regard to their colour relationships, the halogen phthaleïns confirm the general rule that the chromophore bodies pass from red through violet and blue to green with the increase in their molecular weight. Thus, in alkaline solution phenolphthaleïn is red; tetrachlorophenolphthaleïn, red-violet; tetrabromophenolphthaleïn, violet; tetrachlorotetrabromophenolphthaleïn, blue; octobromophenolphthaleïn, greenish-blue; and tetraiodotetrabromophenolphthaleïn, bluish-green. C. A. M.

Colour Reactions of Certain Resins with Halphen's Reagent for Colophony. E. F. Hicks. (*J. Ind. Eng. Chem.*, 1911, **3**, 86-87.)—Halphen's colophony test applied in the manner described by Foerster (ANALYST, 1909, **34**, 108) also gives characteristic colour reactions with certain other resins. The results thus obtained by the author with the pure substances may be summarised as follows:

Colophony.—Green, changing to blue and violet, then slowly to purple, and, finally, to deep indigo.

Dammar.—Brown to lilac-brown, gradually changing to reddish-brown (maroon).

Elemi.—Indigo-blue (immediately), gradually deepening in colour, and sometimes acquiring a purplish tint.

Kauri.—Azure-blue, changing rapidly through violet to purple. At point most remote from the bromine becomes dark olive-green.

Manila Gum (spirit soluble).—Very faint brown-green (slowly), changing through violet to purple. Chocolate-brown at point furthest from bromine.

Mastic.—Reddish-brown, becoming carmine nearest the bromine, and coffee-brown at the most remote point.

Sandarac.—Lilac (immediately). At point remote from bromine gradually changes to violet-brown.

Shellac.—No colorations when pure.

Zanzibar Copal.—Light brown (slowly), changing to brown-violet, and, finally, to chocolate-brown with violet hue.

The intensity of the colours depends upon the proportion of resin present, and the results should be compared with those given by resins of known purity. The test may also give valuable indications in the case of mixtures, though, should colophony be present, the intensity of its reaction will mask the other colorations. The sensitiveness of the test is reduced by the presence of water, alcohol, or ether.

Lac Resin from Baroda, India. (*Bull. Imp. Institute*, 1910, 8, 371-372.)—The samples were collected from the *Inga Saman*, or "rain-tree" (*Pithecolobium Saman*), which has only recently been used as a host for the lac insect. The following results were obtained on analysis:

	Lac Resin removed from Broken Twigs after Receipt. Per Cent.	Seed-Lac Resin as Received removed from Twigs. Per Cent.
Moisture	2·8	2·7
Ash	1·4	2·2
Wax	9·0	6·6
Colouring matter	7·2	12·4
Insoluble matter	8·1	8·6
Resin	71·5	67·5
IODINE NUMBER:		
Before purification	5·6	4·5
After purifying from dust, etc.	4·0	3·9

Distillation of Tars Containing Water. C. R. Downs. (*J. Ind. Eng. Chem.*, 1911, 3, 110-111.)—The bumping which results from the falling back of condensed water from the thermometer and neck of the flask when a mixture of tar and water is distilled may be avoided as follows: Two concentric cylinders of 30-mesh brass gauze are made, one just small enough in diameter to fit inside the neck of the flask, the other a little smaller. Both are long enough to extend from the side tube of the distilling flask to a point half-way between the end of the neck and the surface of the liquid, at the commencement of distillation. They are attached by wires to the cork which carries the thermometer.

INORGANIC ANALYSIS.

Estimation of Arsenic and Antimony in Copper. G. L. Heath. (*J. Ind. Eng. Chem.*, 1911, 3, 78-82.)—The paper includes a criticism of methods which depend on the volatilisation of arsenic (and antimony) chlorides, and describes in great detail the precautions necessary to obtain highly accurate results by co-precipitation of arsenic and antimony with iron. The author prefers to remove copper from the solution by electrolysis, and to titrate the arsenic in the exhausted electrolyte after suitable treatment. Two 10 grm. portions of the metal are dissolved in a slight excess of nitric acid, 17 c.c. of sulphuric acid are added to the contents of each beaker, and the whole evaporated to dryness. If selenium or tellurium is present, the copper sulphate is dissolved in water, the solution heated to 40° C., and a rapid current of sulphur dioxide passed through it. The solution is then filtered from any separated selenium or tellurium, acidified with 12 c.c. nitric acid, brought up or down to 120 c.c. by addition of water or concentration, and electrolysed, preferably by the slow method described by the author (see following abstract). In absence of selenium and tellurium the copper sulphate is dissolved in 12 c.c. nitric acid and about 110 c.c. of water, and electrolysed. In very accurate work the deposited copper is redissolved in 14 c.c. nitric acid (sp. gr. 1·42), 20 c.c. sulphuric acid (sp. gr. 1·84), and 50 c.c. water, and the solution made up to 120 c.c. and again electrolysed. The small portions withdrawn from the electrolyte, to determine by testing with hydrogen sulphide whether all the copper has been removed, are treated with a crystal of potassium bisulphite and a few drops of sulphuric acid, and evaporated to decompose the sulphides. The resulting solution is added to the exhausted electrolyte, which is next treated with 3 grms. of potassium bisulphite, and evaporated until the nitric acid is removed and the sulphuric acid has fumed for five minutes. In absence of more than traces of antimony, the liquid is next freed from the last traces of nitric acid by the method described later. If antimony must be separated, the solution is diluted with 1½ vols. of water, 2½ vols. of strong hydrochloric acid are added, and the arsenic separated in the cold by hydrogen sulphide. The arsenic sulphide is dissolved in fuming nitric acid, and when the sulphur has disappeared, 3 grms. of potassium bisulphite and 25 c.c. of strong sulphuric acid are added, and the solution evaporated until fumes of sulphuric acid have been in evidence for five minutes. To remove the last trace of nitric acid, the cooled solution is washed into a long-necked Kjeldahl flask and again evaporated, until the acid has fumed for five minutes. The neck of the flask is then heated, to drive out any condensate which may contain traces of nitric acid. The acid solution is made slightly alkaline by addition of ammonia, and then very faintly acid, after which 5 grms. or more of sodium bicarbonate and 3 drops of a 10 per cent. solution of potassium iodide are added, and the solution titrated with very dilute iodine solution (1 c.c. = 0·001 grm. As) and starch. With the precautions described for eliminating the last traces of nitric acid, the method is shown to be more accurate than any gravimetric method for the estimation of arsenic in copper. When the quantity of arsenic present is less than 0·05 per cent., two 10 grm. assays are combined, but for quantities less than 0·01 per cent. the error introduced by a trace of platinum, which always finds its way into the electrolyte, is appreciable, and tends to make the results a little high. G. C. J.

Exact Electrolytic Assay of Refined Copper. 1. Standard Method. 2. Rapid Assay by Rotation of the Electrolyte in a Solenoid. G. L. Heath. (*J. Ind. Eng. Chem.*, 1911, 3, 74-78.)—*Standard Slow Method.*—Five grms. of drillings are dissolved in 40 to 60 c.c. of the acid mixture, described later, contained in a beaker 12 cms. high and 6 cms. in diameter, the mixture being heated just short of the boiling-point. The solution is brought up to 120 c.c. by addition of water, and is electrolysed, using as cathode a plain foil cylinder 5 cms. high and with a total area (counting both sides) of 150 sq. cms. A split cylinder is preferred on account of ease of manipulation. The assays are started overnight with a current of 1½ ampères (1 ampère per 100 sq. cms.), and in the morning, as soon as the liquid is colourless, the split watch-glass covers are washed down and the current reduced to 0·5 ampère. Assays should finish in sixteen or eighteen hours without more than a trace of evolution of gas at the cathode. Otherwise they are best rejected, but it is possible to avoid oxidation or hydrogen absorption by reducing the current to 0·25 ampère, if, at the end of eighteen hours, deposition is not quite complete, and the cathode shows bubbles of gas. When deposition is complete, as shown by mixing 1 c.c. of the electrolyte with a few drops of hydrogen sulphide solution in a porcelain vessel, the stand supporting the beaker is withdrawn, the beaker replaced by one containing distilled water, and the electrode disconnected, washed with water and alcohol, and the last traces of the latter removed by burning. The acid mixture used for dissolving the copper is made up from 7 volumes nitric acid (sp. gr. 1·42), 10 volumes sulphuric acid (sp. gr. 1·84) and 25 volumes water. For the purest copper containing less than 0·03 per cent. arsenic, 40 c.c. of this solution is taken, with 0·03 to 0·1 per cent. arsenic, 50 c.c., and for copper containing 0·1 to 0·5 per cent. arsenic, 60 c.c. The results are accurate to within 0·01 per cent., providing the copper does not contain more than traces of antimony, selenium, or tellurium, in which case preliminary purification of the electrolyte is necessary. If there be doubt as to the freedom of the deposit from arsenic, it may be redissolved in 40 c.c. of the acid mixture, the solution diluted to 120 c.c. and the copper reprecipitated.

Rapid Assay by Rotation of the Electrolyte in a Solenoid.—The solenoid is constructed by winding 500 turns of No. 13 B. and S. gauge magnet wire upon a copper cylinder 7 cms. in diameter and 8 cms. high. The cylinder is brazed to two soft steel plates, 14 cms. in diameter and 2 mm. thick, the whole forming a spool, on which to wind the wire. The centre of the upper steel plate is cut out so that only a flange remains, and a 1-inch hole is also bored in the lower plate to provide for ventilation. The bottom plate carries three small knobs to support the beaker. The wire coil is conveniently put in series with the assay, and a current of 4·5 ampères is found most satisfactory. With this ampèrage there is no necessity to reduce the current towards the end of the assay, and it suffices for the deposition of 5 grms. of copper in two and a half hours. The cathode must be removed as soon as the last trace of copper is removed. It is necessary to complete success with the rapid method to use a gauze cathode of the general dimensions given for the foil cathode, but constructed of gauze with about 40 meshes per inch. Such an electrode, with edges suitably bound, weighs about half an ounce. Not more than 50 c.c. of the acid mixture must be used, or the heat and strong current will finally cause the metal to redissolve from the cathode. The results are as accurate as those given by the slow method. G. C. J.

Efficiency of Borax-Bead Tests for Nickel and Cobalt in Admixture.

L. J. Curtman and P. Rothberg. (*J. Amer. Chem. Soc.*, 1911, **33**, 188-189.)—The authors have determined the reliability of the borax-bead test in detecting the presence of nickel in admixture with cobalt, and *vice versa*. Solutions of the nitrates of these metals in varying proportions were mixed, and the sulphides completely precipitated from ammoniacal solutions. Portions of the freshly precipitated sulphides were fused in borax beads of approximately uniform size, and the beads viewed in daylight after treatment in both the oxidising and the reducing flames.

The results obtained were exactly similar when precipitated nickel and cobalt hydroxides were employed.

The results show that 1 part of cobalt can be detected in the presence of 30 of nickel, in which case a blue bead is obtained in the oxidising flame, and a bead of uncertain violet colour in the reducing flame. Proportions of Ni and Co from 20 : 1 to 1 : 1 gave in each case, both in oxidising and reducing flames, a blue bead. If the ratio of Ni to Co be increased, uncertain results are obtained till the proportion is 50 : 1, when a decidedly brown bead shows the presence of nickel, though, of course, 1 part of Co in 50 Ni is not shown by this reaction. Borax-bead tests can therefore only be relied on when the results are affirmative. A. R. T.

Bismuth Ochres from California. W. T. Schaller. (*J. Amer. Chem. Soc.*, 1911, **33**, 162-166.)—From analyses of the bismuth ochres found at several mines yielding lithium minerals in San Diego County, Colorado, the author is of opinion that the existence of natural Bi_2O_3 is not established, and that natural "bismite" or bismuth ochre, when pure, is more probably a hydroxide of bismuth. The bismuth ochres examined in this instance are either bismuth hydroxide or bismuth vanadate (pucherite), or mixtures of these two substances.

The analyses are as follow:

		I. Yellow Ochre (Stewart Mine).	II. Yellow Ochre (Pala Chief Mine).	III. Grey Ochre (Stewart Mine).
	Bi_2O_3	64·43	66·14	64·90
	V_2O_5	12·11	25·80	0·80
Gangue	Soluble in HNO_3	2·27	—	9·50
	Insoluble in HNO_3	17·63	7·37	13·50
H_2O	at 107° C.	0·32	0·21	0·40
	at 240° C.	0·24	0·32	0·30
	on ignition	3·43	0·84	11·40
		100·43	100·68	100·80

Remarks.—I. Mixture of vanadate and hydroxide of Bi. II. $Bi_2O_3.V_2O_5$ (amorphous "pucherite"). III. $Bi_2O_3.3Aq$. Vanadium an impurity from adhering yellow ochre.

The method of analysis was as follows: After ignition, the residue was dissolved in nitric acid, and the solution precipitated by hydrogen sulphide, the bismuth being converted into carbonate, and weighed as Bi_2O_3. The filtrates were evaporated to dryness, and the vanadium separated from the residue by a current of dry hydrochloric acid gas, the oxychloride of vanadium formed being collected in water, reduced and titrated with permanganate, after evaporating the chloride with sulphuric acid. The vanadium-free residue consisted chiefly of silica, alumina, and lime.

A. R. T.

Estimation of Very Small Amounts of Calcium by Means of Permanganate. L. T. Bowser. (*J. Ind. Eng. Chem.*, 1911, 3, 82-84.)—To the solution to be tested, about 5 or 10 c.c. in volume, a few drops of ammonia and 0·4 grm.

ammonium chloride are added. The mixture is heated to boiling, and 0·2 grm. ammonium oxalate is added. Boiling is continued for a moment, and the solution is then diluted with its own volume of 3 per cent. ammonia and allowed to stand two or three hours. The precipitate is collected on asbestos (previously treated with permanganate and washed), and washed with 3 per cent. ammonia, preferably hot. The asbestos pad is then transferred to a beaker, mixed with a little water, and, after addition of 1 c.c. of sulphuric acid (1 : 1), the mixture is heated nearly to boiling, and a slight excess of permanganate is added, the excess being determined by titration with oxalic acid. The solutions of permanganate and oxalic acid used are only $\frac{N}{200}$, and must be standardised against a calcium solution of known strength, for such highly dilute solutions are said to correspond to much less calcium than is indicated by theory. Narrow burettes are used, and it is shown that quantities in excess of 0·3 mgrm. of calcium can be estimated with an error not exceeding 0·03 mgrm. Quantities less than 0·3 mgrm. tend to be overestimated, and, accordingly, very weak solutions should be concentrated before applying the method. G. C. J.

Application of "Cupferron" in Quantitative Analysis. R. Fresenius. (*Zeitsch. anal. Chem.*, 1911, **50**, 35-43.)—The list of metals which can be separated from iron by precipitation of the latter by means of "cupferron" (the ammonium salt of nitrosophenyl-hydroxylamine, *cf.* ANALYST, 1910, **35**, 327) is now extended to include manganese, cobalt, zinc, and the alkaline earth metals. The separation of iron and alumina can be carried out more conveniently and with greater certainty of obtaining accurate results by this than by any other gravimetric method. The method serves well for the estimation of iron in ferromanganese or in manganese ores, but with ores the estimation of the manganese in the filtrate is more troublesome than is the similar estimation after an acetate separation, when this is conducted by an experienced operator.

The results obtained by Biltz and Hödtke with copper (ANALYST, *loc. cit.*) are confirmed, but bismuth is added to the list of metals which must not be present. Not only may iron and copper be separated from other metals by means of the reagent, but it may be used to separate iron from copper. To the acetic acid solution of the metals ammonium acetate is added and then excess of cupferron. The precipitate is washed with ammonia until the filtrate is no longer blue, and finally with water. In the filtrate the copper is thrown down by addition of acetic acid and a little more cupferron to render the precipitation complete. The copper precipitate is then treated as directed by Biltz and Hödtke. Small quantities of iron may be overestimated by as much as 5 per cent., but, in the absence of metals which interfere, copper can be estimated with an error not exceeding +0·2 per cent. G. C. J.

Quantitative Estimation of Lithium. E. Murmann. (*Zeitsch. anal. Chem.*, 1911, **50**, 171-174.)—The separation of lithium from sodium and potassium by precipitation as phosphate is apt to give high results, owing to the inclusion of impurities in the precipitate. The best procedure for carrying out this method consists in neutralising the solution of mixed chlorides and evaporating to dryness in a quartz dish with a few crystals of sodium phosphate. After cooling, the residue is extracted with dilute ammonia solution (1 : 1) and the insoluble phosphate is collected, dried and incinerated. The evaporation and filtration should be performed at least twice, if a substantial loss is to be avoided. The method yields fairly good results under favourable conditions, but there is a tendency on the one hand to incomplete precipitation of the lithium phosphate, and on the other hand to an accumulation of impurities if the precipitation be repeated frequently. The application of a correction for insoluble impurities is unsatisfactory.

The author has investigated an alternative method based on the extraction of lithium chloride by organic solvents. With anhydrous pyridine, lithium chloride may be separated with satisfactory results from sodium and potassium chlorides. The separation is very sharp; but, since the crystals of the other chlorides may retain traces of lithium chloride in their interior, it is perhaps advisable to redissolve the residue from the first extraction with pyridine, evaporate and extract a second time. The pyridine extract is evaporated to dryness in a platinum dish, the lithium chloride is treated with a slight excess of $\frac{N}{1}$ sulphuric acid, dried and heated to dull redness, and weighed as sulphate. If the latter be slightly coloured, the sulphate may be dissolved in water and a correction applied for the insoluble matter. In evaporating the solution of mixed chlorides for weighing, it must be borne in mind that lithium chloride is volatile at a low red heat. J. F. B.

Criticism of Magnesia Method for Estimation of Phosphoric Acid. W. C. Dumas. (*Chem. Engineer*, 1910, **12**, 185-190.)—The criticism is confined to methods in which the phosphoric acid is first separated by means of molybdate. It is shown that the composition of the precipitate most closely corresponds to the formula $MgNH_4PO_4.6H_2O$, when the precipitation is made slowly in solutions which are nearly neutral. After fifteen minutes a considerable quantity of ammonia is added and the process continued as usual, but the presence of even 1 c.c. of ammonia (sp. gr. 0·96) in each 50 c.c. of liquid at the moment of addition of magnesia mixture considerably reduces the percentage of magnesia in the precipitate. Rapid addition of magnesia mixture (6 or 7 drops per second) gives rise to a precipitate containing more than the theoretical amount of magnesia. Precipitates of abnormal composition behave abnormally on heating in a blowpipe flame, but even those of normal composition after the first five minutes' heating may continue to lose weight at a nearly uniform rate of 0·1 mgrm. per two minutes for half an hour or more. A protest is raised against the use of "analysed" samples as controls. The author recommends the use of pure silver phosphate for purposes of control. The silver phosphate is dissolved in nitric acid, the silver precipitated as chloride, and the phosphoric acid in the filtered solution precipitated by means of magnesia mixture after addition of as much molybdic acid as would be present in an actual determination, followed by addition of ammonia to very faint alkaline reaction. The use of molybdic acid in the control experiment is advised because, in presence of molybdic acid, precipitates of abnormal composition are less likely to be obtained.

G. C. J.

Electrolytic Estimation of Manganese. J. Köster. (*Zeitsch. Electrochem.*, 1911, **17**, 57-58.)—Otin's criticism (ANALYST, 1909, **34**, 415) of Engels' method for the estimation of manganese is based on a misreading of the directions of Engels, who specified the addition to the electrolyte of 10 grms. of ammonium acetate—not sodium acetate—together with 2 grms. of chrome alum. With the use of this electrolyte current densities as high as 2 to 2·6 ampères per 100 sq. cm. of anode surface do not lead to the deposition of even 0·1 mgrm. of manganese on the cathode. With such high-current densities a deposit does appear on the cathode, but this is not manganese, but chromium. Repetition of Otin's experiments, using sodium in place of ammonium acetate, showed that the cathode deposits observed by him were mainly chromium, with, however, about 1 mgrm. of manganese peroxide.

The one objection to Engels' method is the risk of chromic acid adhering to the deposit on the anode, even when this is washed with hot water after ignition, and the author therefore prefers to avoid the use of chrome alum, and to conduct the electrolysis in presence of alcohol, with high-current densities and mechanical agitation (*cf. Zeitsch. Electrochem.*, 1904, **10**, 553). G. C. J.

Separation of Platinum and Tin. L. Wöhler and A. Spengel. (*Zeitsch. anal. Chem.*, 1911, **50**, 165-171.)—Owing to the close similarity of their chemical functions and the formation of complex ions, the separation of platinum and tin presents considerable difficulties. Tin cannot be extracted from platinum-tin alloys by means of acids, reducing agents afford no separation from solutions, and the sulphides cannot be separated either by concentrated hydrochloric acid or by sodium hydroxide. A practicable but tedious method of separation may be based on the volatilisation of stannic sulphide in an atmosphere of sulphuretted hydrogen, or on the volatilisation of stannic bromide in a current of bromine vapour, which is preferable to chlorine for this purpose. The hydrolytic decomposition of the platinum stannic compounds by sulphuric acid only affords a complete separation if conducted at a temperature of 150° to 200° C. in a closed tube; at temperatures below 100° C. a certain amount of platinum is generally absorbed by the colloidal stannic oxide. The simplest and most accurate separation is obtained by precipitation of the stannic acid by heating with dilute sulphuric acid, and subsequently depositing the platinum by electrolysis from the clear liquid over the precipitate of stannic acid. For instance, a solution was prepared, containing 1 grm. of platinum and 3 grms. of tin, in 25 c.c. each of nitric and hydrochloric acids, subsequently diluted to 500 c.c. Fifty c.c. of this solution were treated with 25 c.c. of $\frac{N}{2}$ sulphuric acid, and the stannic acid was precipitated by boiling. After standing for twenty-four hours the liquid was electrolysed, with a tension of 1·1 to 1·7 volts, $N_{D100} = 0·2$ ampère, either at the ordinary temperature or at 50° to 60° C. The completion of the reaction was indicated by the decreased yellow coloration of the liquid when tested with stannous chloride. During the electrolysis the precipitate should not be disturbed, but at the end occasional stirring is necessary to complete the separation. Subsequently the stannic acid is converted into a flocculent condition by the addition of ammonium nitrate, and filtered off. J. F. B.

Estimation of Potassium as Potassium Platini-Chloride. H. Fresenius and P. H. M. P. Brinton. (*Zeitsch. anal. Chem.*, 1911, **50**, 21-35.)—A study of the influence exercised on the results of this determination by notable amounts of calcium or magnesium chloride when these are not first separated. The experiments were all made with approximately equal amounts (0·5 grm.) of potassium chloride and the other chloride. In presence of its own weight of calcium chloride, 0·5 grm. of potassium chloride is overestimated by no more than 0·5 per cent., and this error may be reduced to 0·3 per cent. by re-treatment of the weighed precipitate with alcohol, filtering, etc. The disturbing effect of magnesium is less—not exceeding 0·3 per cent. The influence of varying strengths of alcohol was also tried, and the use of the customary 80 per cent. spirit is confirmed as most satisfactory. Weaker alcohol leads to low results, even 70 per cent. spirit reducing the results nearly 1 per cent. The use of very strong alcohol may lead to high results in presence of sodium platini-chloride, which may be partially reduced, the resulting platinum getting weighed as potassium platini-chloride, but the error due to the use of alcohol as strong as 95 per cent. is negligible. The authors separate their precipitate from the filter, wash the latter with hot water, evaporate the filtrate in a tared dish, add the precipitate, dissolve this in hot water, re-evaporate and dry at 130° C. Constant weight is attained in two hours. If bulky precipitates are not dissolved in the dish, to ensure their distribution in a thin layer, water will be retained even after sixteen hours' drying, and may give rise to results 0·2 to 0·3 per cent. too high. G. C. J.

Dissolving Silicon Alloys. G. C. Davis. (*J. Ind. Eng. Chem.*, 1911, **3**, 42-43.) —It is found that 50 per cent. ferrosilicon can be readily decomposed by a mixture of strong hydrofluoric acid with hydrochloric or sulphuric acid. Solution is complete in a few minutes at a low temperature, and it is not necessary to reduce the sample beyond 10 mesh. Silico-spiegels with 20 per cent. silicon, 40 per cent. manganese, and 40 per cent. chromium may be similarly decomposed. G. C. J.

New Method of Estimating Sulphuric Acid and Sulphates. V. Auger and M. Gabillon (*Comptes rend.*, 1911, **152**, 441-443.)—The method is based upon the reduction of the sulphuric acid or sulphate by means of hydriodic acid, and the volumetric estimation of the liberated hydrogen sulphide by means of a standard solution of iodine. The hydriodic acid is prepared in the flask in which the estimation is made by the interaction of a mixture of phosphoric and pyrophosphoric acids with potassium iodide. The iodine liberated in the reaction of the sulphuric acid with the hydriodic acid is reconverted into hydriodic acid by the addition of phosphorous acid. The hydrogen sulphide produced in the reaction

$$H_2SO_4 + 8HI = H_2S + 4H_2O + 8I$$

carries forward some iodine and hydriodic acid, the first of which is eliminated by passing the gas through a column of calcium iodide, and the latter by means of an aqueous solution of the same acid decolorised by the addition of phosphorous acid. Finally, the hydrogen sulphide is absorbed in a solution of zinc acetate, and the sulphide estimated by means of iodine in the usual way. The reaction begins at about 80° C., and finishes at 110° C., and is complete in twenty to twenty-five minutes. To obtain good results, it is essential that the mixture of phosphoric acid used shall be free from metaphosphoric acid (which would cause too energetic reduction of the phosphorous acid, with the liberation of red phosphorus, etc.), and that the reduction flask shall be free from moisture so as to prevent the hydrogen sulphide being oxidised by the iodine into sulphur and hydrogen iodide. The apparatus required for an estimation consists of a 50 c.c. flask, provided with a long neck, with a lateral tube, through which the gas escapes, and with means for the introduction of a tube for the admission of dry carbon dioxide throughout the operation. The lateral tube is connected with a glass tube, about 25 cm. long and 1 cm. in diameter, charged with iodine for a length of 3 cm., and then filled up with calcium iodide. Attached to the other end of this tube is a small washing flask, containing about 5 c.c. of hydriodic acid solution, whilst the apparatus is completed by two absorption vessels, together containing about 100 c.c. of zinc acetate solution (25 grms. per litre). The reduction flask is charged with about 20 grms. of phosphoric acid (obtained by diluting the acid of 60° Bé. to five-sixths of its volume), 2 grms. of phosphorous acid, 3 grms. of powdered potassium iodide, and about 0·2 grm. of the finely-powdered sulphate under examination. As soon as all air has been expelled from the apparatus by the current of carbon dioxide, the flask is heated in an oil or sulphuric acid bath. The method gives results closely agreeing with theory, and is applicable to all sulphates except barium sulphate, which is attacked too slowly to be analysed in this way. C. A. M.

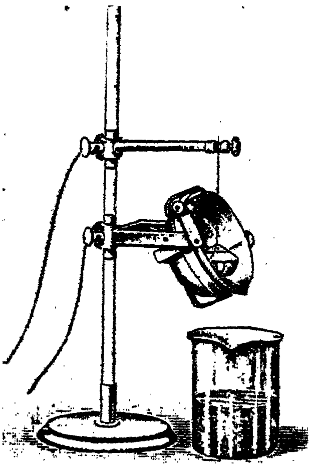
Estimation of Tellurium. A. Rosenheim and M. Weinheber. (*Zeitsch. anorg. Chem.*, 1911, **69**, 266-269.)—Gutbier's method for the estimation of tellurium (*Ber.*, 1901, **34**, 2724), by reduction with hydrazine in weakly alkaline solution, fails to throw all the tellurium out of solution, and yet gives results above the truth because the separated tellurium suffers oxidation during the prolonged boiling which is necessary to secure even approximately complete precipitation. By conducting the reduction in an autoclave, the method may be made more exact. To the solution contained in a Jena beaker, a sufficient quantity of a slightly ammoniacal 10 per cent. solution of hydrazine sulphate is added, and the beaker covered with a clock-glass, and placed in an autoclave, which is then heated up to about 130° C., and kept at this temperature for thirty minutes. The separated tellurium is collected in a Gooch crucible, washed with a very dilute solution of sulphur dioxide, and dried at 105° to 115° C. in a current of carbon dioxide. No trace of tellurium can be found in the filtrates. Oxidation of the precipitate is not wholly avoided, but the error on a weighing of 0·1 grm. never exceeds +0·7 mgrm., and is usually +0·5 mgrm.

Telluric acid can be titrated with fair accuracy like boric acid in presence of a sufficient quantity of some polyhydroxy compound such as glycerol. The aqueous solution of telluric acid is mixed with an equal bulk of glycerol (sp. gr. 1·26) and titrated cold with $\frac{N}{10}$ caustic alkali, using phenolphthaleïn as indicator. Each c.c. $\frac{N}{10}$ alkali = 0·0225 grm. H_6TeO_6, the glycerol-telluric acid reacting as a monobasic acid. The error of the method may be as great as ±3 per cent. on small readings of less than 15 c.c.

More accurate results can be obtained by addition of an excess of $\frac{N}{10}$ caustic soda containing some barium chloride, to a solution of telluric acid, and titration of the excess of caustic alkali by means of oxalic acid with phenolphthaleïn as indicator. Direct titration with barium hydroxide is not successful, as the end-point of the titration is indistinct, and barium tellurate is much more soluble in water than in solutions of barium hydroxide. On addition of excess of caustic soda containing barium chloride, barium tellurate separates almost completely, and the excess of alkali must be determined at once without filtration by titration in the cold with oxalic acid. Each c.c. $\frac{N}{10}$ alkali $= 0{\cdot}01125$ grm. H_6TeO_6, the telluric acid here behaving as a dibasic acid. The extreme error of the method is ±1 per cent. G. C. J.

Reaction of Uranium Salts. J. A. Slemssen. (*Chem. Zeit.*, 1911, **35**, 139.)—A solution of commercial ethylenediamine affords a sensitive reagent for uranium salts, which, when present even in traces, react with it immediately to form a bright yellow crystalline precipitate, which dissolves on adding an excess of the reagent. The test is quite as sensitive as the potassium ferrocyanide reaction and hydrogen peroxide test of Aloy. C. A. M.

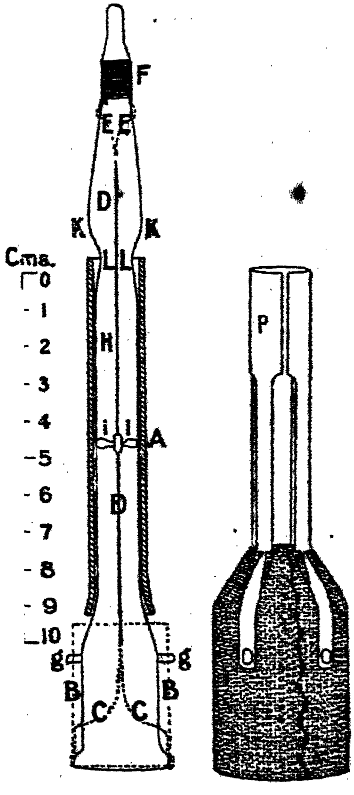
APPARATUS, ETC.



Holder for Classen Dish. F. Blume. (*Chem. Zeit.*, 1911, **35**, 12.)—The dish rests in a basket constructed of strips of nickel sheet instead of in the usual ring. This basket can be turned on a horizontal axis, and means are provided for holding it rigidly during the electrolysis proper. When this is at an end, the basket is tipped through 90° and the contents caught in a beaker. The arrangement permits of the use of very small quantities of wash-water—40 c.c. in place of 400 c.c.—a considerable advantage when the electrolyte and washings have to be used for the determination of other constituents. The apparatus is made by R. Hase, Hanover. G. C. J.

Gooch Crucible for Micro-Analysis. J. Donau. (*Monatsh.*, 1911, **32**, 31-40.)—The author and Emich (Analyst, 1910, **35**, 137) have described apparatus for filtering minute quantities of material. The author now describes a miniature Gooch crucible for use in the place of the paper discs previously described. From platinum foil of 0·0035 mm. thickness, a disc 15 mm. in diameter is punched. To the edge of this disc a platinum wire, 20 mm. long and 0·1 mm. thick, is welded. The disc is then laid on a piece of paper on a smooth glass plate, and 80 to 100 small holes are pricked in it by means of a fine needle, no holes being pricked within 3 or 4 mm. of the edge, which may be covered with an annular piece of paper. The disc is then reversed and laid on a soft rubber stopper, so that the burred side is uppermost, and a cylindrical piece of glass, brass, etc., with perfectly smooth table end, about 8 mm. in diameter, is pressed firmly against the pricked centre, and the disc given the form of a little dish 8 mm. in diameter and 3 to 4 mm. high. This dish is used as a Gooch crucible with the apparatus before described, its under surface just fitting the capillary funnel of Emich and Donau. In the ordinary way it is packed with about 0·5 mm. of asbestos, free from dust or long fibre, but it may be converted into a Munroe crucible by heating in it ammonium platinichloride, pressing, repeating the charge of platinichloride, and repressing. The attached platinum wire is for convenience in manipulation, ignition, weighing, etc., and is usually bent into a hook. G. C. J.

Apparatus for Rapid Electro-Analytical Determination of Metals. H. J. S. Sand. (*Chem. News*, 1911, **103**, 14-15.)—The apparatus has been designed to retain as far as possible the features of the apparatus previously described by the author (*J. Chem. Soc.*, 1907, **91**, 373; 1908, **93**, 1572) whilst reducing the use of platinum to a minimum. The anode is made largely of glass, the cathode of silver or nickel. The wide glass stem of the inner electrode (left in cut) rotates inside the glass tube A, which latter is gripped by the collar, P, of the outer electrode. In the inner electrode, platinum is only used in the gauze cylinder B, in the strips of gauze, C, which lead into the interior of the electrode to the copper wire, D, and in the strips, E, leading out at the top, which are wound over by the platinum wire F. All the connections through the glass are made by strips of platinum gauze of threefold thickness at the top, and with a width not less than 1 cm. below, so that it is possible to pass currents up to 10 ampères without endangering the electrode. The gauze cylinder, B, is fitted to the bottom of the electrode by blowing the glass against it. At the top, the cylinder stands off from the glass by 2 to 3 mm. in order to allow the gas bubbles to escape readily. It is held securely by four small protuberances, *g*, on the glass. The copper wire is held in the interior of the tube H by the enamel support *i*. The stem is widened at K just enough to prevent the tube A from being pulled off, but not enough to hinder the collar, P, from being slipped over it. The contraction of the stem at L allows the space between the stem and A to be washed down readily with a few drops of water before disconnecting.



For copper determinations a cathode of silver is employed, and the deposits are removed at the end of an experiment by means of hot dilute sulphuric acid. In constructing the cathode, a frame is cut from a single piece of metal sheet about 0·5 mm. thick and bent into the shape shown in the unshaded portion of the right-hand sketch. A cylinder of Kahlbaum's coarse gauze is then constructed, and the final form is obtained by introducing eight small pleats at the top. Gauze and frame are held together by four stout rivets, of which two are shown. Silver being brittle, loose ends are best avoided by removing a few horizontal wires at the bottom and melting the end of the projecting vertical wires in the oxygen blowpipe. The vertical joint is made by removing a few vertical wires, twisting together the opposite horizontal threads and fusing. Nickel cathodes for zinc determinations are made in a similar way from gauze of 11 meshes per cm., but of course no attempt is made to fuse the ends of the wires, nor is this necessary with nickel on account of its superior mechanical properties. G. C. J.

Electrolytic Estimation of Copper and Zinc using Sand's Apparatus.

W. M. Smalley. (*Chem. News*, 1911, **103**, 15-16.)—The apparatus used was that described by Sand (see preceding abstract). Copper was deposited from warm solutions containing only very small amounts of nitric acid (0·1 to 0·5 c.c.) to minimise the difficulty of washing the deposits without loss. About 0·7 c.c. of sulphuric acid was contained in the 25 to 75 c.c. of solution operated on. A current of 10 ampères was employed so long as the solution remained visibly blue, it was then reduced to 5 ampères until the ferrocyanide test showed the liquid to be free from copper, and finally increased to 10 ampères during the process of disconnecting. Providing the amount of nitric acid did not greatly exceed 0·1 c.c., quantities of copper up to 1 grm. could be deposited in 10 minutes with an error in no case exceeding −0·4 mgrm. With as much as 0·5 c.c. nitric acid present, the error may reach −0·6 mgrm.

Zinc was determined with the apparatus, following the usual procedure, the results being equal to those yielded by platinum apparatus. It was found that the use of citric acid in place of acetic acid reduced the tendency to occasional high results, but the improvement was small and the time required for deposition was nearly doubled.

A black deposit which forms on the silver electrodes may be removed as far as possible with a silk handkerchief, but it is not advisable to remove it entirely by ignition, as this leaves the surface in a porous state, in which it is more readily attacked by ozone in subsequent determinations. G. C. J.

Errors in Determining Sizes of Mineral Grains and the Use of Surface Factors.

H. E. Ashley and W. E. Emley. (*J. Ind. Eng. Chem.*, 1911, **3**, 87-91.) —It is inaccurate to express the size of microscopic mineral grains in "diameters," unless the term is carefully defined. The volumes calculated from microscopic measurement require multiplication by correction factors. For example, about 100 particles of sand were weighed, and their volume calculated by dividing this weight by the sp. gr. of quartz. The particles were then measured in two directions by means of an eye-piece micrometer, and, as they appeared on plan to approximate a rectangular rather than a circular shape, their volume was calculated from the formula $n(l \times b)^{\frac{3}{2}}$, where l represented the average length, b the average breadth, and n the number of the particles. The use of this formula overestimated the volume of the particles more than twofold in one case, and more than threefold in another. Calculation of the volume from the apparent mean diameter, on the assumption that the particles approximated a spherical shape, would have given a nearly correct value in the first case, but still one much in excess of the truth in the second, and the particles bore no resemblance to spheres. Obviously their depth was much smaller than their horizontal dimensions, and with kaolin or a micaceous sand the error would be even greater.

The distribution of sizes in any fraction of clay obtained by mechanical analysis may follow several laws; hence the various formulas proposed for calculating the mean size are all liable to error. A simple empirical correction factor to the arithmetical mean is, apparently, as accurate as any more elaborate calculation. Mellor's (*Trans. Eng. Cer. Soc.*, 1910, **9**, 94) surface factor, $\frac{6}{s}\left(\frac{W_m}{d_m}+\frac{W_n}{d_n}+\frac{W_o}{d_o}+\ldots\right)$, or Purdy's simpler form, $\frac{W_m}{d_m}+\frac{W_n}{d_n}+\frac{W_o}{d_o}+\ldots$, best represent the results of a mechanical analysis.

The surface factors become incomparable if different size limits are used in calculations for the smallest sizes. It is advocated that Seger's limits—0·04, 0·025, and 0·010 mm.—give results of most value to clayworkers. Other workers (*e.g.*, Purdy, *Illinois Geol. Survey Bull.*, **9**, 152) have subdivided the finest group into particles above and particles below 0·001 mm. mean diameter; but this gives predominance to the finest group, which may only amount to 10 per cent. of the whole, and yet accounts for 80 per cent. of the calculated surface, which then comes out very high. There is a doubt whether these very fine particles retain their crystal condition or whether they do not pass over to the colloid state, and there is no doubt that for some ceramic purposes clays with only slight residues coarser than 0·01 mm. possess grave disadvantages. Hence the preference expressed for Seger's simpler grading.

G. C. J.

Determination of the Electrical Conductivity of Soils. J. König, J. Hasenbäumer, and H. Meyering. (*Zeitsch. angew. Chem.*, 1911, **24**, 103-106.)—For the determination of the electrical conductivity of soils, the authors make use of the telephone method, placing the soil between platinum electrodes in an ebonite box of special construction. The vertical electrodes are 10 cm. long by 5 cm. high, and are fixed 1 cm. apart in the box, which is just long enough and high enough to accommodate them, and 2·5 mm. broad. The bottom of the box is provided with numerous perforations and is covered with a sheet of paper. The space between the electrodes is filled with air-dried, finely divided soil, the box stood in a glass vessel containing conductivity water, and the whole placed in a large desiccator containing dilute sulphuric acid and caustic potash. When moisture is seen to have risen to the surface of the soil, the box is left one hour longer in the desiccator, dried and weighed. It is then returned to the pan of water in the desiccator for a few hours or overnight and reweighed. When the weight is constant, the box is transferred to a rectangular glass vessel just large enough to accommodate it, and this is placed in a water-bath at 18° C. for at least an hour. Both the rectangular glass vessel and the water-bath have covers provided with holes through which the terminals of the electrodes project. The conductivity is then determined in the usual manner, and compared with that of a $\frac{N}{100}$ solution of potassium chloride contained in the same cell. Before use the electrodes are coated with platinum black by immersion in a solution containing 3 grms. platinum chloride and 0·02 to 0·03 grms. lead acetate in each 100 c.c.

The specific conductivity of soils is of the order $10^{-4} - 10^{-3}$, and experiments are described which show that it is reduced by cropping, in some cases by as much as 50 per cent., confirming the view that the conductivity depends in a great measure on the presence of those substances which serve as food for vegetation. The soil of several experimental plots was examined as to its conductivity, and the results compared with the weights of dry produce per acre. The soil of highest conductivity (97×10^{-5}) gave the largest yield, that of lowest conductivity (14×10^{-5}) the lowest yield. The intermediate members of the series did not grade well, but it is held that the conductivity of a soil is a fair index to its fertility, and a more certain index than the "osmotic water absorption" (*cf.* König and Hasenbäumer, *Zeitsch. angew. Chem.*, 1909, **22**, 1009), though in most cases the conductivity, osmotic water absorption and fertility (judged by weight of produce) rise and fall together. G. C. J.

Application of the Osmotic Pressure and Electrical Conductivity in the Examination of Soils. J. König, J. Hasenbäumer, and J. Meyering.

(*Landw. Vers. Stat.*, 1910, **74**, 1-56; through *Chem. Zentralbl.*, 1911, **1**, 259.)—In the estimation of the osmotic water-absorption capacity of a soil, the discrepancies formerly encountered may be almost entirely avoided by carrying out the determinations at a constant temperature. A temperature of 18° C. was found to be most favourable. Instead of estimating the osmotic absorption capacity, the soluble constituents of the soil may be measured by determinations of the electrical conductivity of the soil. This method is simpler and more rapid. But, on the other hand, the determination of the osmotic water-absorption capacity, given an efficient osmometer, appears to have the advantage of greater certainty and accuracy. The values found by both methods are satisfactorily concordant. The conductivity was determined by Kohlrausch's method. Since the electrical conductivity increases with the degree of fineness of the soil, it is advisable in comparative tests to use soils of the same degree of fineness. By these methods the authors have investigated the adsorption of nutrient salts by soils. The salts were employed at $\frac{N}{50}$ concentration for di-ionic salts and $\frac{N}{75}$ for tri-ionic compounds and potassium and acid calcium phosphates. The soils moistened with these solutions showed increases in the above characters, except in the case of dipotassium hydrogen phosphate, a circumstance which shows that with this salt both the potassium and the phosphoric acid are completely adsorbed by the soil. Other problems in the chemistry of soils have also been studied by means of the methods described above. J. F. B.

Volumetric Analysis with Small Volumes of Liquid. F. Pilch. (*Monatsh.*, 1911, **32**, 21-29.)—By means of the apparatus figured, very small quantities of the order of 1 mgrm. may be estimated with an error not exceeding 0·5 per cent. The reactions take place in the bulb *R*, which has a capacity of about 20 c.c. The burettes *a* and *b*, which are used to deliver any $\frac{N}{100}$ solutions appropriate to the purpose, are about 40 cm. long and 3·5 mm. in internal diameter. Iodeosin as recommended by Mylius and Förster (*Ber.*, 1891, **24**, 1482) is preferred as an indicator. Experiments are described showing that the accuracy obtainable is as stated, whether the apparatus be applied to alkalimetry, iodometry, or to estimation of chloride by Volhard's method. The apparatus has also been applied to nitrogen estimations by Kjeldahl's method. In this case, the ammonia is distilled from a small (100 c.c.) flask through a wide (1 cm.) glass tube bent obtusely, so that any products of the action of steam on the glass may flow back with condensed water to the flask. The vertical portion of this wide tube is packed with broken porcelain, and is drawn out to smaller bore at its lower end, which pierces the cork of the distillation-flask. From the upper end of the obtusely-bent tube, which carries a rubber cork, the vapours of ammonia, together with steam, are led through an acutely bent platinum tube of 5 mm. bore into the bulb, *R*, of the apparatus. The upper part of the vertical limb of the platinum bend carries a small (5″) condenser. By the use of a Nernst micro-balance 1 mgrm. or so of a substance of which very little is available may be weighed out accurately, and a sufficiently accurate nitrogen determination made in the manner described. G. C. J.

REPORTS.

Vitality of Typhoid Bacilli in River Water, with Special Reference to the Question of Storage. A. C. Houston. (Metropolitan Water Board. Sixth Research Report, 1910.)—Previous experiments conducted by the author (ANALYST, 1908, **33**, 403) had shown that typhoid bacilli perished fairly rapidly in stored river water. The water was infected with the bacilli and allowed to stand in the laboratory, when 99·9 per cent. of the bacilli perished in one week, and all of them in nine weeks. The bacilli used were strains cultivated in the laboratory in the ordinary way, and it did not follow necessarily that uncultivated bacilli—that is, those obtained directly from the human subject—would perish in the same manner. An opportunity recently arose of performing the experiment with the uncultivated bacilli. The urine from a carrier case of typhoid fever, which was swarming with typical living bacilli, was centrifuged, and the deposit added to 5 litres of raw Thames water in a partially filled bottle which was stored in the dark at 64-67° F. At the commencement of the experiment the infected water contained 770,000 typhoid bacilli per c.c. At the end of one week these had been reduced to 4 per c.c. in the shaken sample, at the end of two weeks none could be detected in 100 c.c., and the same result was obtained on subsequent occasions for thirty-four days. On the 24th and four following days a half-pint of the shaken sample was drunk by the author without any ill effects. A second experiment with a fresh sample from the same case was made. The water after infection contained 1,650 typhoid bacilli per c.c., and at the end of one week there were none present in 100 c.c. In this experiment, also, a half-pint of the water was drunk on the twenty-third day from the start, and the four following days, without ill-effect.

A comparable experiment was made with bacilli from the same source, but cultivated in the laboratory for nine days on three changes of media before being added to the water. After one week's storage the number of typhoid bacilli in the infected water had been reduced from 15,800 to 200 per c.c., but it was not until after six weeks that they completely disappeared from the water.

It is thus seen that the uncultivated bacilli perish more quickly than the cultivated bacilli in the stored water, so that the conclusions previously expressed as to the efficacy of storage are confirmed, and their value enhanced by these experiments. As it is the uncultivated bacilli which naturally gain access to water, it is clear that even one week's storage of the raw river water is an enormous protection against the conveyance of typhoid fever, and that less than a month's storage would be apparently an absolute protection.

The methods employed were the same as in the previous report, but full details of the composition of the culture media used are given. J. H. J.

Report on the Solubility, Extraction, and Reactions of Certain Colouring Matters used in Foods. H. M. Loomis. (*U.S. Department of Agriculture, Bureau of Chemistry, Circular No.* 63, January 17, 1911, pp. 1-69.)—Although no report can nclude all food colouring matters, yet the greater number of the natural and coal-tar colours usually employed are here mentioned, and their reactions described. The report consists in the main of a number of comprehensive tables, comprising (1) determinations of the solubility of the colouring matters, in various solvents, by weighing the residue obtained on evaporation of the saturated solutions of the colours; (2) estimations of the amounts of colouring matter extracted by immiscible solvents in neutral, alkaline and acid solutions; (3) and (4) observations of the colour reactions of dyed fibres obtained from 0·5 per cent. solutions (of coal-tar colours), and 5 per cent. solutions (of natural colours), and of the colouring matters in aqueous solution, and with the dry colour and sulphuric acid before and after dilution. A few details of the methods of manipulation with regard to the examination of oils and fats, the detection of mixed colours, and the methods of mordanting wool are also given. A. R. T.

Extracts from the Proceedings of the Association of Official Agricultural Chemists, 1910. (*U.S. Department of Agriculture, Bureau of Chemistry, Circular No.* 66, 1911, 1-27.)—In this circular are given the various methods of analysis and modifications of methods which have been investigated and adopted by the association. The methods relate to the analysis of soils, inorganic plant constituents, insecticides, waters, dairy products, foods and feeding stuffs, sugar, tannin, medicinal plants and drugs, etc. W. P. S.

REVIEWS.

ALLEN'S COMMERCIAL ORGANIC ANALYSIS. Fourth Edition. Vol. III. "Hydrocarbons," by F. C. Garrett, D.Sc.; "Bitumens," by S. S. Sadtler, S.B.; "Naphthalene and its Derivatives," by W. A. Davis, B.Sc.; "Anthracene and its Associates," by S. S. Sadtler; "Phenols," by S. S. Sadtler; "Aromatic Acids," by E. Horton, B.Sc.; "Gallic Acid and its Allies," by W. P. Dreaper; "Phthalic Acid and the Phthaleins," by W. A. Davis; "Modern Explosives," by A. Marshall. 1910. London: J. and A. Churchill. Price 21s. net.

Since the issue of the last edition of this work, the lamented death of the author and the rapid growth of subject-matter has necessitated the work of revision being divided amongst a number of specialists, each responsible for a section. The volume under notice contains a mass of information indispensable to the analyst, and it is evident that a great amount of labour has been spent on the work of revision, though some parts have been better done and more thoroughly brought up to date than others.

The opening chapter on "Hydrocarbons" has been condensed by the elimination of textbook matter, without the addition of much new material and without a thorough revision of the text. Under bromine absorptions the latest reference is to McArthur's paper in 1888; no mention is made of McIlhiney's work, nor of the fact that carbon tetrachloride is now generally used as solvent in preference to carbon disulphide. Data concerning commercial acetylene are still given from Fowler's paper in 1898, without any reference to the more recent Cantor Lectures and treatise on the subject by Lewes, and the later work of Caro and others. Later and more complete analyses of the gas should have been given than those on p. 9. Instructions for the assay of crude shale oil have been reduced to very meagre dimensions; and although coke oven tar has been rewritten as a separate section, and some useful additions made to the instructions for the assay of coal-tar and coal-tar pitch, also some analyses of water-gas tar, the information on the tars generally seems capable of being made more complete and useful.

In contrast to the foregoing, the chapter on "Bitumens" has undergone a thorough revision, and much new matter has been added, chiefly, however, from American sources, the pages having increased in number from 141 in the third edition to 206. In connection with the determination of sulphur in petroleum, reference might have been made to the method of Garrett and Lomax (*J. Soc. Chem. Ind.*, 1905, **24**, 1212), which is similar to that of Sadtler, was published independently at about the same time, and does not need a crucible of special pattern. The analytical methods for asphalts have been rewritten and brought up to date, the official methods of the Society (American) for testing materials, and those of Clifford Richardson, being given in full, and new sections added on asphalt fluxes and bituminous road materials; the analyses of crude land pitch and Trinidad Lake pitch printed at the top of p. 62 are, however, not intelligible, owing to the omission of the headings to the columns. Other serious printers' errors are the omission from p. 122 of the illustration of the Abel flash-point apparatus, described as Fig. 2, and from p. 155 of the Doolittle Torsion Viscometer, said to be shown in Fig. 6, which represents the Redwood Viscometer. There is a paucity of illustrations; the Pensky-Martens Tester, or the modified form introduced by Gray, essential for oils of high flashing-point should, we think, have been illustrated, and figures might have been given of the Elliott and Foster Testers and the Tagliabue Cup, used in the United States.

In the new section on gas oil it is surprising to find no reference to the important papers on the composition and valuation of gas oils by Ross and Leather, published in the ANALYST in 1906-7. Fuel oil is not mentioned. Much useful information is given on lubricating oils, though it would have been better if the term "viscosity" had not been used where "efflux time" or "relative efflux time" is meant. Reference might have been made to the method worked out by Archbutt and Deeley ("Lubrication and Lubricants") of standardising commercial viscometers with mixtures of glycerol and water so that the results may be expressed in absolute measure. A formula by Ubbelohde for calculating "specific viscosity" from Engler "degrees" is given on p. 173, but no reference is made to the original paper, and the particulars given are too brief to be of use; the meaning of "Engler degrees" does not seem to be anywhere explained. The paragraphs on "Inner Friction" contain some inaccurate and curious statements. The definition of "absolute inner friction," by which the reviser means "viscosity," is not correct in all its terms, and is not expressed in intelligible language. It is curious to read that "capillary tubes give somewhat truer values than a viscometer, such as the Engler." The fact is that capillary tubes of the dimensions necessary to insure steady viscous flow are alone capable of giving true values, and commercial viscometers, such as the Engler, having very short and comparatively wide jets, merely measure rates of flow which happen to be nearly proportional to the viscosities of oils not lower in viscosity than sperm oil at 60° F., but which are far from proportional in the case of more fluid oils and water. The application of the formula given on p. 174 to commercial viscometers would therefore be quite useless. Loss by heating, a most valuable test for cylinder and superheater oils, and for comparing together mineral oils from different crudes, is much more accurately and satisfactorily determined by passing a known current of air over a weighed quantity of the oil in a tube heated in an air-bath than by the crude method described on p. 159. A useful section has been added on Lubricating Greases, and the American methods of assay have been added to the article on "Benzene." The reference in note 2 at the bottom of p. 176 should be 170, and not 162.

L. ARCHBUTT.

Naphthalene and its Derivatives—Anthracene and its Associates—Phenols—Aromatic Acids—Gallic Acid and its Allies—Phthalic Acid and the Phthaleins.—The section on naphthalene and its derivatives includes a synopsis of the physical and chemical properties of this hydrocarbon and those of its derivatives which are employed as antiseptics. The picric acid method of estimating naphthalene is fully described, and due attention is given to the analytical reactions of α- and β-naphthol.

Anthracene is similarly dealt with, and the chemistry of the constituents of crude anthracene is briefly outlined. Reference is made to the compounds obtained from picric acid and these associates of anthracene, as in some instances the products afford a valuable means of identifying these hydrocarbons. The important Luck test for anthracene is given with full details, including the improvement in the method introduced by Messrs. Meister, Lucius, and Brüning.

The next section is devoted to a consideration of phenol and its homologues of the benzene series. In the descriptive portion of this chapter are included the processes commonly employed in manufacturing these substances. The analytical treatment is very full, and deals both with the characteristic reactions of the purified compounds and with the analysis of such commercial articles as crude carbolic acid, carbolic disinfectants, sheep-dips, etc.

The important and intricate group of substances included in the category of creosote and creosote oils is adequately dealt with, and many references are given to original communications bearing on this very involved branch of organic analysis.

Unfortunately, this section contains many typographical errors (see pp. 289, 308, 314, 315, 351, 383), and the terminology is not always consistent. On the same page (321) one finds the expressions "ferric chloride" and "sodium chlorid," De Forcrand's definition of phenates and phenoxides, as having respectively the formulæ C_6H_5OH,MOH and C_6H_5OM, where M is a metallic atom is given on p. 294; but on p. 299 it is stated that from ammonium tribromophenoxide, $NH_4.O.C_6H_2Br_3$, other tribromophenates may be obtained. On p. 300 reference is made to ammonium tribromophenate and sodium tribromocresolate, and on p. 333 one finds three isomeric substances described as "orthocresoxide," "paracresoxide," and "metacresylate." These vagaries in nomenclature are perplexing to students who may consult this work.

The section on aromatic acids is a useful compilation which includes description of the chemical properties and analytical reactions of the principal aromatic carboxylic and sulphonic acids, together with fairly complete references to such important compounds as benzaldehyde (oil of bitter almonds), saccharin, cinnamaldehyde, coumarin, and vanillin.

In view of the interest attaching to salicylic acid as a preservative and a drug, considerable space is devoted to the detection and estimation of this substance in a large variety of commercial products. In this connection reference is made to the colorimetric methods of estimating salicylic acid, which were formerly described in the ANALYST (1903, **28**, 2; 1905, **30**, 124, and 1907, **32**, 286).

The analytical reactions of pyrogallol are summarised and compared with those of gallotannic and gallic acids in a special section devoted to these polyhydric phenols and their esters and ethers.

The section on phthalic acid and the phthaleïns contains a short account of the employment of phenolphthaleïn and similar indicators in acidimetry and alkalimetry.

G. T. MORGAN.

Modern Explosives.—Mr. A. Marshall's article on "Modern Explosives" occupies fifty-eight pages in the volume under review. The author had an opportunity, of which he has, unfortunately, not availed himself, to contribute a detailed and critical account of the methods of analysis of high explosives and smokeless sporting powders.

There is, in this respect, a distinct gap in the literature of explosives, and it is to be regretted that some effort was not made to deal with this branch of analytical chemistry. It is improbable that the analyst who is not connected with explosive manufacture would, in the course of general practice, have to report on cordite, guncotton, or nitro-glycerin; but, if this were the case, full information would be found in the Government specifications. On the other hand, it is quite possible that samples of either high explosives or sporting smokeless powders would be submitted to him. Should he turn to Mr. Marshall's article for help, no adequate information will be found. Even a tabulated list of the main groups of high explosives and sporting powders, with examples of the compositions of the more characteristic members of each group, would have been of use and assistance. In a work on commercial analysis, to confine attention, from the analytical point of view, almost wholly to the question of cordite and its ingredients is, in the reviewer's opinion, an error of some magnitude. Cellulose nitrates have been dealt with concisely, and the necessary references to recent literature are included. The writer cannot, however, from his own experience, agree with the author's statement that the Schultze-Tiemann method for the determination of nitrogen in guncotton gives results 0·1 per cent. to 0·2 per cent. higher than the Lunge nitrometer. On averaging a large number of comparative tests carried out by the same operator, the results are practically identical. The statement that all but the very low nitrated products of nitrocellulose are insoluble in pure alcohol is inaccurate. Collodion cotton, containing from 12·0 to 12·3 per cent. of nitrogen, intended for the manufacture of blasting gelatine, cannot be classed as one of the lowest nitrates; yet a good collodion cotton, intended for this purpose, will have a solubility, in absolute alcohol, of nearly 50 per cent. Whilst on this subject it should be mentioned that the author's suggestion that the easiest method of determining the suitability of collodion cotton for blasting gelatine is to investigate its viscosity in solvents, has only an academic interest. The only reliable laboratory test is to make a "jelly" with nitroglycerin containing 2 to 3 per cent. of collodion cotton by heating the mixture in a small porcelain basin on the water-bath. The section upon nitroglycerin also includes notes upon dinitroglycerin and the mixed esters of glycerol, and here it should be noted that on a single page four minus signs have been omitted in the data for freezing-points. Picric acid has been dealt with at a length in excess of the requirements of explosives, but, as tinctorial chemistry had also to be considered, it was perhaps natural that this part of the article should have been expanded to deal with a number of tests for detecting traces of picric acid. In dealing with fulminate of mercury, the author has very wisely quoted, at considerable length, from Brownsdon's work upon the analysis of cap composition. Under the heading of "Stability Tests" the well-worn paths of the Home Office Specification have been trodden once more, and the only point of interest here is that details of the heat-tests in use in the United States have also been included. The tests proposed by Guttmann, Spica, Vieille, Will, Bergmann, and Junk, and the German tests at 135° C., are shortly dealt with, and, in addition, the British Government silvered vessel test and the United States Army tests at 115° C. are briefly referred to. The question of the detection of mercury in explosives has been dealt with by quoting verbatim Messrs. Dupré's methods from the Annual Report of the Inspectors of Explosives for 1907, and the microscopic test of Hargreaves and Rowe is also referred to. Among instances of uncorrected errors, the following may be mentioned: Wood pulp and starch are stated to contain no oxygen. On p. 593 "saturated lime" should read "saturated brine," and the maximum percentage of moisture allowed in M.D. cordite should be 1·5 per cent., and not 1 per cent. On p. 615 the word "boiling" should be "heating."

GEORGE W. MACDONALD.

MICRO-ORGANISMS AND FERMENTATION. By ALFRED JÖRGENSEN. Translated by S. H. DAVIES, M.Sc. 1911. London: Charles Griffin and Co. Price 15s. net.

This new edition of Jörgensen's well-known textbook is the fourth which has appeared in English, and is a translation of the fifth German edition published in 1909. The wide extent of the investigations made during the course of the last ten years has necessitated considerable increase in the bulk of the book, which may, indeed, be regarded more as a new work than as a new edition.

The familiar characters of the previous issues are, however, retained, special attention being paid to the use of pure cultures of yeasts inaugurated by Hansen nearly thirty years ago. The work of the Danish school of micro-biologists is naturally accorded an important place, but that of other investigators also receives notice, although the discussion of the theory of fermentation contains no reference to the excellent work of Slator and only brief notices of the researches of Ehrlich and of Harden and Young.

The author first gives a short account of the methods employed in the microscopical and physiological examination of micro-organisms, the subjects treated of including staining, sterilisation, antiseptics, nutrient media, pure cultures, etc. This section might have been greatly increased in value by the inclusion of a more detailed description of the technique adopted in the author's laboratory. Next comes a discussion of the procedure followed in the biological examination of air and water, principally with reference to the requirements of the brewery. Chapter III. deals with the actions and conditions of growth of zymogenic bacteria, and Chapter IV. with the occurrence and life-history of most of the common mould-fungi.

The fifth section, occupying nearly one-half of the whole volume, is devoted to the yeasts, all the more important culture and wild varieties being considered in their relations to the fermentation industries. This part of the book gives, in addition, accounts of the history of fermentation and of the various investigations which have been carried out on variations in the *Saccharomycetes*, the morphology and anatomy of yeast-cells, and a number of allied matters. A description is also given of the manner in which Hansen applied the phenomenon of spore-formation to the analysis of yeasts.

Chapter VI., which has been considerably reduced in volume, deals briefly with the means employed for the preparation of mass-cultures of pure yeast for industrial purposes.

The book will commend itself to all those who, engaged in practical brewing and distilling, do not desire to carry on their work in a mere rule-of-thumb manner. The ground covered by the author is wide, and many of the questions dealt with are necessarily touched upon but lightly. But, even where this is the case, the brewer or distiller will be able to extract much valuable information and many suggestive hints on practical points.

The quality of the translation is, on the whole, good; the grammar and nomenclature are, it is true, faulty in places, but in no instance is the meaning obscure. Very few misprints are apparent.

A feature which increases the usefulness of the book, and which was not included in any of the previous editions, is the provision of a subject-index. A fairly complete bibliography is also given. T. H. POPE.

PHYSICO-CHEMICAL TABLES. Vol. II. By JOHN CASTELL-EVANS. London: Charles Griffin and Co., Ltd. 1911. Pp. xiv + 688. Price 36s. net.

This volume completes the work, and contains Part III., devoted to Physics, and Part IV., on Analytical Chemistry. The last section does not appear to be quite complete, as a number of tables which have appeared in current literature during the past few years, and which are of use to analysts, have not been included. Criticism on this point is disarmed by the fact that the work is a posthumous one.

In the publishers' note the work is truly described "as a fitting monument to the energy, perseverance, and deep devotion of the author," and no one studying the book can fail to be struck by the thoroughness and intimate grasp of the subject displayed. It might be urged as a possible failing that the source of the tables is not given, but on reading carefully it becomes apparent that no table is simply copied; all have been carefully checked, and in very many, if not in all, cases recalculated. The authority for the figures is John Castell-Evans. The very tables themselves inspire confidence, and one instinctively comes to feel that the omission of the source does not matter and that the guarantee of the author is sufficient.

The chief fault to be found with the work is also its greatest merit—its extreme accuracy. In very many cases, in a busy laboratory, a table is used to calculate results obtained under conditions which do not permit of more than three or four significant figures being reliable; Castell-Evans presents tables giving six, seven, or even nine figures, and their very bulk defeats the author's object. The book is for the reference library, or for use when the utmost precautions to insure accuracy are used, but not one to lie upon the working bench for daily use.

To review the Analytical portion seriatim—the tables of factors to convert weights of precipitates and c.c. of standard solution used into the constituent to be determined are unusually complete, but in some cases the factors are based on methods which are obsolete. Thus factors for volumetric boron estimation are given only for the method of titration with baryta till the solution is just clear of the turbidity which forms at first, while the method of titration in the presence of polyhydric alcohols, which requires a factor just half that given, is ignored. For glycerol, Hehner's bichromate method and Benedikt's acetin method are not mentioned, and none of the factors given, which are for methods now superseded by the above, apply. No other table requires comment till the section of Alcoholimetry is reached. This is a marvellous compilation, nearly complete, and a masterly review of the work which has been done, but all mention of proof spirit has been omitted. Possibly this was intentional, and certainly most analysts will agree that "proof spirit" is a relic of the barbarous past, but so long as it is a legal expression of alcoholic strength it should appear in alcohol tables.

Much of the Physical portion will be of use to the analyst. Over 100 pages are devoted to specific gravities of solutions of almost every substance of usual occurrence, and such subjects as solubilities, viscosity, and surface tension are treated of in a useful manner. The present volume, like its predecessor, is one which will well repay, not mere perusal, but careful study by the analyst, as it will not only give him an insight into those branches of science of which more use might be made in analytical chemistry, but will show him where he can turn in case of need.

H. Droop Richmond.

* * * * *

INSTITUTE OF CHEMISTRY.

The Thirty-third Annual General Meeting of the Institute of Chemistry was held at 30, Bloomsbury Square, on March 1, Dr. George Beilby, F.R.S., President, in the chair.

After the routine business had been transacted, the President delivered his address. After referring to the losses of the Institute by death, mentioning especially Professor Campbell Brown, Mr. Michael Carteighe, and Mr. Oscar Guttmann, he dealt with the progress and work of the Institute. The membership continued steadily to increase, notwithstanding the high standard of the examinations; while the position of the Institute, as an organisation existing for public service, never stood so high as at the present time. Over 96 per cent. of the appointments of public analysts in the United Kingdom are held by Fellows of the Institute, the Final Examination in the Chemistry of Food and Drugs being conducted on lines prescribed by the Local Government Board, and specially recognised by them for these appointments.

The Council had under consideration the institution of a series of lectures, the object of which would be to bridge over the gap between academic training and practice. Without depreciating the value of a broad scientific education, it was realised that students entirely trained in an academic atmosphere missed some of the advantages of the old system of private pupilage in the laboratories of practising Fellows or in works. This loss was met, in some instances, by students preparing for the Final Examination in such laboratories; but there was a need for a means of introducing something analogous to the clinical instruction afforded to medical students. It was proposed, therefore, to ask Fellows having expert knowledge to give lectures which would give students an insight into the actual work of the chemist, whether engaged in the application of his science to commerce and industry, or to the scientific control of the affairs of daily life. Apart from the value of the information which could be imparted by such experts, considerable advantage would accrue to the students from the mental contact with such men, while they would acquire a proper sense of proportion in respect of the work of chemists in various branches of practice.

The President then remarked on the successful working of the Appointments Register, by which means the Institute introduced properly qualified chemists to authorities and manufacturers requiring their services, and he acknowledged the valuable help given by the Honorary Corresponding Secretaries of the Institute to members taking up appointments in various parts of the Empire.

Continuing, he referred to the appeal which had been made for funds for new buildings. It had been estimated that £15,000 would be required for this purpose, and the Council were able to record promises amounting to £7,566, of which about £5,000 had actually been received. This included contributions from four of the great city companies and from a few manufacturing firms. He hoped that others would show their appreciation of the work of the Institute in the same practical manner, and he appealed to the Fellows and Associates themselves, as far as they were able, to promote the successful raising of the fund.

Professor MELDOLA, in moving a vote of thanks to the President for his address, said it would give him much pleasure to see the Institute take an active part in the education of chemists, and he cordially supported the new departure as to the institution of the proposed lectures, which would make the student realise more fully the value of the practical side of his subject. The Institute had always been happy in the selection of its officers, and he (Professor Meldola) paid a high tribute to the services of Dr. Beilby, the present President, for his zeal and attention to the affairs of the Institute.

The following Fellows were re-elected as Censors: Professor Percy F. Frankland, Mr. David Howard, Professor J. Millar Thomson, and Sir William Tilden.

The following were elected Officers and Council:

President.—George Thomas Beilby, LL.D., F.R.S.

Vice-Presidents.—Frank Clowes, D.Sc.; Percy Faraday Frankland, LL.D., Ph.D., F.R.S.; George McGowan, Ph.D.; Raphael Meldola, F.R.S.; John Millar Thomson, LL.D., F.R.S.; Sir William Augustus Tilden, D.Sc., F.R.S.

Hon. Treasurer.—Alfred Gordon Salamon, A.R.S.M.

Members of Council.—Francis William Frederick Arnaud; Edward John Bevan; Bertram Blount; William John Atkinson Butterfield, M.A.; Francis Howard Carr; Charles Edward Cassal; Alfred Chaston Chapman;* Arthur Crozier Claudet, A.R.S.M.; James Connah, B.Sc.; William Salvador Curphey; Cyril Dickinson, B.Sc.; James Johnston Dobbie, Ph.D., LL.D., F.R.S.; William Porter Dreaper; John Alfred Foster; Walter Charles Hancock, B.A.; Frank William Harbord, A.R.S.M.; Frederick Gowland Hopkins, M.A., M.B., D.Sc., F.R.S.; William Jackson Pope, M.A., M.Sc., F.R.S.; Thomas Slater Price, D.Sc., Ph.D.; Charles Proctor; Sir Boverton Redwood, D.Sc.; Henry Droop Richmond; Alfred Smetham; Edward William Voelcker, A.R.S.M.: John White; Sydney Young, D.Sc., F.R.S.; William Maurice Gathorne Young.

---

* Mr. Chapman, who has been appointed examiner, has resigned his seat on the Council, and Sir Alexander Pedler, C.I.E., F.R.S., has been co-opted in his place.

MAY, 1911. Vol. XXXVI., No. 422.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The ordinary meeting of the Society was held on Wednesday evening, April 5, in the Chemical Society's Rooms, Burlington House. The President, Mr. E. W. Voelcker, A.R.S.M., F.I.C., occupied the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. H. G. Battye, G. D. Elsdon, B.Sc., N. Evers, B.Sc., A.I.C., and A. W. Knapp, B.Sc., F.I.C., were read for the second time; and a certificate in favour of Mr. Alfred Douglas Heywood, A.I.C., 73, High Street, Southend-on-Sea, chemist to the Hygienic Dairy Society, Salisbury, was read for the first time.

Messrs. J. Clifford, A.R.C.S.I., C. H. La Wall, J. Connah, B.Sc., F.I.C., H. F. Knight, W. R. Mummery, F.I.C., and W. M. Seaber, B.Sc., F.I.C., were elected members of the Society.

The following papers were read: "The Analytical and Microscopical Examination of Compound Liquorice Powder," by G. E. Scott-Smith, F.I.C., and John Evans, F.I.C.; "Note on Gerber's 'Neusal' Milk Test" and "Note on Abnormal Cotton Cakes," by John Golding, F.I.C.; "A Further Contribution to the Question of Turpentine Substitutes," by J. H. Coste, F.I.C., and L. Myddelton Nash, F.I.C.; "Note on Almond and Apricot Kernel Oils" and "Constants of Chicken and Turkey Fats," by Raymond Ross, F.I.C., and Joseph Race, F.I.C.

* * * * *

EXAMINATION OF SHREWSBURY AND KNAPP'S PROCESS FOR THE ESTIMATION OF COCOANUT OIL.

By RAYMOND ROSS, F.I.C., JOSEPH RACE, F.I.C., AND FRANK MAUDSLEY, B.Sc., F.I.C.

(*Read at the Meeting, March* 1, 1911.)

Last year Messrs. Shrewsbury and Knapp described a process for the estimation of cocoanut oil in butter (Analyst, 1910, **35**, 385). Although a considerable number of English butters were examined, very few of foreign origin were investigated, and of the three examples given in this latter division two were classed as suspicious.

It therefore appeared advisable to examine a number of foreign butters and cocoanut oils by this process. The samples in question were obtained for us from the wholesale market, and every possible precaution was taken to insure their authenticity. The following results were obtained :

Butter.	Shrewsbury and Knapp Figure.	Iodine Value.	Per Cent. of Triolein (calculated).	Shrewsbury and Knapp Figure of Residual Fats calculated at Triolein = 28.	Shrewsbury and Knapp Figure of Residual Fats calculated as Triolein = 65.

Cocoa butter	16·5	31·2	36·2	6·4	—

Shrewsbury and Knapp (*loc. cit.*) give 32 as a suggested maximum, but our results seem to point to a maximum of 35·5.

The effect of variations of the amounts of triolein in butter is dwelt on by these authors. Our experience with triolein is distinctly unsatisfactory, as great variations in the number obtained occur. This is probably due to the fact that a really good separation of the fatty acids in the alcohol-water solution rarely takes place. With oleic acid, however, fairly uniform results were obtained, the figure varying from 25 to 29·5 with the various samples at our disposal.

The figure 65 for triolein, and more so the somewhat higher ones obtained by us, must be excessive, because butters which differ considerably in their percentage of triolein as measured by the iodine value do not differ proportionately in their Shrewsbury and Knapp figure. This would not be likely if 65 or any higher figure were correct for triolein. Probably the number obtained by us for oleic acid is approximately right.

In the table given above the percentage of triolein is calculated from the iodine absorption, and from this the Shrewsbury and Knapp number is obtained by calculation for the residual fats on the assumption of a Shrewsbury and Knapp figure for triolein of 28 for one column and 65, as given in their paper, for the other. From these it is evident that, if 65 were correct, no value could be assigned to anything but the amount of oleic acid present, and the whole process would be no better than an iodine value. That this is not the case is seen from the table, where a rise in iodine absorption does not necessarily imply a rise in the Shrewsbury and Knapp figure.

The constitution of the residual fatty acids after separation from the alcohol water solution is given below, and is rather interesting. It seems to point to proportional quantities of all the constituents being dissolved. The main factor in the Shrewsbury and Knapp figure would be dependent then, as contended by the authors, on the proportion of lower and more soluble fatty acids present:

RESIDUAL FATTY ACIDS.

Name.	Iodine Value.	Zeiss at 45° C.	Molecular Weight.	Oleic Acid Per Cent. (calculated).	M – O.
Finnish...	44·0	31·5	259·7	49·0	238·2
Danish	47·0	31·5	259·1	52·2	234·1
Siberian	40·2	31·0	263·3	44·7	248·3
Irish Creamery ...	39·5	30·5	264·0	44·0	250·0
Irish Factory	40·8	31·5	257·0	45·3	236·4
Irish Dairy	43·2	32·0	261·3	48·0	242·3
Swedish	—	31·0	—	—	—

In considering the genuineness or otherwise of a butter, it is doubtless advisable not to rely entirely on any particular figure, but to consider the case as a whole. A figure that we have found to give instructive results is obtained by calculating the iodine value of the fatty acids to oleic acid, and from this the molecular weight of the residual fatty acids, by the following formulæ:

$$\frac{\text{Iodine value per cent.} \times 100}{90} = \text{oleic acid} = \text{O},$$

$$\text{Molecular weight of residual fatty acids} = \frac{100\ \text{M} - (282 \times \text{O})}{100 - \text{O}},$$

where M = molecular weight of the fatty acids and O = oleic acid per cent. The figure thus obtained for genuine butters is generally about 235, and the addition of cocoanut oil tends to reduce the figure considerably.

We find that it is absolutely necessary to follow the process exactly as described by Shrewsbury and Knapp, especially as regards glycerol saponification. With alcoholic potash only extraordinarily high results were obtained; for example, Swedish butter gave 112, and Danish butter 77. If, however, the correct quantity of glycerol is added after saponification, the results are normal.

The method will probably be of use in helping to determine the approximate composition of margarine. Thus a high-class margarine, A, showed very different results from a cheap one, B, and the former probably contained a considerable amount of cocoanut oil:

	A.	B.
Zeiss butyro-refractometer (25° C.)	52·5	61·0
Sp. gr. (37·8° C.)	0·9097	—
Shrewsbury and Knapp figure	47·5	19·5
Koettstorfer value	232·8	204·9
Per cent. of insoluble acids left in funnel after Shrewsbury and Knapp	65·8	85·1
Reichert-Meissl	9·0	4·7
Polenske	6·7	1·4

Mr. Knapp sends the following note:

"The figure given by us for triolein was obtained from a single sample, which had a butyro-refractometer reading at 40° C. of 59·0. Lewkowitsch gives 56·5 for pure triolein. I think it would add to the value of the several figures obtained by Messrs. Ross, Race, and Maudsley for oleic acid if they indicated the purity of their samples. With regard to their calculation to show that 65 is too high a figure for triolein, it should be remembered that this calculation is based on the supposition that the various fatty acids do not interfere with each other's solubility. In the process, we are actually dealing with the relative solubilities of oleic, etc., acids in the water-alcohol mixture and in the separated fatty acids. What is required is the figure which olein gives in presence of the other butter constituents, and the calculation very usefully shows that 65 is too high for this figure. Mr. Shrewsbury and I would welcome 28 as the figure for olein, as it would increase the value of the process, and enable us to understand why both cocoanut-oil-free margarine and lard give lower Shrewsbury and Knapp figures than butter."

THE ANALYTICAL AND MICROSCOPICAL EXAMINATION OF COMPOUND LIQUORICE POWDER.

By G. E. SCOTT-SMITH, F.I.C., and JOHN EVANS, F.I.C.

(*Read at the Meeting, April* 5, 1911.)

COMPOUND liquorice powder, prepared in accordance with the directions of the British Pharmacopœia, contains:

	Per Cent.
Senna, in fine powder	16·7
Liquorice root, in fine powder	16·7
Fennel fruit, in fine powder	8·3
Sublimed sulphur	8·3
Refined sugar, in powder	50·0
	100·0

We understand that it is customary on the manufacturing scale to grind the whole ingredients into powder together, gradually sifting and returning the gruffs to the mill until they are reduced to a very low bulk, usually a few pounds. These are set aside and added to a succeeding batch, which is then treated in the same manner. By this process the correct ratio of the various ingredients is slightly altered, as the sulphur and sugar yield no gruffs, while the senna, liquorice, and fennel yield gruffs in varying quantities.

During the last three years we have examined over 100 samples of compound liquorice powder, the majority of which were submitted by the Inspectors under the Sale of Food and Drugs Acts. We have been much impressed with the great diversity in appearance of the samples, and several instances of careless manufacture have come under our notice. In several samples the sulphur was present to the extent of 16 per cent.—that is, nearly double the quantity prescribed by the British Pharmacopœia—whilst in other samples the sulphur was entirely omitted. Again, in our microscopical examination of several samples, the liquorice root was so predominant that the senna and fennel were identified with difficulty, and might justly be described as traces.

Many instances of gross adulteration with ground olive stones and ground almond shells have also come under our notice. These adulterants, we understand, find their way into compound liquorice powder through using foreign ground liquorice root, which is subject to these adulterations.

Upon referring to the literature on the subject, we find that the following standards have been suggested:

1. The Local Government Board (Ireland): Ash, 4·5 per cent.

2. J. C. McWalter (*Pharm. J.*, 1902, **69**, 89): Moisture should be from 4 to 6 per cent.; ash, not above 5 per cent.; soluble ash, not exceeding 3 per cent. Not less than 4 per cent. should be dissolved in 70 per cent. alcohol.

3. C. G. Moor ("Suggested Standards for Food and Drugs," p. 179): Water should not exceed 6 per cent.; ash should be about 4 to 5 per cent.; soluble ash about 2·5 per cent.

4. H. W. Gadd (*Year-Book of Pharmacy*, 1901, p. 390) gives the following results of analysis of three samples of compound liquorice powder:

	Moisture per Cent.	Ash per Cent.	Soluble Ash per Cent.	Extractive in Tincture per Cent.*
A	6·35	4·5	2·80	4·83
B	5·40	4·5	3·15	3·73
C	4·15	4·8	2·68	4·47

5. J. F. Liverseege (*Year-Book of Pharmacy*, 1906, p. 269): The amount of ash found in twenty-one samples was 3·8 to 6·4 per cent. This author suggests a method

---

* The tincture was prepared by macerating 5 grms. of the powder in 70 c.c. of 70 per cent. alcohol.

of analysis by extracting the powder first with strong alcohol; then with carbon bisulphide, to obtain the sulphur; and finally with water, to obtain the sugar.

The amount of moisture in the samples examined by us varied from 3·7 to 4·2 per cent.

The following table shows the amount of ash found in commercial samples:

	Maximum.	Minimum.	Average.
Total ash	6·78	4·36	5·35
Insoluble ash	3·98	1·62	2·54
Soluble ash...	3·20	2·48	2·80

Several samples not included in the above table contained abnormal proportions of total ash, even amounting to 8·5 per cent. In all these samples the ash insoluble in hydrochloric acid (sand) was excessive, amounting to nearly 4 per cent. In our opinion these samples were prepared from inferior or improperly cleaned drugs.

The disturbing action of the sulphur on the total and insoluble ash, due to the combination of the sulphur with the mineral constituents of senna, liquorice, and fennel, was pointed out by one of us in a previous paper (*Pharm. J.*, 1905, **74**, 363).

The presence of sulphur in the preparation not only causes an increase of total ash over the actual amount of mineral matter present in the several ingredients, but it also converts some of the insoluble into soluble ash.

The following table will illustrate this point:

	Compound Liquorice Powder. B. P.	Compound Liquorice Powder without Sulphur + 8 per Cent. Extra Sugar.
Total ash	4·66	3·75
Insoluble ash	1·68	2·76
Soluble ash	2·98	0·99

These two samples were prepared from the same ingredients.

Thus it will be seen that the percentage of soluble ash is of no value in detecting exhausted drugs in compound liquorice powder; even if exhausted drugs had been employed, the percentage of soluble ash would still be raised, due to the conversion of the insoluble carbonate into soluble sulphides and sulphates. Again, the amount of extractive matter yielded to 70 per cent. alcohol, as suggested by some observers, is of little value for detecting the presence of exhausted ingredients, as the whole of the sugar is soluble in 70 per cent. alcohol; thus the alcoholic extract would contain a large amount of sugar, together with a smaller amount of extractive matter from the drugs, and a slight variation in the proportion of sugar would vitiate the results. Sugar is soluble even in 95 per cent. alcohol.

The determination of the sulphur presents no special difficulty. The following is the method employed by us: One grm. of the powder is treated with 15 to 20 c.c. of concentrated nitric acid and heated; and if the sulphur fuses, a small quantity of bromine is added. When oxidation is complete, hydrochloric acid is added, and evaporated to remove excess of nitric acid, diluted with water, and filtered from any siliceous matter, and finally precipitated as barium sulphate. The amount of sulphur actually present, either as sulphates or organic sulphur, in the senna, liquorice, and fennel, is very small, and may be neglected. The determination of the sulphur by means of carbon bisulphide cannot, in our experience, be relied on, as commercial samples of sublimed sulphur are not always completely soluble in this reagent.

Before entering upon the consideration of the adulteration of compound liquorice powder with foreign vegetable powders, it is necessary that we should be thoroughly acquainted with the microscopic characters of those ingredients of which it is composed. The media employed by us in the routine microscopical examination of compound liquorice powder are water, glycerine, and a strong solution of chloral hydrate (50 grms. in 20 c.c. of water). Iodine water is also used for the better observation of the starch granules.

The histology of the senna leaf presents many characters by which it can be easily identified, even in such a complex mixture as compound liquorice powder. It has an iso-bilateral structure—that is, there is palisade tissue on both the upper and under surfaces—and between the two palisade tissues there is a layer of spongy parenchyma. It has peculiar hairs scattered over both the lower and upper surfaces. These hairs are one-celled and conical, they may be straight or curved, and are usually slightly contracted at the base. They are thick-walled and have a warty appearance. The stomata are surrounded by two large cells, which are parallel to the ostiole or opening of the stomata, and as a rule one of these cells is much larger than the other. The epidermal tissue is further characterised by the scars of fallen hairs and the peculiar radiating arrangement of the cells surrounding the base of the hair. Besides the foregoing, elements derived from the bundles of the midrib and veins possess certain characteristics. Thus, in a longitudinal section of a leaf bundle, wood vessels are followed by pericylic fibres, and outside these comes a single layer of parenchymatous cells containing prismatic crystals of calcium oxalate. Though the presence of these crystal cells is not strictly diagnostic, a strip of the senna leaf bundle can always be recognised in a microscopic preparation of powdered senna by the sequence of the elements—namely, wood vessels, pericylic fibres, and a single row of cells containing prismatic crystals.

The British Pharmacopœia describes liquorice root as the peeled root and peeled subterranean stem of Glycyrrhiza glabra. It is this decorticated portion that should be used in the manufacture of galenical preparations. It contains about 30 per cent. of starch, and the predominating feature of powdered liquorice root, when examined microscopically, is the abundance of starch granules. These granules vary both in outline and size, and present no distinct hilum or markings. They vary in outline from circular to elongated ellipses, but the majority are circular or elliptical. In size they vary from mere dots to even 20μ, and they average about 10μ. Some of the granules have even slight protuberances resembling budding yeast cells. Liquorice root is further characterised by groups of thick-walled yellowish fibres and large thick-walled yellow-pitted vessels. The yellow colouring matter of liquorice root is almost entirely situated in the fibres and vessels. The best fibres of liquorice root are accompanied by regular rows of cells containing single prismatic crystals of calcium oxalate.

Fennel is the dried ripe fruit of *Fœniculum capillaceum* (N.O. Umbelliferæ), and consists of two readily separated mericarps. Each mericarp has five primary ridges, and in a transverse section shows six large vittæ, or oil canals. In the powder, fragments of the vittæ are easily recognised by their dark brown colour. Powdered fennel may be identified by the presence of large parenchymatous cells with spiral or reticulate thickening. The cells of the endosperm are polygonal in shape and have rather thick walls, and contains aleurone grains, oil globules, etc. Starch is absent. Groups of narrow elongated cells, arranged parallel to one another, are also seen in the powder; they are derived from the inner epidermis of the fruit. The fragments of vessels, sclerenchymatous fibres and tracheids, are derived from the fibro-vascular bundles of the fruit, and from the carpophore and pedicel of the fruit.

Mention was made earlier that some of the adulterants we had met with consisted of ground olive stones and ground almond shells. Fig. IV. is a characteristic example of compound liquorice powder adulterated with ground olive stones. The elements of senna, liquorice, and fennel are shown, and in addition will be observed peculiar sclerenchymatous cells which are foreign to any of the constituents of compound liquorice powder, and characteristic of such things as olive stones, date stones, and almond shells.

DISCUSSION.

Mr. C. A. Hill said that the ash of powdered Alexandrian senna was higher by 1 or 1½ per cent. than that of Tinnevelly senna. In a sample of compound liquorice powder which he had examined for a special purpose, the ash, calculated from the ash contents of the several constituents, worked out at 3·79 per cent., while the compound powder yielded 4·25 per cent. of ash. The question of purity or genuineness was only likely to arise with the cheapest qualities of compound liquorice powder, which would certainly be made with Tinnevelly senna.

Mr. F. W. Richardson said that he had not found the proportion of ash to be of any great assistance, but it was very useful to examine microscopically the fibre obtained after treatment with dilute acid and alkali. This fibre generally amounted to about 16 per cent. The proportion of matter soluble in water, apart from the sugar, was usually about 12 per cent., and a determination of the total soluble matter, which with the sugar should amount to about 62 per cent., was also very useful. It might be mentioned that the proportion of sulphur even in genuine samples was liable to considerable variation, since the powder was sometimes comparatively coarse, and separation of the ingredients occurred.

THE "NEUSAL" MILK TEST.

By J. GOLDING, F.I.C.

(*Read at the Meeting, April 5,* 1911.)

The difficulties which the "Neusal" milk test (invented by O. Wendler) is designed to overcome do not exist for the analyst working in his own laboratory. Certain points of chemical interest are, however, brought out by an investigation of the method, and also the greatly-extended use to which the mechanical testing of milk is now put, frequently involves the calling in of expert advice on the methods chosen and the results obtained.

It is only necessary to mention, as an example, the valuable work done by the Milk Record Societies, where men are employed to travel round a circuit of farms testing and weighing the milk from each cow in the herd both night and morning, to give an instance of a case where great advantage would accrue were it possible to replace the large quantities of sulphuric acid required for Gerber's acid test by some more portable reagent. To meet this difficulty various methods have been tried, such as the "Sin-acid" method, and Gerber's "Sal" method. In these, solutions of alkaline mixtures of salts were used with amyl or butyl alcohol (added separately), to dissolve the milk.

In 1905 I investigated these methods, and came to the conclusion that both methods were unreliable, because, when the milk is dissolved with an alkaline solution, the fat which separates consists not only of butter-fat, as in Gerber's acid method, but that the volume is swollen by the alcohol which the fat dissolves from these alkaline solutions of the milk. For this reason slight inaccuracies which could hardly be avoided in measuring the alcohol resulted in considerable variations in the volume of fat to be read off; also, there was nothing to show that this had taken place. Allowance is made in Gerber's "Sal" method by taking 10 c.c. of the milk in the same bottles in which 11 c.c. were required for the acid test. Variations of 0·5 to 1·5 c.c. of the amyl alcohol made no difference in the acid test, but in the "Sal" test such variations caused the fat layer to be more than doubled. It is, therefore, not surprising that these methods have not replaced the older acid methods.

The patent of Dr. O. Wendler for the "Neusal" method states that the milk is treated with a mixture consisting of one or more salts of a hydroxybenzoic acid (*e.g.*, sodium salicylate), a sucrate, and a fat-clarifying agent (butyl alcohol); the quantity of fat separating from the milk is then measured. The salt is sent out in a bag containing 260 grms., which is directed to be dissolved in 600 c.c. of water. The salt gives a blue coloured solution; with this is also a bottle containing 255 c.c. of isobutyl alcohol of a certain purity. This has to be added to the blue solution, and the bottle rinsed out with the liquid. The alcohol, though fairly insoluble in water, is very soluble in the solution of the salt. I have also found that a solution of sodium salicylate readily dissolves the alcohol with frothing, making a clear solution. The total volume of the solution obtained by dissolving the alcohol in the salt solution is about 1,000 c.c.

Two sizes of butyrometer tubes are supplied; to the smaller of these 2 c.c. of this "Neusal" solution are added, and 4·85 c.c. of milk. To the larger 4 c.c. of "Neusal" solution, and 9·7 c.c. of milk. The bottles are then corked, well shaken, and placed in water at 50° C. for four minutes, shaken again, and spun in the centrifugal machine for three minutes. It is then directed to place them in water at 45° C. for three minutes, after which the fat may be read off. If the acid butyrometers are to be used, the "Neusal" solution is diluted with an equal volume of water, and 12 c.c. of the mixture used with 9·7 c.c. of milk.

The sodium salicylate and butyl alcohol completely digest the milk at this temperature, and a very clear reading of the fat is obtained. Examples of the results obtained are given in the following table:

TABLE I.

Sulphuric Acid.	—	—	—	10 c.c.	Rose Gottlieb (*a*).
Milk.	4·85 c.c.	9·7 c.c.	9·7 c.c.	11 c.c.	Extraction (*b*).
"Neusal."	2 c.c.	4 c.c.	12 c.c. diluted.		
	Small Tubes.	Medium.	Large.	Acid.	
Milk, No. 1 ...	3·75	3·75	3·70	3·75	3·82 (*a*)
	3·85	3·80	3·70	3·75	3·82 (*b*)
" No. 2 ...	3·45	3·45	3·45	3·40	3·56 (*a*)
	3·40	3·45	3·45	3·45	3·54 (*b*)
" No. 3 ...	4·55	4·45	—	4·50	4·57 (*b*)
" No. 4 ...	1·45	—	—	—	1·53 (*b*)
" No. 5 ...	3·00	3·00	3·15	3·00	3·00 (*b*)
" No. 6 ...	—	—	6·00	6·00	6·09 (*b*)

I find that it is necessary to read the "Neusal" tubes to the bottom of the meniscus, while with the acid tubes I get results agreeing most nearly with the extraction method by reading to the middle of the meniscus. The "Neusal" tubes seem to require slightly longer spinning than the acid tubes; but if they are not spun sufficiently, a pearly appearance is seen at the bottom of the fatty layer, which serves as a valuable warning. Similar results are reported by M. Siegfeld in the *Molkerei-Zeitung* for May, 1910.

It is obvious from the fact that 9·7 c.c. of milk are taken in the same tubes in which 11 c c. are taken for the acid method, and in both the same volume of fat is read off that in this method as with the "Sal" method we are reading off a volume of fat plus dissolved alcohol; and, as would be expected, experiments in which varying quantities of "Neusal" were taken with the same quantity of milk showed this to be the case.

TABLE II.—ACID BUTYROMETER TUBES TAKEN WITH MILK CONTAINING 3·8 PER CENT. OF FAT.

"Neusal."	Water.	Milk.	Fat.
c.c.	c.c.	c.c.	Per Cent.
5·5	6·5	9·7	3·40
6·0	6·0	9·7	3·75
6·5	5·5	9·7	3·80
7·0	5·0	9·7	3·90
7·5	4·5	9·7	3·90

The experiments were repeated in tubes to which 0·5 c.c. of melted butter-fat had been added (see Table III.).

TABLE III.—0·5 C.C. BUTTER-FAT AT 50° C., TAKEN IN GERBER TUBES WITH—

Water.	Dilute "Neusal."	"Neusal" Alcohol.	50 per Cent. H_2SO_4.	1 per Cent. H_2SO_4.	1 per Cent. NaOH.	Fat.
21·5	—	—	—	—	—	3·60
9·5	12·0	—	—	—	—	4·50
15·5	6·0	—	—	—	—	3·70
—	21·5	—	—	—	—	5·35
19·5	—	2	—	—	—	4·50
—	—	2	19·5	—	—	3·60
—	—	2	—	19·5	—	4·50
—	—	2	—	—	19·5	4·50

TABLE IV.—EFFECT OF VARYING THE QUANTITY OF ALCOHOL: MILK OF 3 PER CENT.; FAT, 9·7 C.C.; 88 GRMS. OF SODIUM SALICYLATE MIXTURE DISSOLVED IN 200 C.C. OF WATER.

Solution.	Water.	Alcohol.	Result.
c.c.	c.c.	c.c.	
5	about 6	less than 1·4	cloudy fat
5	" 6	1·4	3 per cent. fat
5	" 6	1·5	3 per cent. fat, clear
5	" 6	1·6	3 per cent. fat
5	" 6	1·8	3·5 per cent. slightly milky
5	" 6	2·0	3·8 " " "
5	" 6	2·5	5 per cent. cloudy
5	" 5	3·0	about 6 per cent. cloudy

The variations are not so great as when more alkaline solutions are used (over 7 per cent. obtained). The table shows that the fat dissolves the alcohol from the solution. Varying the quantity of "Neusal" salt produced no alteration in the percentage of fat even if the quantity recommended was doubled; with less salt the readings of fat could not be obtained. In these experiments the alcohol was added separately (1·5 c.c.). The effect of varying the quantity of alcohol is shown in Table IV.

In conclusion, while the method gives satisfactory results when the exact quantity of alcohol is used, the fact that it is not pure fat which is being measured, but a solution, the volume of which will vary with the quantity of alcohol used, makes the method inferior in accuracy to the acid Gerber method, a fault which is likely to be increased if it is put into the hands of inexperienced persons. On the other hand, it is cheaper, safer, and more portable, and might be safely recommended to dairy farmers and others, to replace the acid method where this offers serious disadvantages; but the introduction of another possible error will prevent it from replacing the original Gerber method for more accurate work, though the method is a great advance on the previous alkaline methods.

DISCUSSION.

Mr. RICHMOND remarked that the fact that the method depended upon the differential solubility of iso-butyl alcohol in the fat and in the aqueous portion seemed to be a disadvantage. According to Mr. Golding's figures, the butyl alcohol appeared to be twice as soluble in the fat as in the aqueous portion, and it was obvious that such approximation to correctness as was obtained was due simply and solely to strict adherence to the conditions specified. This meant that one was entirely in the hands of the manufacturers, and, since the composition of the reagents in such cases was generally more or less secret, there was no means of ascertaining for oneself whether the correct conditions were really being fulfilled. The acid method was much more reliable, but here also, even in experienced hands, the results were liable to vary, as was instanced by the fact that, whereas Mr. Golding obtained correct results by reading half-way down the meniscus, he (Mr. Richmond) found it necessary to read, if anything, a little below the meniscus. Both Mr. Golding and himself knew what were the causes of these differences and could allow for them, but the unskilled person could not. As a matter of fact, all these methods—even the acid method—were merely approximate ones, and although in trained hands they might be satisfactory, the results were necessarily less trustworthy than those of actual analysis.

Mr. GOLDING said that the difference in the reading point was probably due to the fact that, while he used a hand-worked apparatus, Mr. Richmond had the advantage of mechanical power, and thus probably was able to extract the fat more completely.

* * * * *

A FURTHER CONTRIBUTION TO THE QUESTION OF TURPENTINE SUBSTITUTES.

By J. H. COSTE, F.I.C., and L. MYDDELTON NASH, F.I.C.

(Read at the Meeting, April 5, 1911.)

There is abundant evidence of the presence of cyclic hydrocarbons (benzene and its homologues) in greater or less amount in petroleum from almost all sources.* In some varieties the proportion is very considerable. The examination by one of us of several materials sold as turpentine substitutes showed that these substances contained large percentages of such hydrocarbons, in addition to the more commonly recognised paraffins or cyclo-paraffins (Analyst, 1910, **35**, 438). The limiting effect of aromatic hydrocarbons on the process proposed by F. W. Richardson and J. L. Bowen (*J. Soc. Chem. Ind.*, 1908, **27**, 613) was indicated, and the intelligent application of Armstrong's method of polymerisation was advocated. It was shown that diluted sulphuric acid of the strength recommended by that author (*J. Soc. Chem. Ind.*, 1882, **1**, 480) had but little action on the turpentine substitutes then examined.

Richardson and J. E. F. Whitaker (*J. Soc. Chem. Ind.*, 1911, **30**, 115), in a later paper, agree with us that certain petroleums contain very appreciable amounts of benzene homologues, but apparently consider that only in Borneo petroleum is their amount worth taking into account. They state that the products of American petroleum are by far the most extensively used for adulterating turpentine, that for a year no Borneo spirit has been imported into Europe, and that they have never met with any turpentine substitute or turpentine adulterant composed of Borneo spirit.

In our experience, based on a knowledge of the materials in the London market, Roumanian spirit is by far the most extensively used for this purpose, although some American and Borneo spirit is also used. The reason is that the yield of "spirit" is greater (in the proportion of about 7 : 4) from Roumanian petroleum than from American, which, on the other hand, yields a better burning oil.

There is on the market a large quantity of pure Borneo spirit which is suitable for, and is used as, a turpentine substitute or adulterant. About 5,000 tons a year are imported, of which some 3,000 tons are used for this purpose. It is true, however, that no Borneo crude oil has been imported recently, as it is now distilled on the spot. The Borneo oil and spirit now being obtained are entirely different from that obtained a few years ago, the wells being sunk very much deeper and yielding a much lighter oil.

We agree that petroleum spirit, and not crude petroleum (by which is probably meant burning oil, crude petroleum being a thick brown liquid), is used to adulterate turpentine. The burning oil is not nearly sufficiently volatile for the purpose. American petroleum (burning oil) on distillation would only yield 90 per cent. at about 330° C.; whereas the petroleum spirit suitable for turpentine substitute would yield 90 per cent. at about 210° C., and an ordinary good turpentine substitute will yield 95 per cent. at about 210° C., and, in the case of Borneo spirit at a somewhat lower temperature.

---

* Steuart (*J. Soc, Chem. Ind.*, 1900, **19**, 989). Poni (*ibid.*, 1906, **25**, 214 ; 1907, **26**, 958). Zaloziecki and Hausmann (*ibid.*, 1907, **26**, 1132). Edeleann (*ibid.*, 1908, **27**, 438). Jones and Wootton (*J. Chem. Soc.*, 1907, **91**, 1146).

Benzene, which is mentioned as a possible adulterant, should be out of the question, on account of its inflammability. Turpentine containing even 10 per cent. of benzene inflames at the ordinary temperature, and serious trouble with insurance companies and carriers would arise, to say nothing of the danger of making and using varnishes and paints with such spirit. For the same reason "gasolene," which Richardson and Whitaker also mention, and with which they have made various experiments, is an equally improbable adulterant. It is unlikely that spirit flashing below 73° F. is used for this purpose.

Richardson and Whitaker apparently realise that the use of a physical method of analysis is only possible in very restricted cases, when the nature of the constituents is accurately known and their amounts only are in doubt. They have supplemented the original method, which was probably sound in the simple case assumed by them by a chemical one which is certainly useful. They determine the "barium sulphate coefficient," which is a measure of the amount of sulphonation occurring when the liquid is treated with sulphuric acid under certain definite conditions. Their figures seem to show that under these conditions the sulphonation (of benzene) is not complete, as the amount of barium sulphate obtained is less even than that required for toluene. Experiments with Borneo and American petroleum and with American turpentine, which are quoted by them, show that whereas Borneo oil contains a large amount of constituents which can be sulphonated, American oil contains less, but still a notable amount, as does American turpentine (cymene, probably, formed by the action of the acid itself).

As no considerable amount of constituents boiling below 140° F. has been found by us, the presence of benzene or toluene is, apart from the commercial considerations already set forth, improbable in turpentine substitutes or adulterants, and, in our opinion, it is not desirable to return either of these hydrocarbons as present without direct proof of their presence. For these reasons we cannot consider the examples given by Richardson and Whitaker of analyses of mixtures containing benzene as in any way representing those likely to occur* in practice, nor do we think that with unknown constituents it would be possible to return analyses in the form given by them—*i.e.*, as percentages of turpentine, petroleum, gasolene, and benzene—but only as terpenes, homologues of benzene, and paraffins and cyclo-paraffins.

The separation from turpentine by fractional distillation of any adulterant likely to be employed is highly improbable of accomplishment, if not absolutely impossible.

In all cases where a sample of turpentine is suspected, its "close flash" (Abel test) should be taken. This figure for the pure article has not been found in the authors' experience to vary more than a few degrees, and all samples which they have examined have a close flash of 90° to 94° F. Any departure from these figures will make it necessary to examine the turpentine very closely. The simplest method, however, to determine whether or not the sample is pure is simply to shake it, when any froth will indicate that the turpentine is impure, and suggest the presence of petroleum adulterants (Nash, ANALYST, 1908, **33**, 231; 1909, **34**, 151). Coal-tar benzene does not give any froth, but, as previously stated, this could not be used.

---

* We use advisedly the expression "likely to occur," since neither of us has for some years found an adulterated sample of turpentine.

Distillation of the sample will also give valuable information, as most turpentine substitutes and adulterants show a considerable rise in temperature towards the end of the distillation. Old and oxidised turpentine may also show a considerable rise, on account of the large amount of "residue" contained. A difference of as much as 13° C. has been noticed by one of us in the temperature at which the 95 per cent. fraction distilled in the case of two samples taken from bulk—deliveries of genuine American turpentine—the residue being respectively 4 per cent. and 1·9 per cent. An examination of the residue will show at once whether the rise was caused by petroleum spirit or by oxidation of the turpentine. We give the results of the examination of a few samples of turpentine substitutes obtained recently, which appear to be of special interest.

95 ,, ,, ...	174·5	200·0	203·0	212·0

These are typical of the materials now in common use as turpentine substitutes, and in physical and chemical properties are similar to other earlier samples examined by us (Coste, ANALYST, *loc. cit.*), and to several recently obtained from ordinary trade sources. They are obviously mixtures of aromatic and aliphatic hydrocarbons containing considerable proportions of the former class of bodies. It has been shown that such mixtures are very little acted on by diluted sulphuric acid of the strengths recommended by Armstrong; and as it appeared desirable to make certain that this behaviour was not affected by the presence of terpenes, the following series of experiments was made.

---

* This is an approximate indication of the amount of aromatic hydrocarbons.

Measured quantities (from 100 to 200 c.c.) of mixtures of American turpentine and turpentine substitutes, such as are actually used, were treated with the diluted acids used by Armstrong for polymerisation, the treatment with the stronger acid being repeated as advised by him. The modification suggested by Morrell (*J. Soc. Chem. Ind.*, 1910, **29**, 241) was adopted, but in view of the probable presence of aromatic hydrocarbons treatment with strong acid was omitted, it being sought to confine the action to one of polymerisation. The results are given in Table II.

It was found in 1910 that the average loss suffered by turpentine substitutes when treated as above was 3 per cent. Armstrong states that about 5 per cent. of unpolymerisable liquid is left by pure American turpentine. If desired, the percentages of terpenes and of other hydrocarbons found can be corrected for these amounts. We give these corrected results in the third column. The correction is naturally less accurate when the proportion of either constituent is very small.

TABLE II.

	Volume Percentage of Adulterant.	Volume Percentage of Unpolymerised Distillate.	Corrected Volume Percentage of Adulterant.
I.	35	36·5	34·5
II.	12	15·2	11·5
III.	90	90·9	92·2
IV.	75	73·5	74·6
V.	16	19·3	15·8
VI.	5	8·2	3·7
VII.	20	23·0	19·8

These results confirm those previously obtained by us and those of Morrell (*loc. cit.*).

Finally we conclude that—

1. The substances most likely to be used to adulterate turpentine are those which are sold on a large scale as substitutes for it.

2. These are in most cases prepared from such varieties of petroleum as yield, in the fractions which are of suitable volatility, large proportions of aromatic hydrocarbons.

3. Such mixtures of hydrocarbons as are mentioned above are, either alone or in the presence of terpenes, but very slightly affected by sulphuric acid of a strength sufficient to effect the polymerisation of the normal constituents of American turpentine, and that this circumstance affords the best means of their separation* and the estimation of their amount.

4. The admixture of these substances with turpentine has such an effect on its volatility and surface tension as to render the flash-point† (Abel close test) and frothing test the best means of detecting their presence. The latter test also gives

---

* We note that Richardson and Whitaker fully appreciate the *qualitative* value of this process.

† The close flash of turpentine substitutes has been found by us to range between 74° and 104° F., and therefore a normal "flash" does not necessarily preclude adulteration.

useful quantitative indications under certain circumstances (Nash, ANALYST, 1909, **34**, 151). Fractional distillation should also be carried out.

5. The proportion of aromatic hydrocarbons in mixtures from which terpenes have been removed can be estimated approximately by either a method of nitration, as used by Steuart, Jones, and Wootton and Coste; or one of sulphonation, as used by Richardson and Whitaker, and suggested also by Coste.

DISCUSSION.

Mr. CHAPMAN asked if the authors could say what was the general view held by turpentine users as to whether the presence of pine-wood oil—the oil distilled directly from the wood—should be regarded as an adulteration or not.

Mr. COSTE said that in the London County Council *v.* Holzapfel it was held that any mixture which contained a substance coming within the definition of petroleum laid down in the Petroleum Acts, and of which the flash-point was below 73° F., must be regarded as petroleum to which such Acts apply,* so that many of the adulterated samples referred to by Mr. Richardson could not lawfully be stored except under licence from the authority administering the Petroleum Acts, and therefore, as had been indicated in the paper, the conditions with which Mr. Richardson had to deal were somewhat unusual. With regard to the Armstrong process, their point was rather that the turpentine substitutes ordinarily sold at the present time contained large proportions of aromatic hydrocarbons, and that, this being the case, it was injudicious to employ any treatment with sulphuric acid that could cause the sulphonation of such hydrocarbons. Jacobsen and Ivan Levinstein had shown that ordinary concentrated sulphuric acid would dissolve, with sulphonation, both m- and o-xylene in the cold, and many other hydrocarbons were similarly sulphonated; so that, in using Armstrong's process for the purpose of determining modern turpentine substitutes in turpentine, one must be careful that the chemical processes going on were understood, or one might be sulphonating the hydrocarbons, and possibly forming additive compounds of any olefines that might be present.

Mr. NASH said that he had not found American turpentine coming into this country to be adulterated with pine-wood spirit. This spirit, when properly rectified, yielded an excellent white product, very similar in physical properties to American turpentine, and personally he should be inclined to use it almost as readily as American turpentine. Nevertheless, it was, of course, not turpentine, and if he found American turpentine to contain it he should feel bound to say that it was not pure American turpentine.

Mr. CHAPMAN asked if Mr. Nash had found the Herzfeld test for pine-wood oil to be satisfactory. He (Mr. Chapman) had recently met with some samples, which he believed to be pine-wood oil, which did not give the reaction.

Mr. NASH said that so far as he knew the Herzfeld test was satisfactory. A strong reaction was given by Finnish and Russian turpentine, or by any turpentine distilled from the wood. With regard to Roumanian spirit, he had been informed by some of the largest suppliers of turpentine substitutes in this country that the spirit they used was Roumanian spirit, the reason being that American petroleum yielded better burning oil than Roumanian, and also that Roumanian oil yielded far more spirit than American. He was surprised to hear from Mr. Richardson that benzene and gasoline were used in the North, because light spirits were much in demand for motors, etc., and the heavier kinds were much more suitable for turpentine substitutes.

---

* This decision is adopted by Order in Council of May 7, 1907, whereby the Acts are made to "apply to any mixture of petroleum with any other substance . . ."—Statutory Rules and Orders, 1907, No. 483.

Messrs. F. W. RICHARDSON and J. E. F. WHITAKER send the following note: We are at a loss to understand the remark that no spirit flashing below 73° F.—hence no gasoline—is used, or that benzol, on account of its inflammability, is likely to be employed for the adulteration of turpentines; but Messrs. Coste and Nash say that they have not met with an adulterated sample of turpentine for some years, and as we have analysed a number of commercially adulterated turpentines we speak from actual experience.

We have analysed several so-called "turpentines" which flashed at the ordinary temperature and which contained gasoline. We only suggest the possibility of the use of benzol on account of its very low price—so low that motorists have turned to it as a cheap substitute for petrol. The adulterator does not concern himself with possible difficulties with insurance companies as long as he sells his material. We do not affirm the possibility of always being able to separate turpentine adulterants by mere fractional distillation. By using Young's still head we can absolutely separate gasoline and also benzol with fair accuracy from turpentine which has a much higher distilling temperature. In the absence of Borneo spirit and Roumanian spirit, hitherto not found by us in use as turpentine substitutes—an absence proved by the low barium sulphate coefficient—we do maintain that the Richardson and Bowen method of calculation, using the refractive indices of the fractional distillates, gives good results. American petroleum products are used in quite overwhelming proportion to any others for turpentine adulteration. In certain cases it would no doubt be advisable to classify the constituents of a mixture as described by Messrs. Coste and Nash; but most of the adulterated samples we have examined have allowed of a more popular grouping, "gasoline" and "petroleum" representing paraffins coming over on distillation at well-defined temperatures, the amounts being calculated from the data given by the distillates.

The term "cyclo-paraffins" might be very confusing to the non-chemical mind. The authors agree with us that "distillation of the sample will also give valuable information."

The Richardson-Whitaker methods allow the analyst to make a classification of the constituents of an adulterated turpentine in such a manner as to give a good general idea of the nature and amounts of the adulterants—not merely a division into turpentines and paraffins.

* * * * *

"CONSTANTS OF CHICKEN AND TURKEY FATS."

By RAYMOND ROSS, F.I.C., and JOSEPH RACE, F.I.C.

(*Read at the Meeting, April* 5, 1911.)

In the following table a number of constants for chicken fat and turkey fat are given:

	Fat.		Fatty Acids.	
	Chicken.	Turkey.	Chicken.	Turkey.
Sp. gr., 100° F.	0·9065	0·9090	0·8866	0·8990
Koettstorfer	204·6	191·6	208·3	195·0
Molecular weight	—	—	270·0	287·0
Iodine value (Wijs)	71·5	66·4	73·6	70·7
Reichert Meissl	1·8	3·8	—	—
Polenske number	2·1	1·6	—	—
Acetyl value	—	—	25·4	18·4
(Ricinoleic acid, per cent.)	—	—	13·7	9·9
Hehner value	94·6	95·1	—	—
Melting-point, ° C.	23 to 27	31 to 38	27 to 30	37 to 38
Zeiss at 50° C.	47·5	46·0	36·5	32·5

Refractive Index, 50° C.:

Nd	1·45760	1·44854
Nc	1·45503	1·44592
Nf	1·46359	1·45433
Ng	1·46862	1·45952

The fats were optically inactive.

An examination of the fat from fowls which had died of overfeeding invariably showed a higher Zeiss number and iodine value than the normal values given above. This result is generally brought about by the use of too much heating food.

The formulæ used for calculating ricinoleic acid and triricinolein were respectively as under:

$$\text{Ricinoleic acid in fatty acids} = \frac{100\ \text{A}}{\text{A}\ (165 - \text{A})\ \frac{340}{298}}.$$

$$\text{Triricinolein in oil} = \frac{100\ \text{A}}{\text{A}\ (159{\cdot}1 - \text{A})\ \frac{1058}{932}}.$$

A = Acetyl value.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Composition of the Pulp of Cassia Fistula. L. C. Griebel. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 283-288.)—The results given in the following table were obtained on the analysis of various samples of cassia pulp:

	Water.	The Dry Substance contained—					
		Soluble Extract.	Insoluble Matters.	Invert Sugar.	Sucrose.	Sugar-Free Extract.	Ash.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Raw commercial pulp after removal of seeds and tissue ...	14·99	92·22	7·78	16·42	53·13	22·67	4·02
Raw pulp, free from seeds and tissue ...	19·89	90·01	9·99	6·79	61·13	22·09	5·67
Ditto	14·39	93·68	6·32	7·05	66·31	20·31	3·98
Purified pulp from same pods as No. 2	41·42	92·18	7·82	10·64	57·22	24·32	4·68
Pulp No. 4, plus 25 per cent. sucrose	33·27	93·81	6·19	7·12	72·36	14·33	2·91
Commercial purified pulp	25·99	92·42	7·58	51·81	26·25	14·36	2·82

These results show that the presence of added sucrose is most plainly indicated by the quantities of ash and sugar-free extract, the sucrose-content affording but little indication of the admixture. Sample No. 6 was of abnormal composition; it did not contain added sucrose or lactose, and the author is at present unable to give an explanation of the figures obtained. The aqueous extract of cassia pulp was found to contain, in addition to sucrose and invert sugar, citric acid, tannin, pectinous substances, and yellow and brown colouring matters. W. P. S.

Quantity of Husk and Germ in Cocoa Products. H. Huss. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 94-101.)—The author has examined a large number of samples of cocoa prepared in different factories, and finds that the better qualities of the product are practically free from husk and germ. He considers that manufacturers should have no difficulty in preparing cocoa-mass containing not more than 2 per cent. of husk and germ; the cocoa manufactured from such cocoa-mass would contain less than 3 per cent. of husk and germ. The manufacturers separate the husk and germ from the beans by means of machinery, and obtain products which consist of almost pure kernel, germ, and husk respectively. The table given below shows the amount of germ and husk present in the various fractions thus obtained, some manufacturers separating the cocoa into more fractions than do others:

	Factory 1. Trinidad Beans.		Factory 2. Bahia and St. Thomé Beans.		Factory 3. St. Thomé Beans.		Factory 4. Mixed Beans.		Factory 5. Trinidad and Caracas Beans.		Factory 6. St. Thomé Beans.	
	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.
Fraction 1	1·3	0·05	—	—	1·6	0·01	0·38	0·005	0·12	0·25	1·60	0·05
Fraction 2	1·0	0·01	—	—	0·01	1·5	0·28	0·005	0·20	10·0	25·0	1·5
Fraction 3	1·8	0·20	—	—	—	—	0·40	2·0	—	—	—	—
Fraction 4	14·0	7·50	0·30	0·02	—	—	0·50	11·0	—	—	—	—
Fraction 5	35·0	—	0·75	5·65	—	—	—	—	—	—	—	—
Fraction 6	—	—	10·0	—	—	—	—	—	—	—	—	—

	Factory 7. Mixed Beans.		Factory 8. St. Thomé Beans.		Factory 9. Arriba Beans.		Factory 10. St. Thomé Beans.		Factory 11. —	
	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.	Husk per Cent.	Germ per Cent.
Fraction 1	0·5	0·05	1·8	0·13	0·01	0·02	0·01	0·10	—	—
Fraction 2	20·0	30·0	3·0	5·0	1·50	8·0	7·57	0·45	2·0	15·0
Fraction 3	—	—	—	—	—	—	21·4	0·27	—	—
Fraction 4	—	—	—	—	—	—	8·0	2·0	—	—

The fractions containing much husk and germ are used only for the preparation of cheaper qualities of chocolate. The following method is described for the approximate estimation of husk and germ in cocoa; it depends on the fact that all the cocoa tissue, starch, etc., is dyed by the colour known as Brilliant Blue, whilst the mucilaginous cells of the husk and the tissue of the germ remain uncoloured. Congo red is also added, in order to dye particles of the inner skin of the bean which may be present, and the addition of the colour Soudan III. dyes the fatty droplets. The reagents employed are prepared as follows: Congo red, 1 per cent. aqueous solution; Brilliant Blue, 1 grm. of the colour dissolved in a mixture of 20 grms. of glycerol and 80 grms. of water; Soudan III., 0·1 grm. of the colour dissolved in a mixture of 50 grms. of glycerol and 50 grms. of 95 per cent. alcohol. A quantity of from 0·01 to 0·05 grm. of the cocoa or chocolate is rubbed down on a microscope slide with a drop of the Soudan solution, and the mixture is heated gently. A drop of the Congo red solution is now added, and, after the lapse of about one minute, 1 or 2 drops of the Brilliant Blue are well mixed with the mass. A hot cover-glass is then placed over the slide, and the specimen is examined under the microscope. It will be observed that the oil-drops are coloured reddish-yellow and the particles of the inner skin red. Starch cells are coloured blue. The husk and germ tissue which may be present are not coloured, and are readily detected in the blue or violet-coloured field. The quantity of husk and germ present may be estimated by comparing the slide with similarly treated specimens of cocoa containing known amounts of these two substances. W. P. S.

Estimation of the Doughing Value of Flour. A. A. Besson. (*Chem. Zeit.*, 1911, **35**, 245-246.)—Arragon has described two methods for the estimation of the "doughing value" of flour: first by the addition of increasing quantities of flour to a fixed quantity of water, secondly by adding water to a fixed quantity of flour. The second is the better method, and the first always gives higher values. The author has endeavoured to standardise the second method and to investigate the sources of error. If too much water be added all at once, the results are too high; if the water be added too gradually, they are too low. These errors are due to irregularity of composition of the dough. Very energetic kneading is necessary, using the whole hand, especially the palm, the dough being squeezed with the tips of the fingers pressing tightly against the palm. 150 or 200 grms. of flour are treated with 50 per cent. of water, added all at once, in a large porcelain basin. With the help of a glass stirrer a dough is made as stiff as possible. The rod is withdrawn, wiped with the hand, and the dough is kneaded to break down all dry portions, with the further addition of as much water as may be necessary, until all portions are uniformly wetted. The process is complete when a dough is obtained which no longer sticks to the fingers. If the first experiment shows that 50 per cent. of water is too much, the trial must be repeated with less. The dough is finally scraped together with a spatula and weighed. The results of three determinations should agree to within 1 per cent. of added water. Allowance should be made for variations in the percentage of moisture in the original flour, and results expressed in terms of dry substance. The laboratory estimations are accurately comparative, but in no way correspond with the actual proportions of water used in the practical preparation of baker's dough. For instance, a flour absorbing 45·6 per cent. of water in the laboratory was mixed with 72 per cent. in the bakehouse. J. F. B.

Detection of Fusel Oil in Brandy. E. Herzog. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 280-282.)—The reaction described by Hollander (*Chem. Zentralbl.*, 1910, **1**, 671) is found by the author to be simply a test for furfural and not for amyl alcohol; it is, moreover, not a very sensitive test for furfural. Benzaldehyde, fennel oil, and cinnamon oil also give a green coloration with the test.

W. P. S.

Cause of the Poisonous Properties of Certain Brands of German Margarine. W. Plucker. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 257-265.)—Many cases of vomiting and abdominal pains having been caused by the consumption of certain brands of margarine manufactured by a German firm, the author carried out a number of chemical and physiological experiments with the margarines, with the object of ascertaining the nature of the substance, present in the fats, which produced the above-mentioned symptoms. The active substance was found to be a non-volatile, hydroxy fatty acid; the physiological action of this fatty acid was similar to those of crotonic acid and an acid obtained from curcas oil. The margarine was optically active, a 10 per cent. solution showing a rotation of 0·70° in a 100 mm. tube; in this respect the margarine resembled croton oil but not curcas oil, which is inactive. The author has also examined another fat, cardamom or marotty fat, which acts as an emetic and is optically active. The objectionable properties of the margarine were most probably due to the presence of a quantity of one of the oils mentioned.

W. P. S.

Estimation of Potassium Nitrate in Meat. E. Polenske and O. Köpke. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **36**, 291-296.)—The authors find that Stuber's modification of the Schlösing-Wagner method for the estimation of nitrates yields trustworthy results when applied to the estimation of saltpetre in meat; this method consists in converting the nitric acid into nitric oxide by boiling the nitrate solution (in this case the aqueous extract of the meat) with hydrochloric acid and ferrous chloride, and measuring the volume of the nitric oxide liberated. A similar method, proposed by Pfyl, in which the liberated nitric oxide is not measured, but oxidised with permanganate, the excess of the latter being then titrated, also gives accurate results, but Stuber's method is recommended as being more simple. The "nitron" method (ANALYST, 1905, **30**, 256), or the same as modified by Paal and Mehrtens (ANALYST, 1906, **31**, 405), and methods which depend on the conversion of the nitric acid into ammonia, yield inaccurate results, the former because of the interfering action of chlorides, which are not removed completely by lead acetate, and the latter because an aqueous extract of meat yields ammonia when distilled in the presence of an alkali or magnesia, even if nitrates be absent (*cf.* ANALYST, 1910, **35**, 206).

W. P. S.

Seychelles Cinnamon Bark. J. Meyer. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **36**, 372-381.)—The following results were obtained in the analysis of a sample of cinnamon bark obtained from the Seychelles Islands:

	Ash.	Alcohol Extract.	Cinnamon Oil.	Crude Fibre.	The Cinnamon Oil contained—	
					Eugenol.	Cinnamic Aldehyde.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Mixed bark	5·50	10·37	1·12	38·1	—	—
Thin, young bark, 2·5 to 4 mm. thick	6·14	12·10	1·76	39·1		71·2
Thick, old bark, 7 to 12 mm. thick	5·00	9·50	0·90	37·5	14·5	68·2
Ditto, ditto: Inner layer	7·59	15·50	2·68	40·0	16·5	73·5
„ „ Middle layer	—	—	0·96	33·6	17·3	72·6
„ „ Outer layer	4·56	7·94	0·36	19·5	15·7	60·1

These results are very similar to those yielded by Ceylon cinnamon. The odour of the oil is somewhat different to that of the oil obtained from Ceylon cinnamon, the latter oil containing from 4 to 8 per cent. of eugenol, and from 65 to 75 per cent. of aldehyde. The chief difference between these two kinds of cinnamon lies in the fact that Ceylon cinnamon is practically freed from the outer bark before exportation. This cork layer found on the Seychelles bark is almost worthless as a spice, but the other portions of the bark are valuable. W. P. S.

Detection of the Use of Alkali Carbonates in Cheese Manufacture. H. Höft. (*Milchwirtsch. Zentralbl.*, 1911, **7**, 25-31.)

Composition of Goats' Milk, and the Detection of Goats' Milk in Cows' Milk. H. Hager. (*Milchwirtsch. Zentralbl.*, 1911, **7**, 19-24.)—The following were the average results obtained on the analysis of 200 samples of goats' milk: Sp. gr., 1·0324; fat, 3·8 per cent.; solids-not-fat, 9·02 per cent. The presence of not less than 10 per cent. of goats' milk in cows' milk may be detected by the behaviour of the casein towards concentrated ammonia; the latter dissolves the casein of cows' milk, whilst the casein of goats' milk simply swells up without dissolving.

Preservation of Fruit Juices with Hydrofluoric Acid. R. Cohn. (*Zeitsch. öffentl. Chem.*, 1911, **17**, 2-12.)

Adulteration of Linseed Cakes and Linseed Meals in Belgium. L. Bussard. (*Ann. Falsif.*, 1911, **4**, 30-31.)—The principal adulterants found were rice meal, cottonseed meal, earthnut meal, linseed offal, and sand.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Relative Proportions of Arsenic in Marine Algæ and Products derived from them. E. Tassilly and J. Leroide. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 63-66.)—The authors confirm the conclusion of Gautier (*Bull. Soc. Chim.*, 1903 [iii.], **29**, 33 and 863), that arsenic is a normal constituent of certain algæ, though a small proportion of the arsenic found in commercial products derived from them no doubt has its origin in the chemicals used in their manufacture. These commercial processes are partly secret; but when they are imitated so far as is possible, using chemicals which are either free from arsenic or of which the arsenic content is very small, and known accurately, it is found that the whole of the arsenic in the algæ finds its way into the finished product. The following figures are given to show the proportion of arsenic in certain species of marine algæ and fungi, the proportion for any one species being fairly constant. The figures represent mgrms. of arsenic per 100 grms. of the samples, which contained 20 to 30 per cent. of water, and had been washed with water until the washings were free from chloride:

Chondrus crispus	0·070
Fucus vesiculosus	0·010
Corsican moss	0·025
Laminaria digitata	0·050
,, *saccharina*	0·010
,, *flexicaulis*	0·010

G. C. J.

Bacteriological Investigation of Soil. T. Remy and G. Rösing. (*Zentralbl. f. Bakter. u. Parasitenk.*, 1911, 29, 36-77; through *Chem. Zentralbl.*, 1911, 1, 921-922.)—It was found that the composition of a soil had an unmistakable influence upon the decomposition of peptone, both vegetable nutrient substances and other constituents of the soil playing a part in the process. Thus the mixture of humic compounds and silica, obtained by extracting the soil with hydrochloric acid, has a very stimulative effect upon the decomposition, although in many soils there appear to be compounds soluble in water which have a restrictive influence. This influence of the soil constituents is not so pronounced, however, as entirely to outweigh the influence of the biological factors. Under the conditions of the experiments loam had a much greater decomposing action than river sand upon peptone. The intensity of the decomposition of peptone and the putrefaction of albumin, both in soil and in nutrient solutions, stood in manifest relationship to the degree of aeration. Thus, in drawing any conclusions as to the biological capacity of the soil from the degree of decomposition of peptone, the values obtained only hold good for the particular conditions of the experiment. For testing the putrefactive capacity of a soil, nutrient media are prepared containing 1 per cent. of pure gelatin, 0·1 per cent. each of potassium phosphate, magnesium sulphate, and sodium carbonate, and the sterilised aqueous extract of 10 per cent. of the soil. The nutrient solution thus obtained is divided into portions of 50 c.c., and inoculated with the extract obtained by shaking 0·1 to 0·25 grm. of the soil in physiological salt solution. The cultivation temperature should not exceed 20° C. After seven or eight days an estimation is made of the amount of nitrogen displacable by magnesium oxide, but there is no perceptible loss of total nitrogen during the decomposition. More decisive data may be obtained by determining the course of putrefaction in a small sample of the soil. For this purpose the slightly dried soil is mixed with 1 per cent. of gelatin, and introduced in quantities of 500 to 1,000 grms. into covered glass basins, the proportion of moisture being then maintained at about 60 per cent. of the water capacity as estimated by Wahnschaffe's method. The basins are allowed to stand for a week at about 20° C., and the total and ammoniacal nitrogen in the soil then estimated. It might also be advantageous to estimate the amount of nitrogen soluble in water saturated with carbon dioxide in the manner devised by Mitscherlich.
C. A. M.

Bacteriological Method of Estimating Available Organic Nitrogen. J. M. McCandless and F. C. Atkinson. (*J. Ind. and Eng. Chem.*, 1911, 3, 174-175.)—The method employed depends upon the observation of the amount of ammonia produced by the action of soil bacteria on the soluble and insoluble proteins of the material under examination (*cf.* also Lipman, *J. Ind. and Eng. Chem.*, 2, 146). One grm. of the sample is washed with hot water on a filter, and the filtrate made up to 500 c.c. The total nitrogen, and nitrogen as free and saline ammonia, are estimated on portions of this solution. A known quantity of soil is next shaken up with the aqueous extract of the material, and a series of definite portions of the filtered liquid incubated for 210 hours at 38° to 40° C., both under aerobic and anaerobic conditions. In the latter case the liquids remain practically free from nitrates and nitrites. The insoluble residue from the sample is also incubated with 50 c.c. of a liquid containing soil bacteria, prepared by shaking the soil with a solution containing 0·1 per cent. potassium phosphate, 0·2 sodium chloride, 0·05 magnesium sulphate, and 0·005 calcium chloride. This incubation is extended over twenty-six days, the daily increase in soluble ammonia being determined by using one of the series of flasks prepared. The authors' experiments show that the bacteria concerned convert the insoluble proteins first into a soluble form, subsequently decomposing the soluble substances into ammonia. Experiments with cottonseed meal, for example, containing 8·20 per cent. of total nitrogen expressed as ammonia, showed this material to contain nitrogen (as NH_3) 1·01 per cent. in the aqueous solution, of which 0·73 per cent. was water-soluble organic nitrogen (as NH_3). Incubation for 210 hours as described produced 0·22 per cent. of ammonia from the water-soluble organic nitrogen, and 2·09 per cent. nitrogen (as NH_3) remained insoluble after twenty-six days' incubation, while 5·10 per cent. was rendered soluble by this treatment. A. R. T.

Biological Examination of Honey (Enzymes). E. Moreau. (*Ann. Falsif.*, 1911, 4, 65-66.)—The presence of catalase, amylase, and invertase, was detected in twenty samples of French honey examined, but anaeroxydases and aeroxydases were absent. The largest quantities of catalase were present in those honeys which contained considerable amounts of proteins, from 4 to 6 c.c. of oxygen being liberated from hydrogen peroxide in twenty-four hours by the action of the catalase present in 5 grms. of the honey. With other samples the volume of oxygen liberated varied from 0·3 to 0·7 c.c. The honeys containing most catalase also contained the greater quantities of amylase, as was shown by their action on starch paste. The invertase was detected by means of its action on sucrose, the enzyme being first precipitated from the honey with alcohol. (*Cf.* ANALYST, 1910, **35**, 165, 259.) W. P. S.

Method for the Estimation of Small Variations in the Quantity of Calcium contained in Blood. N. Voorhoeve. (*Biochem. Zeitsch.*, 1911, **31**, 195-206.)—The method proposed depends on the fact that blood does not coagulate when all the calcium present has been precipitated by the addition of ammonium oxalate. In carrying out the process, a small syringe is one-half filled with a 0·9 per cent. sodium chloride solution containing 229 mgrms. of crystallised ammonium oxalate per 100 c.c.; the needle of the syringe is then inserted into a vein and the other half of the syringe is filled with blood, the total volume of the syringe being 5 c.c. The mixture of blood and sodium chloride-ammonium oxalate solution is now transferred from the syringe to a watch-glass, well mixed, and kept for twenty-four hours in an atmosphere saturated with water vapour. Portions of $\frac{1}{2}$ c.c. are then removed to a number of watch-glasses and mixed with different quantities of a calcium chloride solution containing 30 mgrms. of calcium oxide per 100 c.c. The watch-glasses are then placed in a chamber the atmosphere in which is saturated with water vapour, and after the lapse of twenty hours the contents of the glasses are examined. The point at which coagulation just takes place having been found, the quantity of calcium in the blood is easily calculated, since 100 c.c. of the ammonium oxalate solution are capable of precipitating 90 mgrms. of calcium oxide, and the quantities of calcium oxide introduced as calcium chloride solution are known. The coagulating point may also be observed by drawing the mixtures of oxalate-blood and calcium chloride into capillary tubes; these are placed horizontally for twenty hours, after the ends have been sealed with paraffin wax, and then examined in a vertical position. If coagulation has not taken place, the red corpuscles settle to the lower end of the tubes. W. P. S.

Note on the Bulgarian Bacillus. J. Effront. (*Comptes rend.*, 1911, **152**, 463-465.)—Bacilli isolated by the author from six medicinal preparations of lacto-bacilline differ in their chemical action on milk and peptone from the Bulgarian bacillus of the Pasteur Institute. The latter acidifies milk strongly, forms little volatile acid, and has but a slight action on casein even after thirty days' incubation; whereas lacto-bacilline organisms are strongly proteolytic and produce far less acid, most of which is volatile, and leave the milk as a clear yellow solution. The Bulgarian bacillus was not present in any of the medicinal preparations examined, all of which showed strong proteolytic activity. The author considers the organisms to be really alike, the above differences being due to biochemical variation arising from the conditions of culture. The Bulgarian bacillus retains all its characters when grown in normal milk, but is much changed by variation in the aeration and acidity of the medium. Thus, in a culture containing peptone, calcium carbonate, and glucose, the Bulgarian bacillus behaves like a normal lactic ferment till all the sugar is used up. If at this stage the whole is kept for a fortnight, a spore film-formation occurs, and the culture then gives all the reactions of the lacto-bacilline preparations. The author points out that the therapeutic applications of the Bulgarian bacillus have been made with pharmaceutical preparations, such as the lacto-bacillines examined, and not with the true Bulgarian bacillus. The effects obtained cannot, therefore, be attributed to the lactic acid, which is hardly produced at all, but are due to the proteolytic action. H. F. E. H.

Behaviour of Schardinger's Reagent towards Colostrum. R. Reinhardt and E. Siebold. (*Biochem. Zeitsch.*, 1911, **31**, 294-320.)—The milk (colostrum) yielded by cows immediately after calving, and frequently that yielded during the next few days, decolorises Schardinger's reagent (formaldehyde and methylene-blue; *cf.* ANALYST, 1903, **28**, 32), although somewhat feebly. The first true milk from the cow, however, does not as a rule decolorise the reagent, and only after the lapse of from three to eight weeks after calving does the milk again give a positive reaction. This period of inactivity exhibited by the milk varies greatly in length with different cows; the reason is not known, but it is ascertained that the suckling of the calf does not cause the variation. The amount of enzyme, reductase, in a milk is not dependent on the quantity of fat present, and it is never quite absent from milk at any part of the lactation period. Milk mixed with colostrum decolorises the reagent more rapidly than does the same milk when mixed with water, and the difference in behaviour of milk at the beginning and end of lactation towards the reagent is merely due to the amount of enzyme present, and not to the varying activity of the enzyme. A definite quantity of the enzyme is necessary to decolorise a given amount of the reagent. Illness of the cow and inflammation of the udder influence the reaction. The first milk drawn from a cow contains less of the enzyme than does that obtained at the end of the milking operation, and different teats of the same cow may yield quantities of milk containing different amounts of the enzyme; as a general rule, however, 10 c.c. of milk from a healthy cow at the latter part of the lactation period will decolorise 1 c.c. of the reagent within from four to twelve minutes.

The enzyme is formed in the udder, and milk obtained under sterile conditions from a cow behaves exactly the same towards the reagent as does that obtained by ordinary milking. Temperatures above 65° C. destroy the activity of the enzyme. The highest temperature at which the enzyme decolorises the reagent is 65° C. in the case of milk yielded towards the end of lactation, and 45° C. for milk at the beginning of the lactation period (ANALYST, 1909, **34**, 352). The presence of bacteria in milk causes, after a time, an increase in the activity of the milk towards the reagent, this being due to the production of enzymes by the bacteria. W. P. S.

On the Peroxydase of Cow's Milk and its Detection by Means of the p.phenylenediamine Test. E. Nicolas. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 266-269.)—Bordas and Touplain have expressed the opinion that the coloration obtained when milk is treated with certain reagents (guaiacum, p.phenylenediamine, etc.), in the presence of hydrogen peroxide, may be attributed to the action of the casein on the hydrogen peroxide, and not to the presence of a peroxydase in the milk. The author, however, shows that, whilst precipitated and boiled casein is capable of producing a blue coloration with p.phenylenediamine and hydrogen peroxide, it is the hydrogen peroxide which first reacts with the p.phenylenediamine, and that the casein only combines with the product formed to give the blue coloration. This reaction only takes place between the hydrogen peroxide and the reagent when the former is used in the form of a concentrated solution. The coloration is not obtained with casein if only 2 drops of hydrogen peroxide diluted previously with nine times its volume of water be used, but the addition of a trace of a solution containing a peroxydase (aqueous extract of bran) causes the immediate development of the coloration. It is therefore important, in applying the test for the purpose of distinguishing between heated and unheated milk, to employ diluted hydrogen peroxide.

W. P. S.

Hæmoglobin Preparations. M. Vogtherr. (*Zeitsch. öffentl. Chem.*, 1911, **17**, 41-45; through *Chem. Zentralbl.*, 1911, **1**, 1013.)—In the case of hæmoglobin preparations two conditions are of special importance: the hæmoglobin must be readily and completely soluble in water, and must preserve its physiological and chemical qualities as far as possible unaltered; for instance, it must not have undergone decomposition into hæmatoglobulin and hæmatin. Further, the hæmoglobin should be present, as far as possible, in the form of oxyhæmoglobin; this should not have suffered undue conversion into methæmoglobin and hæmochromogen. Analytical determinations comprise estimations of water, ash, iron, nitrogen, solubility and the observation of the spectroscopic characters. Among a series of samples examined, one preparation showed the best values for nitrogen and the proportion of blood-colouring matter; the unground modification showed the smallest alteration as regards the oxygen constituent. Hæmoglobin carbonate preparations are distinguished by excellent solubility, but undergo decomposition under the action of carbon dioxide. The percentage of moisture in the samples ranged from 5·94 to 7·92. In 100 parts of dry substance were found: Nitrogenous matter, 90·54 to 97·07; non-nitrogenous matter, 0·06 to 6·12; ash, 2·87 to 4·37; pure iron, 0·283 to 0·486. Many commercial hæmoglobin preparations have a basis of cacao, as powder or cake; others are as solutions of hæmoglobin, containing from 47 to 76 per cent. of water. J. F. B.

Chemistry of Honey Formation. M. Kustenmacher. (*Biochem. Zeitsch.*, 1911, **31**, 237-254.)—The physiology of the bee is described by the author, who shows that the nectar of flowers, which is an aqueous solution of sucrose containing other carbohydrates, tannin, organic acids, etc., is converted by the bees into honey. This change is brought about by the aid of invertase, which is obtained from the pollen of the flowers; the saliva of the bees does not introduce this enzyme into the honey, nor does the saliva increase its action. The principal difference between different kinds of honey is due to the aromatic constituents of the plants from which the nectar has been obtained; the quantity of tannin has also some influence on the character of the honey. W. P. S.

Relation of the Normal Yellow Pigmentary Substances of Urine to the Diazo-Reaction, and a Colorimetric Method for Estimating Urochrome and Urochromogen. M. Weisz. (*Biochem. Zeitsch.*, 1911, **31**, 333-356.)—The portion of urine which is precipitated by barium hydroxide and alcohol—that is, the proteic acid fraction—when treated with basic lead acetate, yields a precipitate containing the normal yellow pigment (the urochrome of Thudichum and Garrod) and the urochrome which Dombrowski obtained directly by precipitation with copper acetate. The two pigments are not identical, and may be separated from one another by taking advantage of the insolubility of Dombrowski's urochrome in dilute acetic acid. The nature of the substance which produces Ehrlich's diazo-reaction is not known; it is contained in the proteic acid fraction, and from its properties is termed a urochromogen. Another urochromogen is also present in urine, but this does not give the diazo-reaction; both urochromogens may be converted by oxidation into urochrome. The urochrome may be estimated in urine by treating 25 c.c. of the urine with 20 grms. of powdered ammonium sulphate, filtering off the other colouring matters which are precipitated, and comparing the filtrate in a Dubosq colorimeter with a standard solution of a yellow dye. The quantity of urochrome is expressed in terms of the standard colour. Urochromogens may be estimated in a similar manner after oxidation to urochrome. The occurrence of urochromogens in urine indicates toxic changes in the metabolism of the body. W. P. S.

Separation of Urobilin from Urobilinogen. L. Grimbert. (*Comptes rend.*, 1911, **152**, 727-728.)—The simplest method of detecting the chromogen of urobilin (urobilinogen) in urine is to extract it with chloroform, and to oxidise it to urobilin, which will then give a green fluorescence on adding an alcoholic solution of zinc acetate to the chloroform solution. (*Cf.* ANALYST, 1910, **35**, 367.) Urobilinogen may also be detected by gently heating 1 c.c. of the chloroform solution with 3 or 4 drops of Ehrlich's reagent (2 per cent. alcoholic solution of p.dimethylaminobenzaldehyde mixed with an equal volume of hydrochloric acid), and then adding 0·5 c.c. of 95 per cent. alcohol to obtain a homogeneous solution. In the presence of urobilinogen the liquid becomes reddish purple, whereas urobilin gives no coloration under the same conditions. Although this reaction is also given by indol, it is useful for studying the behaviour of the chromogen in the urine. It is only exceptionally that free urobilin derived from the oxidation of the urobilinogen is found in urine; and, as a rule, when this oxidation has taken place, the urobilin enters into combination with other substances, probably of an alkaline nature, to form a compound insoluble in chloroform, so that, in general, a simple extraction of the urine with chloroform will effect a separation of the two compounds. If, however, as is frequently the case, the urine has been acidified before applying the tests, the liberated urobilin will also be extracted by the chloroform. It may then be removed by shaking the chloroform with a neutral aqueous solution of disodium phosphate, the urobilinogen being then left in the chloroform. In testing urine the liquid is extracted with chloroform, and the extract filtered through cotton-wool, and treated drop by drop with an alcoholic solution of zinc acetate (1 : 1,000) until the initial turbidity has disappeared. The production of a green fluorescence indicates the presence of urobilin. In this case the chloroform is shaken with a few c.c. of disodium phosphate solution (neutral to phenolphthaleïn), and the chloroform layer (which no longer fluoresces with zinc acetate) is mixed with a trace of iodine. Urobilinogen, if present, will thus be oxidised to urobilin, and the chloroform will again show the green fluorescence with zinc acetate. C. A. M.

ORGANIC ANALYSIS.

Direct Estimation of Caoutchouc as Tetrabromide. W. Hinrichsen and E. Kindscher. (*Chem. Zeit.*, 1911, **35**, 329-330.)—The authors have investigated the properties of purified caoutchouc tetrabromide. Kassai caoutchouc was purified by repeated solution in benzene, precipitation of the filtered solution by alcohol, and extraction of the precipitate by acetone. The purified material was then brominated by Hübener's method, repeated treatment with bromine water being employed until the product could be readily reduced to powder in a mortar. After washing with water, the brominated caoutchouc was exhaustively washed with alcohol and then with ether. Caoutchouc tetrabromide, particularly that from vulcanised material, is readily soluble in chloroform, but the tetrabromide from raw caoutchouc leaves a slimy residue which is not completely soluble. From the chloroform solution the pure tetrabromide may be precipitated quantitatively by petroleum spirit. On storage with exposure to light and air, the dry purified tetrabromide gradually changes and becomes less soluble in chloroform.

The authors have found that when caoutchouc tetrabromide is decomposed by nitric acid in presence of excess of silver nitrate for the volumetric estimation of the bromine, the results obtained are much too low. This is due to the volatilisation of bromine compounds, and the loss of bromine is greater the higher the concentration of the nitric acid. The volumetric process recommended by Büdde and by Hübener is therefore unsuitable. As an alternative, the method described by Marcusson and Doescher (Analyst, 1910, **35**, 319), depending on the direct combustion of the substance in a current of oxygen and absorption of the products in standard silver nitrate, gives excellent results. As this requires special apparatus, the tetrabromide may be burnt in a platinum crucible with a mixture of potassium and sodium carbonates, care being taken to boil the precipitate of silver bromide, subsequently obtained, thoroughly with nitric acid. The authors provisionally indicate the following scheme for the analysis of caoutchouc by a modification of the tetrabromide method: Bromination should only be effected after the material has first been thoroughly extracted with acetone. The bromide is collected on a filter, together with the inorganic compounds remaining in it, washed with water, alcohol, and ether, and then dissolved in chloroform. The tetrabromide is precipitated from the chloroform solution by petroleum spirit, and is either dried and weighed directly, or the bromine is estimated by either of the methods described above. The direct weighing is preferable, as the substance is then available for the estimation of the sulphur of vulcanisation.

J. F. B.

Examination of Asphaltum. J. Marcusson. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 47-51.)—The following modification of the author and Eickmann's test for distinguishing between natural and artificial asphaltum (Analyst, 1908, **33**, 476) enables very small quantities of petroleum pitch to be detected: 10 grms. of the sample are dissolved in 15 c.c. of benzene, the solution poured into 200 c.c. of petroleum spirit (b. p. 80° C.), the precipitated asphaltene separated, and the filtrate treated with three successive portions of 15 c.c. of concentrated sulphuric acid to remove the remaining dark-coloured constituents. The liquid is washed with alkali solution and with water until free from acid, and then evaporated, and the residue dried and weighed. In the case of natural asphaltum the residual oil (from 2 to 34 per cent. upon the ash-free material) will be fluid at 20° C., and show no separation of particles of paraffin wax or substances resembling vaseline; whilst in the presence of petroleum residues it will have the consistency of cylinder oils at 20° C., will contain an abundance of vaseline substances, and will amount to 26 to 58 per cent. of the ash-free sample. In doubtful cases an estimation of the paraffin wax in the oily residue will afford valuable information, the amount being less than 1 per cent. in the case of natural asphaltum, and ranging from 3·3 to 16·6 per cent. in the case of petroleum pitch. Thus, if the residue yielded more than 2 per cent. of paraffin wax, the presence of petroleum pitch is indicated. A further test may be based upon the fact that natural asphaltum yields considerable quantities of organic acids on distillation, whereas in the case of petroleum pitch the distillates contain only a slight amount of acids. In applying the test 30 grms. of the sample (or a quantity of material containing about 30 grms. of bitumen) are distilled in a small retort, and two fractions of 4 to 5 c.c. collected. These are dissolved in ether, the solution washed with water to remove any mineral acid, and the acid value estimated in the usual manner. In the case of natural asphaltum the first distillate will show an acid value considerably over 1, whilst that from the petroleum residues will show a value below 1. The second distillate from the natural asphaltum will also still have a considerable acid value, whereas in the case of petroleum residues it is invariably free from acid. Thus the following results were obtained:

	Natural Asphaltum.			Petroleum Residues.			
	Trinidad.	Syrian.	San Valentino (Soft).	From Heavy Wietzer Crude Oil.	Soft Pitch.	Galician I.	Galician II.
Distillate I....	14·0	4·7	1·9	0·53	0·73	0·57	0·87
,, II....	5·6	2·7	1·4	nil	nil	nil	nil

If a sample contained less than 1·7 per cent. of sulphur (upper limit for petroleum residues and lower limit for natural asphaltum), and also considerable quantities of paraffin wax, the presence of petroleum pitch is proved. If, further, the first distillate had an acid value exceeding 1, whilst the second distillate also showed a high acid value, and there was also a considerable amount of sulphur, the sample probably contained natural asphaltum in addition to petroleum pitch. The correctness of these deductions, however, depends upon the absence of fat-pitches (the presence of which is indicated by the production of acrolein on heating), which also give high acid values in the first distillate. In addition to these kinds of asphaltum there are also upon the market varieties obtained by distilling off considerable quantities of oil from naturally occurring soft bitumens. The characteristics of two of these thickened products were as follows:

Commercial Name.	Ash.	Sulphur.	Oily Constituents.			Acid Value of—	
			Nature.	Amount.	Paraffin Wax.	Distillate I.	Distillate II.
	Per Cent.	Per Cent.		Per Cent.	Per Cent.		
Mexico asphaltum	0·2	5·8	Not fluid. Contained vaseline-like particles	35·0	2·8	1·6	0·9
Derna asphaltum-bitumen	5·6	0·9	Ditto.	25·0	1·6	0·7	0·7

These products may thus be readily distinguished from petroleum residues. If present in admixture with petroleum pitch, Mexico asphaltum would be detected by its high proportion of sulphur and the acid values of the distillates. Derna asphaltum, however, would only be detected by these values when present in larger proportion than the petroleum residues in the mixture. The phenols in brown coal-tar pitch, to which Graefe's diazobenzene chloride reaction (ANALYST, 1906, **31**, 204; 1908, **32**, 477) is due, may be extracted by treatment with sodium hydroxide solution. Ordinary coal-tar pitch behaves in a similar manner, but may be distinguished from brown coal-tar pitch by other reactions (presence of free carbon, anthraquinone test, etc.). Wood tar also gives Graefe's reaction, but is easily distinguished from brown coal-tar pitch by its pronounced solubility in alcohol and its ready absorption of sulphur. When a positive result has been obtained in Graefe's reaction, the following test may be applied to determine whether the sample consisted of brown coal-tar pitch or a natural asphaltum, thinned by the addition of brown coal-tar oil (paraffin oil): Ten grms. of the asphaltum are dissolved in 15 c.c. of warm benzene, the solution poured into 200 c.c. of petroleum spirit, and the precipitate collected, washed with petroleum spirit, dried, powdered, and tested for phenols. In order to extract the latter as completely as possible, the powder is boiled for fifteen minutes beneath a reflux condenser with ½ N-alcoholic potassium hydroxide solution, after which the liquid is cooled and filtered, the filtrate evaporated to expel alcohol, and the residue taken up with water. The solution is shaken with sodium chloride to remove colouring matters, and the filtrate tested in the usual way with diazobenzene chloride solution. An addition of 10 per cent. of brown coal-tar pitch, or of 20 per cent. of acid resins, to natural asphaltum could thus be detected with certainty. Mixtures of natural asphaltum with 10 and 20 per cent. of brown coal-tar oil gave a sharp diazo reaction, but when the test was applied to the constituents insoluble in petroleum spirit no colour reaction was obtained. C. A. M.

Use of Carbalkyloxy Derivatives for the Quantitative Estimation of Hydroxyl Groups. K. C. R. Daniel and M. Nierstein. (*Ber.*, 1911, **44**, 701-704.)—Following E. Fischer and Freudenberg's observations on the properties of carbalkyloxy compounds of tannins, the authors have based a method for the estimation of hydroxyl groups in substances of the tannin class on the saponification of these derivatives, the preparation of which offers the advantage that intramolecular changes and splitting up of the sensitive tannin compounds are apparently excluded. The saponification takes place according to the equation—

$$R.O.COOR_1 + H_2O = R.OH + CO_2 + R_1OH,$$

and the quantitative estimation consists in weighing the carbon dioxide split off. The apparatus consists of a distillation flask with dropping funnel, supported in an oil bath and connected with an upwardly inclined Liebig's condenser, the further end of which is connected with a calcium chloride U-tube which leads to the absorption bulbs. Saponification is effected by means of boiling 50 per cent. pyridine, and the U-tube contains a mixture of 2 parts of calcium chloride and 1 part of oxalic acid to absorb any pyridine vapours. For the estimation, 0·3 to 0·5 grm. of the substance, dissolved in 20 to 30 c.c. of alcohol, is placed in the flask, which is heated in the oil bath at a temperature of 115° to 120° C., whilst a current of air free from carbon dioxide is passed through the system. The dropping funnel is slightly warmed, and 80 c.c. of a 50 per cent. solution of pyridine are introduced through it in three portions.

Heating is continued at a maximum temperature of 120° C. with continuous passage of air for three-quarters to one hour. The results of the analysis of a number of carbalkyloxy derivatives of various hydroxylated compounds illustrate the accuracy and convenience of the method. J. F. B.

Influence of Inactive Substances on the Rotation of Lævulose. N. Wender. (*Biochem. Zeitsch.*, 1911, **31**, 357-373.)—Most inorganic acids, when added to solutions of lævulose, increase the specific rotation of the sugar, the increase being in proportion to the acidity of the solution, whilst organic acids vary in their influence. Oxalic acid increases the rotation and acetic acid diminishes it. Alkalis depress the rotation owing to decomposition of the lævulose. Inorganic salts may increase or decrease the rotation, and alcohols and acetone always lower it, the diminution being proportional to the quantity of alcohol or acetone present.
W. P. S.

Characters of Creosote and Tar Oils available for Wood Preservation. C. N. Forrest. (*J. Soc. Chem. Ind.*, 1911, **30**, 193-196.)—A mixture of water-gas tar, freed to some extent from light oils, with coal- and coke-tar distillates, forms the bulk of American creosote of the present time. The simple oils and tars which are now available have the following characters:

	Domestic Distilled Oil.	Foreign Distilled Oil.	Otto Coke-Oven Tar.	Otto Coke-Oven Distilled Oil.	Water-Gas Tar Refined
Sp. gr. 15° C.	1·03	1·04	1·16	1·09	1·13
Free carbon	none	none	5·30	none	0·60
Tarry matter	0·5 to 2·0	0·70	58·00	10·0	51·00
Tar acids	7·0	13·60	trace	trace	none
Solid naphthalene ...	—	18·00	—	—	—
Distillation :	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent
Below 170° C.	0·42	0·70	0·60	1·60	0·50
170 to 205° C.	4·50	1·50	0·90	2·40	0·50
205 to 235° C.	51·95	35·20	6·90	19·80	1·70
235 to 255° C.	22·01	32·60	7·20	7·70	4·10
255 to 270° C.			4·20	7·50	5·80
270 to 315° C.	10·99	20·00	7·90	11·60	15·00
Residue	10·13	10·00	72·30	49·40	72·40
	100·00	100·00	100·00	100·00	100·00
Insoluble in dimethyl sulphate	none	none	none	none	none
Condition of residue ...	soft	soft	hard	soft	hard
Paraffin scale	none	none	none	none	none

The following table shows the analytical characters of three classes of materials extensively used for the treatment of wood-paving blocks :

	Water-Gas Tar.	Coal-Tar.	Distilled Oil.
Sp. gr. 38° C.	1·12	1·17	1·10
Insoluble in CS_2	0·60	3·5	none
Distillation :	Per Cent.	Per Cent.	Per Cent.
Below 170° C.	0·50	0·10	—
170 to 205° C.	0·50	2·00	—
205 to 235° C.	1·70	2·90	—
235 to 255° C.	4·10	7·30	—
255 to 270° C.	5·80	7·20	—
270 to 315° C.	15·00	9·70	25·00
315 to 370° C.	24·60	16·40	60·00
Residue	47·80	54·40	15·00
	100·00	100·00	100·00
Insoluble in dimethyl sulphate ...	none	none	none
Condition of residue	hard	hard	soft
Sp. gr. distillate, (255 to 315°) at 60° C.	1·00	1·02	1·08

The following characters are relied on for the determination of the suitability of preservative material for a specific purpose : Sp. gr., preferably at 38° C. ; free carbon = insoluble in benzene or carbon disulphide ; pitch or tarry matter = insoluble in alcohol or petroleum naphtha ; tar acids = volume removed from distillate by caustic soda solution ; naphthalene = solid from distillate or fraction 210 to 235° C. ; distillation (under standard conditions) ; sp. gr. of certain or all fractions of distillate ; sulphonation and dimethyl sulphate tests of distillate ; refractive index of distillate. Cold solvents for pitch and carbon determinations are advantageous and generally accurate. Tar-acids are not of importance. Solid naphthalene should be pressed from the chilled distillates. As regards distilling apparatus, the method recommended by Von Schrenk, Fulks and Kammerer (*Bull.* 65, *Amer. Rail. Engineer, etc., Association*) is in general use, in which the material (100 grms.) is distilled from an 8-ounce covered retort, the thermometer bulb being ½ inch above the surface of the oil, and distillation at the rate of 1 to 2 drops per second. The dimethyl sulphate test is used to distinguish between oil-products of benzene character or pyro-distillates (soluble), and paraffin or olefine hydrocarbons, produced by the distillation of mineral oil (insoluble in dimethyl sulphate). (See Sommer, *J. Ind. and Eng. Chem.*, 1910, **2**, 186.) A. R. T.

Purchase of Coal under Specifications. G. S. Pope. (*U.S. Geological Survey, Bulletin* **428**, 1-80.)—This paper gives in detail the results of Government purchases of coal for the fiscal year 1908-09, and the list of contracts with abstracts of specifications for the year 1909-10, and summarises the information on this subject obtained by the Survey. Since the publication of the last Bulletin on the subject (*U.S. Geological Survey*, No. 378), more accurate data have been accumulated as the result of experiments by the Survey staff and other chemists and engineers, as to the reduction in efficiency induced by high percentages of ash. As a result, the model specification now published provides for a bonus of 2 cents per ton for every 1 per cent. of ash below the contract standard (as against 1 cent per ton in earlier specifications) and, whilst tolerating 1 to 2 per cent. of ash above standard, imposes penalties for larger quantities of ash which penalties progress more rapidly than the ash percentage. For example, coal with ash 2 to 3 per cent., or 3 to 4 per cent., above standard is only penalised 2 and 4 cents per ton respectively, but 6 to 7 per cent. excess involves a penalty of 18 cents, whilst coal with higher ash content than this may be refused, or, at the option of the purchaser, accepted subject to substantial allowances of 25 to 35 cents per ton. These corrections in price to be paid are independent of and additional to the correction calculated from the ratio of calorific power of coal received to that guaranteed by vendor. In the past, the United States Government has purchased its anthracite on a specification, which simply provided heavy penalties for excessive ash. In future, tenders will be invited for the supply of anthracite on the same terms as apply to all contracts for bituminous coal—namely, payment at contract price multiplied by the ratio of the calorific power of the coal received to that guaranteed by vendor, ± a correction for ash content according to the scale published in this bulletin, and from which some typical figures have been given above. The bulletin gives useful information as to the award of contracts when inviting tenders on this "double basis," as it is called. Sellers in America are now so accustomed to this system that they usually, when offering coal, state the heat value and ash percentage which they are content to have made the basis of the contract, and this is preferred by the Government; but any tenderer may, if he prefers, submit a sample, which is then analysed in the Survey Laboratory, and becomes the basis of the contract, if one is entered into. G. C. J.

Deposits resulting from the Lubrication of Engines. J. E. Southcombe. (*J. Soc. Chem. Ind.*, 1911, 30, 261-264.)—The deposits from certain superheated steam cylinders were found to have the average composition Fe_3O_4, 86 per cent., organic matter 14 per cent. The organic matter included little or no free carbon, but consisted of solid bitumens containing 90 to 94 per cent. of carbon, and 6 to 9 per cent. of hydrogen. A brownish-black powder, formed in the lubricating pipes of forced feed engines using hydrocarbon oils, was found to consist of 54 per cent. unchanged oil (soluble in petrol), 22 per cent. bituminous matter soluble in ether, 12 per cent. bituminous matter insoluble in ether, but soluble in carbon bisulphide, 4 per cent. organic acids, 4 per cent. ash, and 4 per cent. water, etc. (by diff.). Only 87 per cent. of the ash was oxide of iron or copper. A black, gritty deposit, from the lubricating pipes of a steam turbine, gave ether-soluble matter (thick oil) 79 per cent., bituminous matter (soluble in carbon bisulphide) 9 per cent., organic acids 1 per cent., iron and iron oxide 4 per cent., cupric oxide 2 per cent., water, etc. (by diff.) 5 per cent. A black amorphous lumpy mass from the cylinder of a gas engine using producer gas contained tarry matter (soluble in ether) 43 per cent., insoluble bitumen and carbon 13 per cent., free sulphur (soluble in chloroform) 5 per cent., combined sulphur 4 per cent., and oxide of iron 35 per cent. G. C. J.

Characteristics of Oils from Papilionaceous Plants. C. Grimme. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 53-55; 77-82.)—The oils, the characteristics of which are given below, were all obtained by extracting the seeds of the plants with ether. The oils from the seeds of the melilot and white melilot were drying oils, whilst the others were either non-drying or had only weak drying properties:

C. A. M.

Use of Dimethylaminobenzene-azo-benzene Sulphonic Acid as a Reagent in Microchemistry. M. E. Pozzi-Escot. (*Bull. Soc. Chim.* 1911 [iv.], 9, 22-26.)—Dimethylaminobenzene-azo-benzene sulphonic acid forms difficultly soluble metallic salts, some of which differ so much from the others in crystalline appearance as to be of use in microchemical analysis. Twenty-seven such salts are described and twenty figured in the text. It is suggested that the reagent affords a means of detecting small quantities of nickel in presence of much cobalt and *vice versâ*. Nickel gives rise to an amorphous yellowish-green precipitate, soluble in boiling water, from which, on cooling, it deposits pale yellow prisms, whose three dimensions are not very unequal. Cobalt, on the other hand, gives a crystalline precipitate at once, the crystals being violet or nearly black needles, the length of which may equal that of the prisms yielded by the nickel salt, but their other dimensions are very small indeed, being represented by single lines in the microphotographs accompanying the paper. G. C. J.

Influence of Potassium Permanganate upon Organic Bodies. J. Hetper. (*Anzeiger Akad. Wiss. Krakau*, 1910, Series A, 601-605; through *Chem. Zentralbl.*, 1911, 1, 927.)—The behaviour of organic compounds towards an acid solution of potassium permanganate depends upon their constitution, and it is therefore possible in this way to detect the presence of certain groups in the molecule. The method consists in heating a solution of the substance in 27 c.c. of water for one and a half hours at 92° to 93° C. with 25 c.c. of $\frac{N}{5}$-potassium permanganate solution containing 20 grms. of crystallised phosphoric acid per litre, then treating the hot liquid with 25 c.c. of $\frac{N}{5}$ oxalic acid solution containing 50 grms. of concentrated sulphuric acid per litre, and titrating the excess of the latter with $\frac{N}{5}$ permanganate solution. The following provisional conclusions were drawn by the author from results thus obtained: (1) Complete oxidation takes place in the case of all compounds soluble in water, alkali hydroxide solution, or phosphoric acid, provided they contain none of the groupings mentioned in (2), (3), and (4). In particular, all hydroxylated compounds such as polyvalent alcohols, phenols, etc., are completely oxidised. (2) Compounds with the constitution $CH_3.C\langle$, or $C_2H_5.C\langle$, etc., are not completely oxidised, since these radicles are oxidised into fatty acids, which undergo no further change. (3) Compounds containing the CH_3 group are oxidised with difficulty, and the more so in proportion to the nearness with which this group stands in relation to a COOH group, or a group oxidisable to COOH. The greater the distance between the two groups the more readily is the COOH group split up into CO_2 and H_2O, with the simultaneous oxidation into COOH of the carbon atom next to the disintegrated group. In this oxidation there is produced a homologous acid of the lower series. Acetic acid is exceedingly stable towards potassium permanganate, whilst propionic acid is less readily oxidised to acetic acid than is butyric acid to propionic acid. Compounds containing other hydrocarbon groups, such as C_6H_5, in the vicinity of the COOH group appear to behave in an analogous manner. (4) Dicarboxylic acids are completely oxidised when both COOH groups are in immediate contact (oxalic acid), or, at least, in combination with the same carbon atom (malonic acid). Other dicarboxylic acids (*e.g.*, succinic acid) are not oxidised. (5) Inorganic acid and basic groups are converted into the corresponding acids or bases (*e.g.*, NO_2 into HNO_3, NH_2 into NH_3, etc.). For purposes of comparison the terms *molar* and *gram values* are suggested. The molar value is the number of c.c. of N-potassium permanganate solution required to oxidise 1 grm. molecule of the substance; whilst the gram value is the quantity (in c.c.) required to oxidise 1 grm. C. A. M.

Estimation of the Activity of Oxidising Agents by Means of the Quinonoid Imonium Salts of Benzidine. W. Madelung. (*Ber.*, 1911, **44**, 626-631.)—If any oxidising agent be added to an excess of an aqueous solution of benzidine, care being taken to maintain a neutral reaction, a precipitate of cornflower-blue microscopic needles is formed, which is sparingly soluble, and in presence of small quantities of mineral salts is perfectly insoluble. This compound is an analogue of the *meri*-quinonoid salts of diphenoquinone diimine described by Schlenk, the negative radical depending on the particular oxidising agent employed. The formation of the blue oxidation product of benzidine may be applied for analytical purposes, since it retains in the active form the whole of the oxidising power of the active oxygen employed in its formation, particularly in physiological investigations, and in estimating the oxidising power of coloured solutions, which cannot be titrated direct. The benzidine derivative may be precipitated, isolated, and caused to liberate iodine from acidified potassium iodide, which is then titrated with standard thiosulphate. If the blue compound be produced in neutral aqueous solution and collected, the blue colour is immediately discharged on the addition of hydrochloric acid; there remain brown flakes of the dichlorimide, which dissolve when potassium iodide is added as a preliminary to titration. The final result is the same as if the oxidising agent had been titrated directly, but in certain cases the precipitation and separation of the oxidising function presents distinct advantages. In the investigation of blood, and in the study of the activification of hydrogen peroxide by peroxydases, the author has used the method with considerable success. Sodium chloride is employed to increase the insolubility of the precipitate. J. F. B.

Separate Estimation of Potassium Bitartrate and Calcium Tartrate. P. Carles. (*Bull. Soc. Chim.*, 1911, [iv.], **9**, 199-202.)—This is said to be important both to those who extract the marc only with boiling water, thus losing most of the calcium tartrate, and to those who treat the marc with dilute sulphuric acid to recover the whole of the tartaric acid. When working for the recovery of the whole of the tartaric acid in material in which the calcium salt preponderates, it is preferable to recover the whole of the acid in the form of calcium salt.

The marc (200 grms.) is mixed with 200 c.c. of water in which 2·5 grms. of anhydrous sodium carbonate have been dissolved. If necessary, more water is added to cover the sample. The dark-coloured liquid is poured off as far as possible into another vessel and then back on to the marc, and this process is repeated once or twice. At the end of an hour or two the liquid is again decanted. It is now quite pale and neutral or faintly acid to litmus. A further 1 grm. of sodium carbonate (or an equivalent amount of a concentrated solution) is added to it, when it regains its dark colour. It is again poured over the marc and, at intervals of about two hours, is decanted, and, whenever it is found to be substantially decolorised, its alkalinity and colour is to be restored by a further addition of 1 grm. (or 0·5 grm.) of sodium carbonate. This process is continued for forty-eight hours, and about 6 to 7 grms. in all of sodium carbonate is usually required. At the end of the period the liquid should be pale but distinctly alkaline to litmus, and should maintain its alkaline reaction for at least five hours. It is then finally decanted, and the marc allowed to drain for a quarter of an hour. The marc is next covered with distilled water, which is decanted off after two hours, and this washing by decantation repeated twice more. The combined extracts, which contain as Rochelle salt all the tartaric acid originally present as potassium bitartrate, are nearly, but not quite, neutralised with acetic acid, and are concentrated at a temperature below boiling to about 125 c.c. If much pectinous matter separates, resort must be had to filtration; but the extraction of the marc by liquor, which is never strongly alkaline, is designed to reduce the extraction of such matters to a minimum. When the solution has been concentrated to 125 c.c., acetic acid is added until the reaction is distinctly acid, and this is followed by 10 c.c. of a saturated solution of calcium acetate. The mixture is maintained at a temperature near its boiling-point, and, at five-minute intervals, further 10 c.c. portions of calcium acetate are added up to 70 to 80 c.c. in all. Calcium tartrate begins to crystallise at the first addition, and after the last the beaker is set aside for twenty hours. At the end of that time the crystals and mother liquor are transferred to a 250 to 300 c.c. basin, an equal bulk of cold water added, and the liquor decanted into a second basin, and, if it carries any crystals with it, it is decanted from them into a third. Small quantities of pectinous matters and other impurities are thus easily eliminated. The crystals are washed three times with cold water by decantation in the same way, and are then drained, dried, and weighed. The weight × 0·723 gives the weight of potassium bitartrate in 200 grms. of the marc.

The extracted marc is covered with water, and the water decanted off, mixed with 5 c.c. of hydrochloric acid, and again poured over the marc. The acid liquor is decanted off and returned to the beaker twice an hour for three or four hours. At the end of that time it is decanted off and replaced by water, and after an hour this water is decanted off. The marc is washed twice more in a similar manner by decantation, and the united acid liquid and washings are then concentrated to 125 c.c. In this solution, which contains all the tartaric acid originally present as calcium tartrate, the tartaric acid is precipitated as calcium tartrate by addition of a saturated solution of calcium acetate as already described. G. C. J.

Colour Reaction of Proteins with Sodium Nitroprusside. V. Arnold. (*Zeitsch. physiol. Chem.*, 1911, **70**, 300-309.)—A number of proteins, particularly the products obtained by the action of pepsin on albumin or muscular fibre in the presence of hydrochloric acid, yield an intense purple coloration when a small quantity of their aqueous solution is treated with a few drops of a 5 per cent. sodium nitroprusside solution, and the mixture then rendered ammoniacal. The coloration, which is destroyed by acetic acid, is relatively stable, and is produced by the cystein group in the protein molecule; it is not due to sulphur compounds split off from the protein. Egg-albumin does not yield the reaction until after it has been subjected to peptic digestion, but the soluble proteins obtained from the crystalline lens of the eye give an intense coloration, as do also aqueous extract of many of the other organs of the body. Vegetable seeds frequently contain the substance which gives the reaction, but the coloration obtained is always less intense than in the case of animal substances. W. P. S.

Notes on Hubener's Caoutchouc Tetrabromide. R. Becker. (*Gummi Zeit.*, 1911, 25, 531.)—Gutta, and probably balata, yield bromine compounds similar to those obtained in the case of caoutchouc, and Hubener's method (ANALYST, 1909, **34**, 355) is, therefore, not suitable for the separation of gutta from caoutchouc.

Estimation of "Mineral Rubber" and Similar Products in Rubber Articles. R. Becker. (*Gummi Zeit.*, 1911, **25**, 598.)—Carbon bisulphide extracts "mineral rubber," asphaltum, etc., but does not appreciably dissolve rubber.

Estimation of Iodine in Alcoholic Solutions. G. Favrel. (*Ann. Chim. anal.*, 1911, **16**, 12-13.)—Desvigne's process (weighing as silver iodide after conversion into potassium iodide) and the volumetric process suggested by Libeau (titration with silver nitrate after treatment with zinc powder) give the same result as titration with thiosulphate.

Anhydride of Lactic Acid. A. A. Besson. (*Chem. Zeit.*, 1911, **35**, 26.)—Lactic acid frequently contains a quantity of the anhydride; and the total acidity of the substance (acid *plus* anhydride) is only obtained when the sample, after neutralisation of the acid, is treated with an excess of alkali, allowed to stand for ten minutes, then acidified and titrated.

INORGANIC ANALYSIS.

Estimation of Free Acid and Basic Alumina in Aluminium Salts. T. J. I. Craig. (*J. Soc. Chem. Ind.*, 1911, **30**, 184-185.)—The method is based on the fact that an excess of neutral potassium fluoride decomposes aluminium salts, forming two stable compounds neutral to phenolphthaleïn, while any free acid remains unaltered, thus:

$$Al_2(SO_4)_3 + (xH_2SO_4) + 12KF = 2(AlF_3,3KF) + 3K_2SO_4 + (xH_2SO_4).$$

The precipitated aluminium potassium fluoride is insoluble in presence of a moderate excess of potassium fluoride, and is not appreciably attacked by dilute acid or dilute caustic alkali.

Pure potassium fluoride is dissolved in water, and the solution brought to a sp. gr. of 1·45. It is neutralised, if necessary, with caustic potash or sulphuric (or hydrofluoric) acid till about 1 c.c. in 10 c.c. water shows a faint pink colour with phenolphthaleïn. Insoluble matter is filtered off, and the filtrate, without washing the paper, is diluted to sp. gr. 1·35, containing about 0·5 grm. potassium fluoride per c.c. The reagent is stored in a glass bottle coated internally with wax. Standard sulphuric acid and caustic potash must be free from alumina and similar bases, and the acid is standardised against anhydrous sodium carbonate (using methyl orange), the alkali then being run against the acid in about 40 c.c. of water, to which 10 c.c. of the above potassium fluoride solution has been added, phenolphthaleïn being the indicator (0·2 per cent. solution).

The substance to be examined is dissolved in water, so that 1 to 3 grms. alumina are present in 200 c.c. The solution is filtered from insoluble matters, and 20 c.c. gradually added, with stirring, to a mixture of 10 c.c. of potassium fluoride solution, 50 to 60 c.c. water, and 0·5 c.c. phenolphthaleïn solution. If neutral, the liquid will be slightly pink, and one drop of $\frac{N}{2}$ alkali will intensify the colour. If free acid be present, standard alkali is run in till a faint permanent pink is produced. If the substance is basic, caustic alkali will be liberated:

$$Al_2O(SO_4)_2 + 12KF + H_2O = 2(AlF_3.3KF) + 2K_2SO_4 + 2KOH.$$

This alkalinity cannot be directly titrated, however, as a portion is precipitated as a basic double fluoride neutral to phenolphthaleïn. Standard acid is therefore added till the pink colour disappears, and the amount required noted. A similar amount of standard acid, plus a known excess equal to 4 c.c. $\frac{N}{2}$ acid (more if necessary), is then added to a fresh portion of the filtered solution of the basic substance, the liquid heated to cause the basic alumina and the acid to react, and, after cooling, the method carried out as before by addition to the fluoride solution, the amount of free acid shown being noted. The amount of added acid which has disappeared may thus be calculated in terms of basic alumina (1 c.c. $\frac{N}{2}$ acid = 0·0085 grm. Al_2O_3). The volume of liquid after titration may be 60 to 120 c.c. In presence of sodium salts, 20 to 30 c.c. of neutral saturated solution of potassium sulphate are added to the liquid, before it is mixed with the fluoride, to minimise the tendency to form basic sodium double fluoride. Ammonia, if present, must be removed by heating with a known excess of standard alkali before mixing with the fluoride, more of which latter solution is required in the presence of iron salts in the material under examination. If the almost colourless iron potassium fluoride precipitate darkens during the titration, owing to decomposition by the alkali, too little fluoride is present. The amount of free acid in iron and zinc salts may be determined by this method, but larger amounts of fluoride solution must be used. A. R. T.

Estimation of Arsenic in Insecticides. E. B. Holland. (*J. Ind.* and *Eng. Chem.*, 1911, 3, 168-171.)—The author recommends the following method for the estimation of arsenic in arsenical insecticides, including substances, like Paris green, containing copper: 2 grms. of the finely-powdered sample are boiled for five minutes with 50 c.c. of sodium acetate solution (1 : 2). The liquid is cooled, 60 c.c. of diluted (1 : 3) hydrochloric acid added, and the mixture shaken to complete solution, when the liquid is diluted to 500 c.c. and filtered. Twenty-five or 50 c.c. of the solution are neutralised with sodium bicarbonate, 25 c.c. of sodium potassium tartrate solution (10 per cent.) added (in the case of copper arsenites only) to dissolve precipitated copper, and after adding 3 grms. of sodium bicarbonate, and making the volume up to 100 c.c., the solution is titrated with $\frac{N}{20}$ iodine solution in presence of 2 c.c. of starch-paste (1 : 200) till a permanent blue colour is obtained. Towards the end of the reaction the flask should be corked and shaken vigorously. The original residue is weighed as insoluble matter after ignition. The presence of cuprous and ferrous compounds, sulphurous and nitrous acids, or other oxidisable substances, is a source of error in the iodine titration method.

Iodine Method for Arsenates.—Two grms. of the finely-ground sample (*e.g.*, lead arsenate) are boiled with 60 c.c. of diluted nitric acid (1 : 3), the liquid diluted to 500 c.c., and filtered. Fifty or 100 c.c. are evaporated with 10 c.c. of sulphuric acid (2 : 1), the residue heated at 150° to 200° C. in an air-bath to expel moisture, and finally heated on a plate till dense white fumes of sulphuric acid are given off, and all nitric acid is expelled. A little water is added, and the solution filtered under diminished pressure, and the filter washed till a volume of 100 c.c. is obtained. Ten c.c. of potassium iodide solution (16·5 per cent.) are added, and the liquid boiled till the free iodine is expelled, when the solution will become almost colourless. The liquid is diluted, cooled immediately, neutralised with sodium hydroxide, and acidified slightly with sulphuric acid. Starch-paste is added, and if free iodine is present, $\frac{N}{20}$ thiosulphate solution is added carefully, with vigorous shaking, till the blue colour disappears. Excess of sodium bicarbonate is next added, and the titration with $\frac{N}{20}$ iodine carried out as usual, calculating as arsenic oxide. Insoluble matter in the original liquid is weighed as before. Practically no difference was noted in the titration when the lead sulphate was not removed. A. R. T.

Estimation of Ash in Vegetable and Animal Substances. E. Fleurent and L. Lévi. (*Comptes rend.*, 1911, **152**, 715-718.)—The loss of phosphoric acid varies very greatly in estimating the ash by ignition either in the open air or by Schlösing's method (ignition in a current of carbon dioxide followed by a slow current of oxygen). Thus, in the authors' estimations it ranged from 7·31 per cent.

in the case of white haricots, to 49 per cent. of the total quantity of phosphorus in the case of two varieties of barley. The causes of the loss are the action of carbon and of silica upon the acid phosphates in the ash, and also the removal of part of the phosphorus in the form of a volatile organic compound, this being particularly noticeable in the case of substances rich in fat. In order to obtain an accurate estimation of the ash, the authors first extract the fat, when present in large proportion, and carbonise the residue at as low a temperature as possible. The residual mass is then pulverised and mixed with a solution (or cream) of calcium oxide, containing 0·04 grm. to 0·150 grm. of CaO per 10 grms. of the organic material according to its richness in phosphoric acid, and the ignition completed by Schlösing's method. Finally, the amount of added calcium oxide is deducted from the weight. In this way a perfectly white ash is obtained without the losses inevitable by the other methods. Thus, in the analysis of three samples of wheat, the amounts of ash obtained by direct ignition were 15·41, 17·68, and 18·84 per cent., as against 16·92, 19·19, and 20·34 per cent. respectively by the new method. C. A. M.

Colorimetric Estimation of Minute Quantities of Chromium. P. Koenig. (*Chem. Zeit.*, 1911, 35, 277-278.)—The trace of chromium—for example, that occurring in the ash of plants grown in certain soils—is obtained in solution as chromate, and the solution mixed with a solution of disodium, 1·8-dihydroxynaphthalene, 3·6-sulphonate, which develops a distinct and permanent cherry-red coloration when even so little as 0·0008 mgrm. of chromium, as chromate, is present in 10 c.c. of the solution. The solution must not be alkaline, as the reagent gives a pink coloration with alkalis, but it may be made faintly but distinctly acid with any mineral acid, and the addition of a few c.c. of phosphoric acid is recommended in every case, as this addition inhibits the formation of coloured compounds of iron, tungsten, and uranium, which might otherwise interfere. To 10 c.c. of the solution to be tested 1 c.c. of a 1 per cent. solution of the reagent is added, together with a few c.c. of phosphoric acid. The intensity of the coloration developed is compared with that produced by a standard solution of potassium bichromate. The comparison is most easily made when the solutions to be compared contain from 0·001 to 0·01 mgrm. of chromium. Stronger solutions give rise to violet-red colours, which are less easily compared. G. C. J.

New Reaction for the Differentiation of Cobalt and Nickel. H. Weil. (*Bull. Soc. Chim.*, 1911, [iv], 9, 20-22.)—The reaction depends on the formation in neutral solution of precipitates of basic chromate of nickel or cobalt. If a sufficient quantity of a solution of potassium chromate be added to a neutral solution of a cobalt salt, a red-brown precipitate of $CoCrO_4.CoO.Aq$. forms. If the concentration of cobalt exceed 2 grms. per litre, the precipitate appears in the cold within a few seconds. Even very dilute solutions yield a visible precipitate on boiling. The precipitate adheres firmly to the glass vessel.

Nickel gives rise to a chocolate-brown precipitate, but this appears very slowly in the cold, even in concentrated solution. On heating to boiling, however, $NiCrO_4.2NiO$ separates, and is distinguished from the corresponding cobalt compound, not only by its colour, but by the fact that it shows little tendency to form on the sides of the glass vessel. Quantities of cobalt or nickel so small as 0·03 mgrm. may be detected in this way.

When occurring together and both in quantity, cobalt may be detected by the appearance of the precipitate in the cold, and nickel by boiling the filtrate from the cobalt precipitate. Small quantities of nickel in presence of much cobalt may be detected as follows: The filtrate from the cobalt precipitate is boiled, and if the resulting precipitate contains enough cobalt to mask any small amount of nickel, it is dissolved in ammonia and the solution boiled to expel the ammonia. If cobalt only is present, the resulting precipitate will be a dirty green, but a very small amount of nickel will give rise to the characteristic chocolate-brown colour. Nickel can be thus detected in presence of 100 times its weight of cobalt. One part of cobalt in presence of 50 parts of nickel can be detected in the same way. Nickel holds up small quantities of cobalt in the cold, but on boiling both come down. On dissolving in ammonia and reprecipitating by evaporation, if the cobalt-nickel ratio equals or exceeds 1 : 50, the precipitate will have a distinct green tinge. G. C. J.

Separation of Tantalum and Columbium. H. W. Foote and R. W. Langley. (*Chem. News*, 1911, **103**, 103-104.)—The authors have experimented with the method of Weiss and Landecker (*Zeitsch. anorg. Chem.*, 1909, **64**, 65), which consists essentially in fusing the mixed oxides of tantalum and columbium with sodium carbonate, containing a little nitrate, and treating with hot water. A portion of the tantalum remains as insoluble sodium tantalate, and may be filtered off and treated separately. That remaining in solution is precipitated by a current of carbon dioxide, when the tantalum is stated to be completely removed, leaving columbium in solution. Foote and Langley's experience is in harmony with that of Rose and of Ostwald, that both elements are almost completely precipitated by carbon dioxide under the above conditions. Variations in the amounts of reagents used and of the concentration of the solutions yielded no better results. A. R. T.

Indirect Method for determining Columbium and Tantalum. H. W. Foote and R. W. Langley. (*Chem. News*, 1911, **103**, 52-55.)—Penfield and Ford (*Am. J. of Sci.*, 1906, **22**, 61) proposed to calculate the composition of any mixture of columbic and tantalic oxide from its sp. gr. and that of pure columbic and tantalic oxide, on the assumption that the sp. gr. of mixtures was a linear function of the composition. This assumption is shown to be erroneous by the authors, who have determined the sp. gr. of a number of mixtures of known composition; but these experimental results now make it possible to calculate the composition of mixtures of the two oxides. It is important that the oxides be prepared by a uniform process, as the manner of preparation is not without effect on the sp. gr. The mixed oxides as separated in the course of analysis are fused with 6 parts of acid potassium fluoride, the fusion is dissolved in 200 c.c. of hot water containing a little hydrogen fluoride, the solution made alkaline with ammonia, and the precipitate filtered off on a rubber funnel, and washed with ammoniacal water. The precipitate is redissolved in a platinum dish, using as little hydrogen fluoride and water as possible, and the solution evaporated to dryness. Sulphuric acid (10 c.c.) is added to the residue, and the liquid heated to expel hydrogen fluoride, after which 200 c.c. of water and excess of ammonia are added, and the precipitate filtered off and washed with dilute ammonia. Finally, the precipitate is ignited for an hour over a blast-lamp, ground to powder with water, and its sp. gr. determined as follows: The unweighed material and water is transferred to a beaker and boiled hard for thirty minutes by immersing in the beaker a coil through which an electric current passes. As much as possible of the solid material is transferred to a small pycnometer, which is filled with water and weighed after adjustment of the temperature. The solid material is then washed out of the bottle into a platinum dish, the wash-water boiled away, and the residue ignited and weighed. The following results are given:

Composition, Per Cent. Ta_2O_5.	Sp. Gr.	Composition, Per Cent. Ta_2O_5.	Sp. Gr.
0	4·552	65	6·737
5	4·650	70	7·083
10	4·746	75	7·441
20	4·929	80	7·654
30	5·200	85	7·961
40	5·474	90	8·098
50	5·850	95	8·243
60	6·434	100	8·716

Duplicate analyses of minerals calculated by interpolation from the above table do not differ by more than 0·2 per cent. When 1 grm. or more of mixed oxide is available, the results are within 1 per cent. of those yielded by Marignac's method, which is not only tedious, but probably less accurate than this indirect method.
G. C. J.

Pot Assay of Gold and Silver in Ores containing much Copper. **J. Loevy.** (*Chem. Zeit.*, 1911, **35**, 278.)—The necessity for repeated scorification when determining gold and silver in highly cupreous materials may be avoided as follows: If the ore contains less than 12 per cent. of copper, 50 grms. are mixed with 50 grms. of sand, and the mixture divided into two portions, each of which is subjected to ordinary pot assay in a G-size crucible with suitable proportions of sodium carbonate, litharge, borax, argol, and a salt cover. Sufficient argol should be taken to yield a button weighing 30 to 40 grms. from each assay. These two buttons are scorified down together until a button weighing 30 to 35 grms. is obtained. This button will be so far free from copper that it may be cupelled without further scorification. In the case of ores containing 24 per cent. of copper, a mixture of 50 grms. ore and 150 grms. sand is distributed among four G-size crucibles or two J-size crucibles. The resulting buttons are scorified down together until a button weighing 30 to 35 grms. is obtained, and this is then cupelled.
G. C. J.

Estimation of Bromine in Presence of Chlorides and Iodides. P. Clausmann. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 188-192.)—Distillation with a strongly acid solution of potassium bichromate serves well enough for the estimation of notable quantities of bromine, but for the estimation of traces in presence of much chloride it is unsatisfactory, as prolonged distillation is necessary to carry over all the bromine, and water must be added from time to time, as at high concentrations chromyl chloride passes over. It has been proposed to effect the oxidation in a closed vessel, and subsequently to extract the cooled mixture with carbon bisulphide, to wash the carbon bisulphide solution, and then to mix it with iodide of potassium and sodium bicarbonate, and to titrate the liberated iodine. In the author's hands this method gives low results, the error increasing with the amount of bromine to be estimated. Accurate results may be obtained as follows: The saline solution to be examined is concentrated to a few c.c. and placed in a 200 c.c. flask, of which the upper part of the neck has been drawn out to a narrow tube about 6 inches long. From 0·5 to 1 grm. of chromic acid and 2 to 4 c.c. of sulphuric acid are added, and enough water to bring the contents of the flask up to about 100 c.c. The narrow neck of the flask is given a right-angled bend and the end drawn out to a point, easily breakable, and sealed. The flask, with its contents, is then heated for an hour in a boiling brine bath. It is then cooled, and the neck fitted, by means of a rubber stopper, to a condenser. The other end of the condenser carries a bend which dips into an acidulated solution of potassium iodide. The point of the drawn-out neck of the flask is next broken by pressure against the condenser tube, and the contents of the flask heated by a flame. The whole of the bromine (and iodine if present) passes over with the first 50 c.c. of distillate, the concentration of acid in the flask remaining much too low to cause any danger of the formation of chromyl chloride. The liberated iodine is determined by means of thiosulphate and calculated to bromine, after deducting any iodine which a separate estimation may have shown to be present in the sample.

G. C. J.

Estimation of Small Quantities of Iodides in the Presence of other Compounds. R. Bernier and G. Péron. (*J. Pharm. Chim.*, 1911, **3**, 242-248.)—The following modification of the oxidation method of Longi and Bonavia (*Gazz. Chim. Ital.*, 1898, **28**, 325) is claimed to be as accurate as the gravimetric method, and to estimate with accuracy as little as 0·0002 grm. of iodine. A quantity of the solution of the iodide (containing from 0·01 to 0·03 grm. of combined iodine) is diluted to about 50 c.c., neutralised if acid, and then rendered faintly alkaline with sodium hydroxide solution. A few crystals of potassium permanganate, so as to give a slight excess, are now introduced, and the liquid boiled for a few minutes, after which the excess of permanganate is reduced by the addition of about 5 c.c. of alcohol, and the liquid cooled, made up to 110 c.c., and filtered. One hundred c.c. of the filtrate are collected, and acidified with 10 c.c. of acetic acid, 5 c.c. of a 10 per cent. solution of potassium iodide added, and the liberated iodine titrated with $\frac{N}{10}$ thiosulphate solution. The number of c.c. used, plus one-tenth thereof, multiplied by 0·0127 and divided by 6, gives the weight of iodine in the quantity of solution taken. In the case of traces of iodine (below 0·002 to 0·004 grm.) a $\frac{N}{100}$ solution of thiosulphate is used for the titration. The method gives accurate results in the presence of chlorides, bromides, and fluorides, and also of chlorates and bromates, after previous reduction by means of sodium bisulphite. It can also be used in the presence of substances that readily react with iodine (sulphides, sulphites, thiosulphates, etc., arsenites and antimonites). In the case of cyanides the liquid must be boiled with acetic acid to eliminate the hydrocyanic acid. Ammonium salts must also be decomposed by boiling the liquid with alkali before estimating the iodide.

C. A. M.

Separation of Lime from Large Quantities of Magnesia. E. Murrmann. (*Monatsh.*, 1911, **32**, 105-115.)—When the magnesia-lime ration exceeds 50 : 1, the only satisfactory method is that previously described by the author (ANALYST, 1910, **35**, 455). When the magnesia-lime ratio is less than this, the following simple method gives good results: To the neutral solution, which may contain as much as 0·4 grm. magnesia per 100 c.c., 3 c.c. of strong ammonium chloride solution and 3 drops of hydrochloric acid are added, and the mixture heated to boiling. Concentrated oxalic acid solution and 3 or 4 c.c. of quinoline are then added, and after ten minutes the precipitated calcium oxalate may be filtered off. If it is required to estimate magnesium in the same portion of the original solution, quinoline cannot be used, but pyridine may be substituted for the quinoline, and subsequently expelled from the filtrate. When using pyridine, the reaction of the solution needs to be more exactly adjusted by means of methyl orange. The pyridine should be added as a 2 per cent. solution, drop by drop, and the addition must cease before the red colour of the methyl orange gives place to yellow. When using pyridine, the results are slightly improved by cold precipitation and fifteen hours' standing before filtration. The magnesia in the filtrate can be estimated, as usual, after one or two evaporations with ammonia to expel the pyridine. Large quantities of salts of the fixed alkalis lead to lime being overestimated by either of these methods. For example, 3 grms. of alkali chloride or sulphate per 100 c.c. may lead to 0·05 grm. lime being over-estimated by 6 or 7 per cent.; but even in such cases solution of the precipitate in acid and reprecipitation by ammonia and ammonium oxalate will give exact results.

G. C. J.

Differentiation of Minerals by Means of Colour Reactions. P. Gaubert. (*Bull. Soc. Franç. Minéral*, 1910, **33**, 324-326; through *Chem. Zentralbl.*, 1911, **1**, 684-685.)—On adding to the finely-powdered mineral a solution of morphine, naphthol, or other substances in sulphuric acid, a reaction, the appearance of which is sometimes accelerated by the addition of water, is obtained after some time. In addition to the compounds employed by Levy (*Comptes rend.*, 1886, **103**, 1074, 1195) for the identification of metallic acids, a sulphuric acid solution of papaverine may be employed. This gives a red coloration, changing to blue in the case of vanadic, tungstic, chromic, and titanic acids, and to brown with stannic acid. In this way it is possible to distinguish, by means of the colour, between cassiterite and rutile, and, by the speed of coloration, between wulfenite (very rapid) and vanadinite and crocoite (fairly slow). Rutile, brookite, anatase, ilmenite, titanite, and perowskite give, in the finely-powdered condition, a carmine red coloration with morphine. If the test is made with equal quantities of the substance, sulphuric acid and morphine, different periods of time will elapse before the powder assumes a red colour. Thus amorphous titanic acid reacts very rapidly, whilst rutile is coloured less readily than brookite, which in turn offers greater resistance than anatase, although it is not easy to distinguish between the two latter minerals. On the addition of a suitable proportion of water a rose coloration is immediately obtained with all three minerals. Whilst keilhanite shows the reaction within two hours, the colour does not appear with titanite until after twenty-four hours. In the case of perowskite the coloration is produced in two to three hours, or immediately after the addition of water. Minerals containing rare earths will show the reaction after an hour, and without any preliminary treatment with a solvent. Wolframite is less readily acted upon than the other minerals mentioned. The colour reaction with cassiterite is readily produced, and affords a means of distinguishing that mineral from zirconium compounds. C. A. M.

Analysis of Molybdenum Glance. W. Trautmann. (*Zeitsch. angew. Chem.*, 1911, **24**, 207.)—Molybdenum glance of Norwegian origin is now appearing on the market containing 5 to 14 per cent. of magnesia (usually about 6 per cent.), 1 to 5 per cent. of copper as copper pyrites, and 0·3 to 4·0 per cent. of zinc as blende. When attempt is made to estimate the molybdenum in such ores by Gilbert's method (*cf.* Lunge's *Technical Methods*), nearly all the zinc, copper, and magnesium get weighed as MoO_3. The author's method (*Chem. Zeit.*, 1909, **33**, 1106; ANALYST, 1910, **35**, 547) is unaffected by the presence of copper and magnesium, but zinc interferes. In presence of zinc, the molybdenum solution must be boiled with ammonium polysulphide, the zinc sulphide filtered off, and the molybdenum in the filtrate precipitated by addition of acid. The MoO_3 finally obtained must, after weighing, be purified as follows, as it may contain nearly 1 per cent. of impurities: It is fused with potassium bisulphate, the melt dissolved in hot ammonium carbonate solution, and any alumina and silica filtered off and washed with an ammoniacal solution of ammonium nitrate, dried, ignited, and weighed, and its weight deducted from that of the impure WO_3 previously weighed (*cf.* ANALYST, 1909, **34**, 540).

G. C. J.

Estimation of Nitrogen in Nitrates, Gun-Cotton, etc. M. Marqueyrol and D. Florentin. (*Bull. Soc. Chim.*, 1911 [iv.], 9, 231-240.)—Having found differences between the results yielded by Schloesing's and Lunge's methods for the estimation of nitrogen in nitrates, etc., the authors carried out an investigation with the object of discovering the source of the errors. In the case of Schloesing's method (decomposition of the nitrate by boiling with ferrous sulphate and hydrochloric acid, and measuring the nitric oxide formed) it was found that the carbon dioxide, employed for filling the apparatus before the mixture in the flask is boiled, is never quite pure, and always leaves a small residue of gas which is not absorbed by potassium hydroxide; secondly, the hydrochloric acid used evolves a trace of dissolved air when heated; and, thirdly, the nitric oxide reacts with the potassium hydroxide with the formation of potassium nitrite, nitrous oxide, and nitrogen. The first two errors increase the result obtained by the method, whilst the third decreases it, and, in practice, the errors compensate each other if the total time taken for the operation does not exceed twenty-five minutes, and the nitric oxide collected over the potassium hydroxide solution is not shaken with the latter for more than five minutes. The agitation of the gas must, however, be thorough, or another cause of error may be introduced—namely, incomplete absorption of the carbon dioxide. Lunge's nitrometer method gave accurate results, provided that the strength of the sulphuric acid employed was not more than 94 per cent. When a more concentrated acid is used, a portion of the nitric acid is decomposed, and the results obtained are too low.

W. P. S.

Study of the Phenolsulphonic Acid Method for the Estimation of Nitrates in Water. III. Chief Sources of Error. E. M. Chamot, D. S. Pratt, and H. W. Redfield. (*J. Amer. Chem. Soc.*, 1911, **33**, 366-381.)—Continuation of the work of Chamot and Pratt (Analyst, 1909, **34**, 456; 1910, **35**, 321). The authors refer to most of the recent criticisms of the method, notably to those of Farcy (Analyst, 1910, **35**, 81) and of Perrier and Farcy (Analyst, 1909, **34**, 174), and describe experiments made with the object of determining all the sources of error, and so paving the way to a method which shall, as far as possible, avoid all of these (*cf.* next abstract). The principal conclusions reached are as follows: Sulphonic acid reagents containing mono-acids are subject to change with age, and yield results greatly affected by temperature, concentration, variation in character of alkali, etc. They cannot be satisfactorily employed with permanent standards. In order that accurate results may be obtained, chlorides, carbonates, and organic matter must be removed. Nitrites present in small amount (less than 1 part per million) do not appreciably affect the results, but when exceptionally high must be destroyed or corrected for. A sulphonic acid of definite composition should be used (*cf.* next abstract).

G. C. J.

Study of the Phenolsulphonic Acid Method for the Estimation of Nitrates in Water. IV. A Modified Method. E. M. Chamot, D. S. Pratt, and H. W. Redfield. (*J. Amer. Chem. Soc.*, 1911, **33**, 381-384.)—The reagent is prepared by dissolving 25 grms. phenol in 150 c.c. sulphuric acid, adding 75 c.c. of fuming sulphuric acid (13 per cent. SO_3) and heating for two hours at about 100° C. The reagent thus prepared contains no mono-acids and no tri-acids, and may be heated with water residues for hours without any development of interfering colours. It is also far less sensitive to the interfering action of substances causing errors than any of the reagents hitherto described, which all contain notable amounts of mono-sulphonic acid. Before proceeding to estimate the nitrates in a water, its alkalinity and chlorine and nitrite content are determined. If nitrites are present in amount exceeding 1 part per million, they are oxidised to nitrate by means of hydrogen peroxide and a correction applied to the amount of nitrate found. Smaller amounts of nitrite may be neglected. To 100 c.c. of the sample (or less, if the nitrate nitrogen is believed to exceed 10 parts per million) sufficient dilute standard sulphuric acid is

added to almost, but not quite, neutralise the alkalinity, and then a standard solution of silver sulphate almost, but not quite, sufficient to combine with all the chlorine. The mixture is boiled and, after addition of alumina cream, is filtered and the precipitate washed with hot water. The filtrates and washings are evaporated to dryness, 2 c.c. of the disulphonic acid reagent added, and the mixture rubbed with a rod to ensure intimate contact. If much iron or magnesia be present, the residue will appear compact and vitreous, and in such cases warming on the water-bath is advisable. After diluting with water, caustic potash solution is added slowly until the maximum colour is developed. Not much more than 1 grm. of potash is usually necessary, and, provided enough is added, the use of a large excess (*e.g.*, 5 grms.) is without influence on the results. The colour comparison is made with a standard solution of tripotassium nitrophenol disulphonate. This is made as follows: To the phenoldisulphonic acid reagent, powdered potassium nitrate is added in very small quantities at a time, until 0·1076 grm. has been added for each c.c. of reagent taken, stirring after each addition. The product is diluted and treated with dry barium carbonate until a deep yellow colour results. The mixture is filtered and the precipitate washed well with boiling water, to extract the barium nitrophenoldisulphonate. Potassium carbonate is added to the filtrate and washings until these are alkaline, when the solution is filtered and concentrated to recrystallisation. The product is purified by recrystallisation, but no attempt is made to obtain an absolutely pure product, as this involves drying in a current of carbon dioxide. A solution of the crystals is made up and standardised against a known weight of pure potassium nitrate treated with the reagent in the usual manner. The standard solution remains unaltered when exposed for many months to diffused daylight in clear glass bottles.
G. C. J.

Estimation of Dissolved Oxygen. L. W. Winkler. (*Zeitsch. angew. Chem.*, 1911, 24, 341-343.)—The method depends on the colour produced when chloro-quinol (adurol) is dissolved in water containing dissolved oxygen, and a trace of ammonia added. As ammonia may give rise to a precipitate with a magnesian water, an ammoniacal solution of ammonium bromide is used, the bromide being preferred to the chloride because of its greater solubility and the consequent density of a saturated solution, which sinks to the bottom of the water to be tested. A 50 c.c. stoppered flask is filled almost full with the water to be tested, and another similar flask with some of the same water, which has been shaken with air until saturated with atmospheric oxygen. To each flask a pinch of chloro-quinol is added, and then 0·5 c.c. of a saturated solution of ammonium bromide containing 10 per cent. of ammonia. The flasks are stoppered and shaken, and the colour of their contents compared after ten minutes. The aerated water becomes brownish yellow at once, the precise colour at first being to some extent dependent on the temperature, but at the end of ten minutes it assumes a red-brown tint, the intensity of which is independent of the temperature. The water under examination is shown to be free from or saturated with dissolved oxygen if it remain colourless or develop colour equal to that of the aerated water. If it develop some colour, but less than the aerated sample, its content of oxygen may be approximately estimated by direct comparison, or more accurately by comparison with a salt solution of known strength, which is saturated with air and then tested as described. The solubility of atmospheric oxygen in normal, thrice normal, and saturated sodium chloride solution at various temperatures is well known, and such solutions serve as standards. G. C. J.

Titrimetric Estimation of Phosphorus in Small Amounts. L. T. Bowser. (*Amer. Chem. J.*, 1911, 45, 230-237.)—A number of methods for the estimation of small quantities of phosphorus have been proposed, the objection to most of them being that any silica which may be present reacts as phosphorus. The best method is that of Veitch, which the author has now developed and modified. The phosphoric acid solution may contain 0·1 – 0·01 mgrm. of P_2O_5 per c.c. A sufficient quantity of this solution is evaporated to a convenient bulk and treated with 0·5 grm. of ammonium nitrate. When the solution is ready for precipitation, it is important that its volume should be not less than 20 c.c., otherwise the precipitate may contain free molybdic acid. The molybdate reagent is next added, employing 1 c.c. of the reagent when less than 0·8 mgrm. of phosphoric anhydride is present, and 1·5 c.c. when a larger quantity has to be dealt with. Precipitation is effected at a temperature of 55° C., which must be maintained for an hour, and the precipitate is then allowed to stand for two hours. It is then filtered off on a small asbestos pad, about $\frac{1}{16}$ inch thick, and washed with the usual wash-solution of potassium nitrate The precipitate is titrated with a standard solution of potassium hydroxide not stronger than 0·02 *N*. The presence of notable proportions of silica in the phosphate solution has no influence on the results, but when very large quantities are present filtration becomes difficult. It is necessary, however, to correct the results by numbers obtained by conducting a blank experiment with the asbestos used. With quantities of phosphoric anhydride ranging from 0·5 to 1·0 mgrm., the average error does not exceed 3 per cent. J. F. B.

Testing Plaster of Paris. *Report of (German) Standards Committee.* (*Chem. Zeit.*, 1911, 35, 222-223.)—Proposals for uniform testing of plaster put forward by the Committee, acting in association with representatives from Switzerland, Hungary, and Russia. *Sifting.*—Four to five kilos of the sample are to be put through a sieve 60 × 35 × 12 cm., of 2 mm. mesh, 16 meshes per square centimetre. Soft lumps fall to pieces under this treatment and pass through, but coarse impurities remain behind. The sifted material only is to be used for the subsequent tests. *Gauge.*—A glass beaker, 6 cm. high by 7 cm. diameter, is tared, and charged with 100 grms. of water at 15° to 20° C. Plaster is then added by hand until it no longer sinks—that is, until the water-mirror disappears, and a thin, dry layer of gypsum remains visible for three to five seconds. The addition of plaster should be so conducted that this point is reached in from one and a half to two minutes. The beaker is again weighed, and the amount of plaster used is the measure of the gauge. *Slip.*—A quantity of plaster, equal to that used in the last experiment, is added during about thirty seconds to 100 c.c. of water, contained in a basin made by cutting a 12 cm. rubber ball in two. The mixture is well stirred, and then turned out on a glass plate, and given roughly the form of a cake, 10 to 12 cm. in diameter and

5 to 7 mm. thick. At intervals of half a minute a knife, with blade 2 mm. thick, is passed through the cake, cleaning it after each cut. When the walls of the channel thus carved cease to run together, the time (Giesszeit) which has elapsed since the first addition of plaster is noted. *Time of Setting.*—When the cake from the previous experiment shows, by its behaviour under pressure of a finger, that it is nearly set, slices 2 mm. thick are cut from it by means of a sharp knife at one-minute intervals. When the cut surface appears granular and crumbling, the time (Streichzeit) since first addition of plaster to water is noted. *Fineness.*—One hundred grms. are put through a 60×35 cm. sieve of thirty meshes per lineal cm., and 0·22 mm. actual mesh. Fine plaster leaves less than 10 per cent. of residue; medium, 10 to 12 per cent.; and coarse plaster, 20 to 30 per cent. *Tensile Strength.*—Four times as much plaster as was used in the earlier experiments is added to 400 c.c. of water at 15° to 20° C., and the resulting slip used to cast six figure-of-eight blocks, the cross-sectional area of which in the plane where they will be broken is 5 sq. cm. With quick-setting plasters it may be more convenient to mix half the quantities stated, and cast only three blocks at one time. After half an hour the blocks are removed from the moulds, and preserved in a dry room at 15° to 20° C. Blocks should be tested after one and twenty-eight days. *Bending Strength.*—This is also determined by a modification of the Michaelis apparatus, used for determination of tensile strength. Prisms $16 \times 4 \times 4$ cm. are used for the test. G. C. J.

Uniform Methods of Analysis for Portland Cement. F. Framm. (*Chem. Zeit.*, 1911, **35**, 257.)—A report presented to the general meeting of the Association of German Portland Cement Makers, as a result of experiments carried out in the Association's laboratory. The report includes directions as to sampling and the preservation of samples, as to the concentration of the necessary acids and other reagents used in the analysis, and as to the preparation and standardisation of solutions of permanganate, etc. After defining the means to be taken in the preparation of the small sample to be used for analysis, the report proceeds to give detailed directions for the estimation of loss on ignition, silica and insoluble matter, alumina and ferric oxide, lime, and magnesia. Methods follow for the separate estimation of matters remaining insoluble after successive treatment with dilute hydrochloric acid and 5 per cent. sodium carbonate, of sulphate, of iron, of sulphide sulphur, and of alkalis. Before these methods are promulgated by the Association as official, opportunity is to be given for testing and criticism.

G. C. J.

Separation of Strontium from Calcium. L. Moser and L. Machiedo. (*Chem. Zeit.*, 1911, **35**, 337-338.)—The authors have examined Rawson's method (*J. Soc. Chem. Ind.*, 1897, **16**, 113), which depends on the fact that strontium nitrate is but sparingly soluble in concentrated nitric acid. The solubility is, however, now shown to be as high as 20 mgrm. per 100 c.c. of nitric acid of 1·45 sp. gr., the most favourable concentration. Under the most favourable circumstances, therefore, 3 to 4 per cent. of the strontium will pass into the filtrate; and when the apparent error in actual separations falls below 2 per cent., as it may do, this is due to a partial compensation of errors; for, though pure calcium nitrate is readily soluble in nitric acid, in admixture with strontium nitrate the last traces of calcium nitrate stubbornly resist solution. Examination of other methods show that the ether-alcohol method of separation alone of existing methods has any claim to exactness. G. C. J.

Volumetric Estimation of Uranium. F. Ibbotson and S. G. Clark. (*Chem. News*, 1911, **103**, 146-147.)—The authors have used a simple form of the Jones "reductor" for the reduction of uranium solutions, after which they may be titrated with permanganate. The reductor consists of a 15 cm. column of 120 grms. of 20 to 30 mesh amalgamated zinc. With cold solutions, the authors found that five minutes' passage through this reductor was more than sufficient to insure conversion to the uranous condition, the solution being brownish-green instead of clear green, denoting a further stage. The reduction, however, could not be carried to the extent that only $U_2(SO_4)_3$ was present. If the brownish-green liquids, however, be treated by aspirating air through them for a few minutes, the pure green colour is obtained, and titration with permanganate gives correct results. Thus uranous solutions are stable in presence of air. The following method was therefore adopted, requiring only about fifteen minutes to carry out. The uranyl solution, containing from 2 to 5 per cent. by volume of free sulphuric acid, is heated in a flask with 50 grms. of pure, finely divided amalgamated zinc (20 to 30 mesh), till a dark brown colour is developed. The contents of the flask are rapidly cooled, and the cold solution poured through a small pulp filter, which is washed with cold water. Air is aspirated for a minute through the solution, and this is then titrated with $\frac{N}{20}$ permanganate. The zinc may be used a dozen times before reamalgamation is required. Since uranyl solutions are not reduced by sulphurous acid, a mixture of ferric sulphate and uranyl sulphate can be assayed by first reducing the iron with sulphurous acid, titrating with permanganate, and then treating the titrated solution as described.

A. R. T.

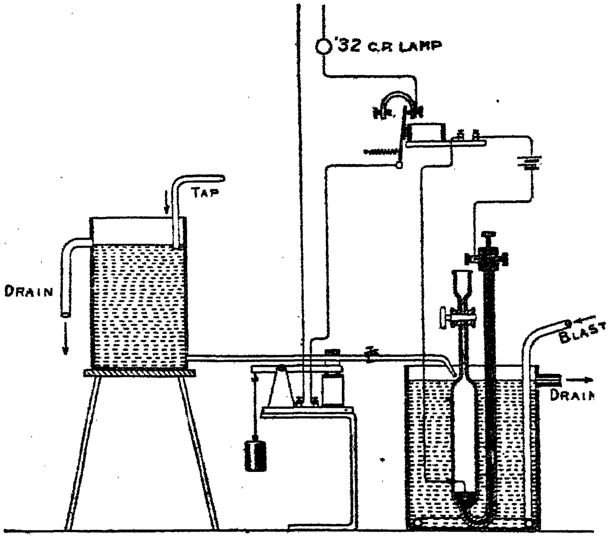
Estimation of Potassium Perchlorate in Potassium Chlorate. K. Scheringa. (*Pharm. Weekbl.*, 1911, **48**, 15-18.)—Sulphur dioxide reduces potassium chlorate to potassium chloride, but does not attack potassium perchlorate.

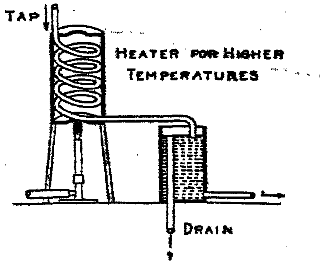
Use of Sulphur Dioxide in Checking Strengths of Volumetric Solutions of Iodine, Alkali, and Silver. E. Elvove. (*Amer. J. Pharm.*, 1911, **83**, 19-23.)—Pure silver is used as the standard, and solutions are prepared in the following order, each serving as a standard for the succeeding one: Ammonium thiocyanate (standardised against pure silver), silver nitrate, hydrochloric acid, sodium hydroxide, oxalic acid, potassium permanganate, sodium thiosulphate, and iodine. The strength of the iodine solution may be checked by reduction with sulphur dioxide and titration of the iodide after neutralisation.

Gravimetric Estimation of Tellurium and Alkalimetric Estimation of Telluric Acid. A. Rosenheim and W. Weinheber. (*Zeitsch. anorg. Chem.*, 1911, **69**, 266-269.)

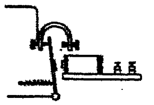
APPARATUS, ETC.

Constant-Temperature Bath for Use at Temperatures both Above and Below that of the Room. J. L. R. Morgan. (*J. Amer. Chem. Soc.*, 1911, **33**, 344-349.)—The bath is the vessel containing the large thermo-regulator, and the principle of the method is to deliver cold or hot water to the bath according as the desired temperature is below or above that of the room. The illustration shows the bath arranged for use at a temperature slightly below that of the room. The bulb of the regulator is 15 cm. by 3 cm., and the lower part of the other limb of the U is capillary (6 mm. external, 0·75 internal diameter). This capillary portion is only





HEATER FOR HIGHER TEMPERATURES



RELAY FOR HIGHER TEMPERATURES

6 mm. long, and the bore of the rest of the limb is 4 mm. Enough mercury is added to the regulator to reach half-way up the capillary, and the bulb is then filled with toluene as usual, the cock being left open. A platinum wire is fused through the glass of the regulator near the bottom, and a threaded brass collar is attached to the wider continuation of the capillary tube. Through this collar passes a threaded brass rod (2 mm. diameter), to the lower end of which is soldered a piece of platinum wire, 0·5 mm. in diameter, which makes contact with the mercury. These terminals of the regulator are shown, put in series with a dry cell and a relay. This relay is so

arranged that the house circuit, in series with a 16 c.p. lamp, can be either made or broken in a large telegraph sounder connected to the other two terminals of the relay. This sounder has attached to it a brass bar, about 5 mm. above the lowest position of the arm, when it is attracted by the magnet. The other end of the sounder arm has attached to it by a wire a weight of several pounds, so that when no current is passing through the sounder, the arm presses tightly against the brass bar. The thin rubber tubing of 4 mm. bore connecting the constant level supply of cooling water with the bath is run between the sounder arm and the bar above it. Cold water is allowed to flow from the constant level supply to the bath until the requisite temperature is attained. The cock above the toluene limb of the regulator is then closed, and the threaded brass rod screwed out until the platinum point no longer makes contact with the mercury. The weight falls, the tubing is pinched, and the water supply is cut off, and remains cut off until the temperature rises sufficiently to complete the circuit once more. For temperatures above 50° C., it is most convenient to surround the bath by a water-bath several degrees above 50° C., and to regulate by using tap-water as cooking-water, as already described. For temperatures between room temperature and 50° C. regulation is best effected by supplying a regulated supply of heated water; and for temperatures below 10° C. it is found most convenient to surround the bath with an ice pail and supply it with a regulated supply of tap water to warm it to the required temperature. In these last two cases the relay needs to be so arranged that the supply of warm water is cut off when the temperature exceeds that required—that is to say, the passage of a current through the relay must break, not make, the sounder circuit. The principle is applicable to comparatively small baths, which may be kept within a few hundredths of a degree of any temperature between 1° and 90° C. Stirring is most easily effected by blowing air, by means of a water-pump, through a coil of tin pipe bored with four small holes. G. C. J.

Still Water Gas Calorimeter. J. H. Coste and B. R. James. (*J. Soc. Chem. Ind.*, 1911, **30**, 258-261.)—Fig. 1 shows the gas-holder, Fig. 2 the calorimeter. The gas-bottle A contains $\frac{1}{10}$ cu. ft. from the point of the metal-rod G, to the bottom of C. The bottle being nearly full of gas, the burner (attached to E) is lighted; and when the level of the water approaches G, the short length of rubber tubing by M is pinched, so that water can only pass by the small by-pass. This makes it possible to determine with sufficient accuracy when the water-level reaches G. The burner is then swung under the calorimeter, and the pressure on the rubber tubing released. The calorimeter proper, B, is of copper, nickel-plated, and polished externally and supported on wooden blocks within the surrounding annular vessel A, from which it is separated by a $\frac{1}{2}$-inch air space. The outer vessel and the calorimeter are filled with water at the same temperature. A central cylindrical chimney, C, of corrugated copper tubing rises from the bottom of the calorimeter and opens into a flat, oval copper box, DD, from the ends of which depend two very much flattened corrugated copper tubes, EE. Suitable deflectors separate the products from the air passing in to support combustion. A long, narrow water-channel, F, separates the side or exit chimneys from the central one, which is the combustion chamber. Strips of copper, GG, divide the ascending current of air and the ribs of copper, HH, promote a rapid transfer of heat from the place where the heated gases first strike the metal to the cooling water. The calorimeter holds 2·1 litres of water, the exact amount of which is fixed by the coincidence of its surface with the silvered point I, depending from the teak-bridge J, which rides on the edges of the vessel, and carries on one side the thermometer and on the other the bearing for the stirrer. KK represents a double horseshoe stirrer, so designed as to divide the water into many small currents. Gas is delivered to the burner M at a uniform rate (about $\frac{3}{4}$ cubic foot per hour for ordinary illuminating gas) and a thermometer divided on an open scale to $\frac{1}{10}$° C. is used to estimate temperatures to the nearest $\frac{1}{100}$° C.

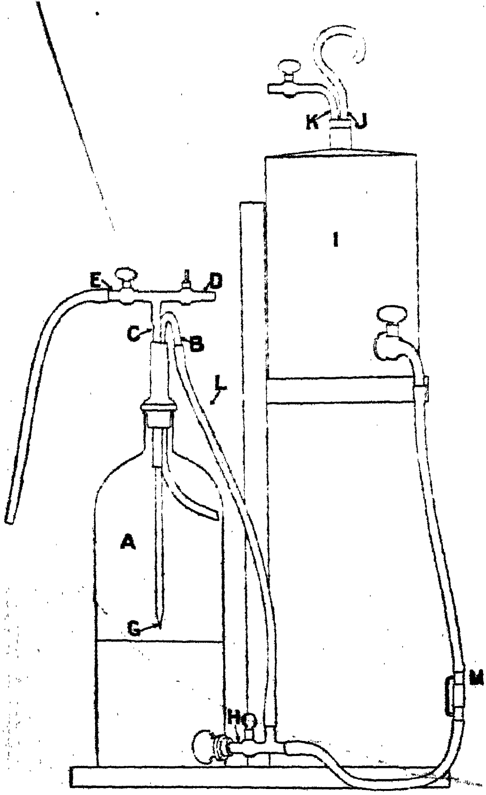


FIG. 1.

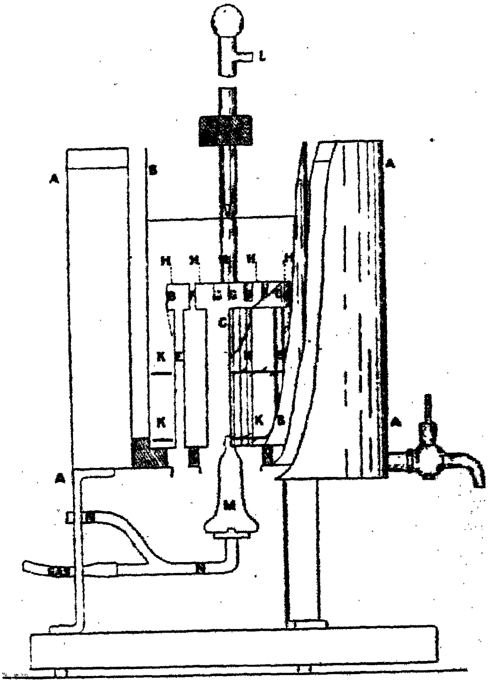

FIG. 2.

G. C. J.

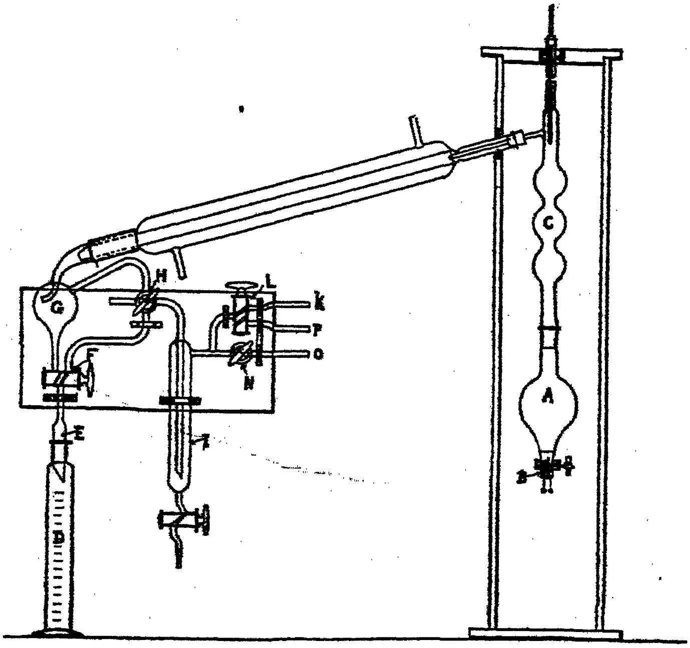
Capillary Analysis. J. Traube. (*Ber.*, 1911, **44**, 556-560.)—The investigation of capillarity constants is one of the simplest and most important of the physical methods applicable to analytical chemistry. The influence of various dissolved bodies on the surface tension of the solvent may frequently be employed for estimations—*e.g.*, of fusel oil, the concentration of alcohol, acetic acid, etc., also for purposes of diagnosing diseases. The measurement of surface tension by means of the capillarimeter and stalagmometer may be utilised with most satisfactory results for the determination of distribution and adsorption coefficients. Many colloidal media —*e.g.*, solutions of dyestuffs such as night blue, Nile blue, wool violet, also lecithin and soap emulsions, suffer a change in their surface tensions (size of droplets) when substances are added which can be described as "colloid poisons." These colloid poisons are identical with blood poisons, and include anions such as iodine, thiocyanate, perchlorate, etc., and cations, as mercury, lead, copper, and many other metals; bases such as alkaloids, snake poisons, acid bodies, phenol, arsenious acid, and many others. This method, using night blue and wool violet, has been employed for the technical estimation of nicotine. Minute quantities of iodine may thus be estimated in presence of large proportions of chlorine, bromine, and other ions—*e.g.*, in mineral waters. The iodine ion behaves quite differently to iodine in organic compounds, which fact is of value in physiological analysis. The method may be applied in the titration of poisonous ions in very dilute condition. If a solution of night blue be mixed with a few drops of mercuric chloride, the solution may be titrated with potassium iodide, and the capillarity constant (drop numbers) of the dyestuff solution will tend to be restored to the original value when the titration is complete. This principle is of very wide application. Alkaloids may be similarly titrated in a medium of wool violet, using tannic acid for the titration.

J. F. B.

Multiple Carbon Dioxide Recorder. (*Chem. Engineer*, 1911, **13**, 62-64.)—This recorder is designed to make continuous determinations of the carbon dioxide content in furnace gases, and in its several sizes will make separate and simultaneous records from one up to ten boilers. A continuous stream of gas is drawn through each section of the multiple machine by a single motor-driven suction fan, and a motor-driven rotary pump handles the paraffin oil in the successive operations which constitute a cycle for measuring off a sample of gas, the absorption of the carbon dioxide contained in it, the recording of this amount, and the expulsion of the sample. A single clock mechanism operates the whole series of drums, one to each boiler, which carry the record charts. The over-all dimensions of a four-record machine are 42″ × 13″ × 39″ high. The only adjustment necessary is setting the pen to zero when running on air. The caustic soda solution needs renewal once in ten days, when the machine is kept running night and day, each section making twenty records an hour. The paraffin oil is never changed, but a filter forms parts of its cycle. The pens are self-inking, and the ink-wells need refilling once a week. The apparatus is so designed that temperature errors are eliminated. The makers are the Sarco-Fuel Saving and Engineering Co., New York. G. C. J.

Extinguishing the Flame of Petroleum Spirit. F. Rathgen. (*Chem. Zeit.*, 1911, **35**, 308.)—The flame of 3 c.c. of petroleum spirit ignited in a basin may be extinguished by means of a simple device constructed upon the principle of the apparatus of the Fabrik Explosionssicherer Gefässe, Salzkotten. A solution of 15 c.c. of sodium carbonate in 200 c.c. of water, to which has been added 1 to 2 c.c. of liquorice extract, is introduced into a wide-mouthed half-litre flask, the cork of which is wired down. In the cork are two openings, through one of which passes a tube about 1 cm. in diameter, the inner portion of which extends a little way into the flask, whilst the other limb outside is bent downwards at an acute angle. Through the other hole passes a glass tube, also about 1 cm. in diameter, the end of which is a thin bulb. This tube is charged with about 15 to 20 c.c. of hydrochloric acid, and its other end is sealed up. On pushing this tube sharply downwards, the bulb will be shattered against the bottom of the bottle, and a stream of froth will issue from the other tube, and, when directed upon the burning petroleum spirit, will extinguish the flame. C. A. M.

Electrically-Heated Vacuum Fractionation Apparatus. H. S. Bailey. (*J. Amer. Chem. Soc.*, 1911, **33**, 447-450.)—The vessel A, in which the liquid is boiled, is of about 150 c.c. capacity, when 50 c.c. quantities are to be distilled, and its shape so chosen that distillation may be continued until only 5 c.c. remains, the line above the coil being a 5 c.c. mark. The heating coil B is of German silver wire, attached to stout platinum leads, which are fused through the glass. Connection between A and the fractionating head C is made by means of a ground joint. The connections K, O, and P connect to the house-pump, a Chapman and a Geryk pump respectively. The Geryk pump alone would suffice; but the use of the other pumps to exhaust most of the air at the start saves time, and, as a rule, oil-immersion pumps work better when they have only a small quantity of air to handle. The whole apparatus is exhausted, finally, by means of the Geryk through P. When it is wished to change the receiver D, cock F is reversed (it is shown



reversed in the figure), thus disconnecting G and D, and connecting E with the lower limb of the cock H. H is then given a half turn, which disconnects the distillation system from the pump, and puts E in connection with the atmosphere D is replaced by another receiver, cock H so turned that this receiver is connected to the pump, and when it is exhausted F is again reversed, and the contents of G allowed to flow into it. I is a trap to catch any liquid, which, in case of accident, might get sucked through the pump connections. G. C. J.

GOVERNMENT REPORTS.

I. On the Bleaching of Flour and the Addition of So-called "Improvers" to Flour; by J. M. Hamill. II. On the Chemical Changes produced in Flour by Bleaching; by G. W. Monier-Williams.

(Reports to the Local Government Board: Food Report No. 12, 1911, 1-65.)

The practice of bleaching flour originated in this country about ten years ago, and was rapidly adopted by millers in the United Kingdom, in America, and elsewhere. Many patents have been granted for bleaching processes and for the application of various chemicals to the bleaching of flour. Ozone, chlorine, oxides of chlorine, bromine, nitrogen peroxide, etc., have been suggested and tried as bleaching agents, but of these substances nitrogen peroxide is the only one which has given satisfactory results, and all commercial bleaching of flour at the present time depends on the use of this substance. The nitrogen peroxide is prepared either chemically or electrically; the electrical method produces a mixture of nitrogen peroxide and ozone, of which the former gas is the active bleaching agent, as it is now generally believed that ozone has no bleaching effect on flour. Inquiries made in connection with the preparation of this Report elicited the fact that bleaching in this country has not yet become universal, even amongst the larger firms; many millers have never bleached flour for sale, and others have abandoned the practice. The precise effect upon flour of bleaching by nitrogen peroxide is a matter of considerable dispute amongst millers and bakers, but the most obvious effect is the change of colour produced; other more subtle changes, such as alterations in the baking qualities of the flour, are also attributed to its use. It seems probable, however, that bleaching, when properly carried out, produces no appreciable effect on the baking qualities of flour, and there is no sufficient evidence that mere bleaching can counteract defects in flour due to unsoundness in the wheat from which it was milled. As regards the detection of bleach in flour, the chemical change most easily demonstrated in flour as a result of bleaching is the formation of nitrites, and the Griess-Ilosvay reaction (ANALYST, 1906, 31, 300) affords an exceedingly delicate test for detecting the presence of nitrites. As flour may absorb traces of nitrous acid from the atmosphere, the detection of mere traces of nitrite in a sample is not sufficient evidence that the flour has been bleached with nitrogen peroxide; only when the quantity of nitrite exceeds 1 part per million does the inference of bleaching amount to practical certainty.

From the results of experiments, it appears that bleaching has a distinctly inhibitory effect on the peptic digestion of flour, but no observable effect on the pancreatic digestion; it is also pointed out in the Report that nitrites have a distinct action on the heart and vascular system, and that, consequently, it is undesirable that small doses of nitrites should be consumed in bread day by day for years.

The practice of adding "improvers," such as acid calcium phosphate, phosphoric acid, sulphur dioxide, phosphorus pentachloride, etc., is considered to be most dangerous, as the addition may be indiscriminate; the miller is not always aware of the nature and character of the "improver," and other persons besides the miller may also add a quantity of an "improver," so that by the time the flour reaches the consumer it may have departed considerably from its original state of purity.

The action of air containing nitrogen peroxide upon flour, in quantities up to 300 c.c. of nitrogen peroxide per kilo of flour, may be summarised as follows:

1. The golden-yellow tint of the flour is destroyed. After being kept a few days, the more highly bleached samples became decidedly yellow, whilst those treated with from 30 to 100 c.c. of nitrogen peroxide per kilo became still whiter, the maximum bleaching effect being attained within these limits.

2. From 30 to 40 per cent. of the quantity of nitrogen peroxide used is absorbed by the flour. After the lapse of several days, the proportion of nitrites present decreases considerably in the higher concentrations, but remains fairly constant in the slightly bleached samples.

3. Approximately 60 per cent. of the total nitrogen introduced as nitrogen peroxide into the flour may be recovered as ammonia a short time after bleaching by reducing the aqueous extract of the flour with a copper-zinc couple.

4. In highly bleached flours a considerable increase in the amounts of soluble proteins and carbohydrates takes place. If 1 kilo of flour is bleached with 300 c.c. of nitrogen peroxide, the amount of soluble protein is doubled. This appears to be due to the solubility of gliadin in nitric acid.

5. If highly bleached flour is allowed to stand for some time after bleaching, the oil undergoes very considerable alteration, and acquires the characteristics of an oxidised oil. About 6 per cent. of the nitrogen introduced is absorbed by the oil.

6. The absorption of nitrogen peroxide by flour does not appear to be accompanied by the production of free nitrogen or diazo-compounds.

7. Sodium nitrite is not found to exert any inhibitory effect on the digestion of soluble starch by saliva, but the rate of digestion is considerably retarded if the starch has been treated previously with nitrogen peroxide. Bleaching also retards the salivary digestion of flour.

The opinion is expressed that it is undesirable that such an indispensable foodstuff as flour, the purity and wholesomeness of which are of first importance to the community, should be manipulated and treated with foreign substances, the utility of which, from the point of view of the consumer, is more than questionable.

W. P. S.

II. On the Presence of Calcium Sulphate in Baking-Powder and Self-Raising Flour. Dr. J. M. Hamill. (*Reports to the Local Government Board, Food Report* No. 13, 1911, 1-16).—The Report deals with the following points: 1. The nature and varieties of baking-powder. 2. The possible sources of calcium sulphate in baking-powders. 3. The strength and preparation of acid calcium phosphate. 4. Formulæ for compounding "phosphate" baking-powders. 5. Comparison of "phosphate" and tartaric baking-powders. 6. Self-raising flour. 7. Consideration of arguments in defence of the presence of calcium sulphate in acid calcium phosphate.

Samples of acid calcium phosphate were found to contain amounts varying from 1 to 56 per cent. of calcium sulphate, as an impurity, the latter quality being used to a considerable extent by makers of self-raising flour. Less commonly this low-grade phosphate is employed in baking-powders sold to the public. The consumer derives no benefit, and is liable to be prejudiced by the use of such material. The existence of an understanding as to the degree of impurity which would entail the rejection of such low-grade phosphates would serve alike the interests of the public and the majority of traders. Apart from any administrative action which may be recommended to public authorities on this matter, it is believed that the following recommendations would be welcomed by many traders:

(*a*) The lowest grade of acid phosphate made by manufacturers to be used as a food ingredient to carry a guarantee that it does not contain more than 10 per cent. of calcium sulphate. Phosphate preparations should not be sold under names suggesting that they contain tartaric acid or cream of tartar. (*b*) Bakers, self-raising-flour makers, and others using acid phosphates, should, if using the lower grades, in all cases stipulate that calcium sulphate is not to exceed 10 per cent. (*c*) Vendors of baking-powders containing acid phosphates should stipulate that the powders do not contain a higher proportion of calcium sulphate than would be contributed by a commercial acid phosphate containing 10 per cent. of calcium sulphate. They should not receive or sell such powders under descriptions which may lead the purchaser to believe that he is buying preparations of tartaric acid or cream of tartar.

Action by Local Authorities under Sale of Food and Drugs Acts.—It would seem desirable that local authorities under these Acts should invite reports from the public analyst as to proportions of calcium sulphate in a series of samples taken in the district of (*a*) baking-powders which appear to contain acid phosphate of lime; (*b*) acid phosphates supplied to confectioners, etc.; (*c*) self-raising flours. When necessary, the institution of proceedings under Section 6 of the Sale of Food and Drugs Act, 1875, should be considered. In an Addendum, C. H. Cribb reports on the alleged utility of calcium sulphate in "phosphate" baking-powders. He finds no justification for its presence. H. F. E. H.

REVIEWS.

Allen's Commercial Organic Analysis. Vol. II.: Fixed Oils, Fat, and Waxes. Edited by Henry Leffmann and W. A. Davis. Fourth edition. London: J. and A. Churchill. 1910. Pp. x + 520. Price 21s. net.

The scheme adopted in the preparation of this volume doubtless presents great advantages, and the writing of articles by those particularly versed in the subjects discussed makes for accuracy and efficiency; nevertheless, one misses the easy style of Allen and there is no longer the same adherence to a general plan, which can only be attained when the whole work is the product of one brain.

Differences of nomenclature occur, such as the use of the term "linolic acid" by Mitchell and Archbutt in their respective sections, and "linoleic acid" by Klein and Robertson; instances of repetition are to be found—for instance, both Mitchell (p. 38) and Gill (p. 512) describe Mackey's "cloth-oil tester"—and there are omissions, the most serious of which is the absence of methods for the examination of candles (apart from wax candles) and candle material. Probably the difficulties of dual editorship in two countries has led to this result, though there is evidence in the numerous cross references that the editors have endeavoured to carry out their onerous task.

Allen was unique; a great scientist, a thoroughly sound chemist, he was, first and foremost, a consulting analyst, holding appointments under the Sale of Food and Drugs Acts, and being engaged as adviser in many industries. He wrote from the point of view of the analyst, and his book was one to which an analyst could turn to find just the information and advice he wanted. The present volume is written by many contributors, some well known and others whose names are not so familiar; but while all have acquitted themselves well, none of them write quite from the same point of view as Allen.

The first portion is by C. A. Mitchell on general properties and analytical methods, and gives a general review of the examination of oils and fats; while it is quite correct to term the radicle $CH_2.CH.CH_2$ *glyceryl*, there is a serious objection to calling it *glycyl*, as this term is now used for the radicle of glycine or amino-acetic acid. The usual methods for the examination of oils and fats are described in quite sufficient detail. It is to be regretted that Hanus' method for iodine absorption estimation is not mentioned, seeing that Hanus' figures are frequently quoted in literature. One or two of the methods mentioned, such as electrical conductivity and heat of combustion, might have been omitted, as no useful information is given about these.

The section on special characters and modes of examining fats, oils, and waxes, by L. Archbutt, is excellent, and perhaps more nearly approaches Allen's style than any other portion of the book. The method of estimating paraffin in waxes by treating the unsaponifiable matter with acetic anhydride is not, however, described; neither in this nor the preceding section is any mention made of chaulmoogra oil nor the interesting series of acids containing closed rings described by Power and colleagues.

Cecil Revis and E. R. Bolton contribute an article on butter-fat. The subject is treated with some originality, a selection only of the numerous methods being given; but the selection appears judicious. The writers attach special importance to the method of Avé Lallemant. The phytosteryl acetate test, an excellent modification of which is given, might have been described in a little more detail, the directions being meagre for those not used to the method. This section is perhaps the best in the book; these writers might with advantage have been entrusted with much more.

C. A. Klein writes on linseed oil, and gives a large amount of technical information.

Higher fatty acids are treated of by W. Robertson. This section might well have been amplified by the inclusion of a notice of the solid acids prepared by various methods from olein, and by some description of the products used in the candle industry.

The section on soap is by Henry Leffmann. This is purely analytical, and probably the technical side has been purposely left alone. The article is well written, and space is economised by the numerous cross-references. It may be modesty on the part of the writer which has led him to omit the useful rapid method for the valuation of soap, by measuring the fatty acids separated from a 10 per cent. solution in a Leffmann-Beam bottle.

The other co-editor, W. A. Davis, contributes an article on glycerol. The subject is treated of in an efficient manner; but it might have been mentioned that Hehner's method is by far the simplest for the estimation of glycerol in oils and fats.

Cholesterol and phytosterol are treated of by J. A. Gardiner, but hardly in a manner which is of use to the analyst; it would have completed the study if some mention had been made of coprosterol. Some of the melting-points in this section are evidently misprints.

The volume is concluded by a section on wool-fat, suint, and dégras, by A. H. Gill, and the article on cholesterol might well have been combined with this. The writer has treated this difficult subject in a lucid manner.

H. DROOP RICHMOND.

THE CHEMISTRY AND TESTING OF CEMENT. By CECIL H. DESCH, D.Sc., Ph.D.
Pp. x+267. London: Edward Arnold. 1911. Price 10s. 6d. net.

In view of the progress which our knowledge of the chemistry of cement has made in recent years, the present volume by Dr. Desch is very welcome, presenting as it does quite a clear and readable account of a subject which, to the large majority at least, has hitherto been somewhat obscure. The work under review "explains the nature of the chemical compounds contained in cements, the reactions involved in their preparation from the raw materials, the changes which take place during setting and hardening, and the methods of controlling, both chemically and mechanically, the quality of the product." After a brief historical introduction and a short but sufficient discussion of raw materials and manufacturing processes, the author confines himself mainly to the most recent and best views of the constitution and properties of the various calcareous cements, ignoring, as we think rightly, the old-fashioned and crude theories. Methods of thermal analysis and microscopical examination are shown to have been mainly instrumental in developing our knowledge of the constitution of cements, while the setting and hardening processes are now recognised as occurring in a colloidal medium. The physical and mechanical properties of cement and cement products are ably discussed in the light of recent knowledge.

The analytical section is perhaps somewhat brief, but the methods given are, as a rule, straightforward and reliable, and described with sufficient fulness for any competent chemist to carry out. Here, as indeed throughout the work, the author has used admirable discretion, and, unlike many others, has withstood the temptation to include fancy alternative methods of doubtful utility. The Schrötter method of determining CO_2 is, however, hardly worthy of a place in such a book. In the determination of manganese in slag, it will be found advantageous to remove alumina by means of caustic soda before separating iron as basic acetate. Moreover, few chemists will agree with the author in his preference for the sulphuric acid method of attacking insoluble silicates over the ordinary, but satisfactory, fusion method.

A description of the sliding weight machine for determining tensile strength would have been preferable to the older shot machine, as being more representative of modern practice. A misleading statement occurs on p. 143, where coarsely ground cement is said to weigh *less* (instead of *more*) than an equal volume of finely ground cement. The statement is contradicted both by the figures given by way of illustration and by a statement on p. 145. The formula for hydraulic calcium ferrite given on p. 72 as $3CaO.Fe_2O_3$ is apparently a misprint for $3CaO.2Fe_2O_3$.

Numerous references to recent investigations are given, and a discussion of the Revised British Standard Specification is appended. The book on the whole is excellent, is well published, and should be read with profit by everyone interested in the subject of cement.

GILBERT J. ALDERTON.

QUALITATIVE CHEMICAL ANALYSIS FROM THE STANDPOINT OF SOLUBILITIES, IONISATION, AND MASS ACTION. By J. I. D. HINDS, Ph.D., LL.D., Professor of Chemistry, University of Nashville and Peabody College for Teachers, Nashville, Tennessee. Pp. vii + 265. London: Williams and Norgate. 1911. Price $2.

A brief account of the physical chemistry necessary for the proper understanding of qualitative chemical analysis is given in the first four chapters of the book. Then follow the usual separation tables and tests for elements, acids, and bases. In the majority of cases the equations given to represent chemical changes are written in the ionic form, and this departure from the usual practice is certainly a good one, as it enables the student to realise what element or radicle of a reagent is concerned in the test for which that reagent is applied. Another good feature of this book is that the solubilities of many precipitates are given, and also the degree of ionisation of many acids in normal and decinormal solutions.

The phraseology is at times somewhat ambiguous, and shows a want of care in the preparation of the book which detracts from its value. Thus, on p. 39 we find the following: "Osmotic pressure may be regarded as the measure of the tendency of a solid to go into solution, and may be called *solution pressure*. The solution is saturated when the solution pressure and the osmotic pressure are equal." Again, on p. 183 we have the statement that "Phosphorus forms two regular oxids." Why regular?

Errors and omissions are rather numerous, and amongst the former we note on p. 215 the statement that calcium tartrate is insoluble in acetic acid, and on p. 211 that lead, aluminium, iron, and copper, form sparingly soluble acetates. With regard to the omissions, we find no mention of Denigès' test for citric acid, or of the resorcinol test for tartaric acid.

H. R. LE SUEUR.

BACTERIOLOGICAL AND ENZYME CHEMISTRY. By GILBERT J. FOWLER, D.Sc., F.I.C., Lecturer in Bacteriological Chemistry, Public Health Department, Victoria University of Manchester. First edition. Price 7s. 6d. net. Published by Edward Arnold.

This book, as is clearly stated in the preface, is an attempt to give a general outline of the chemical aspects of bacteriological and enzyme action. Such an attempt is undoubtedly beset with difficulties, as the various subjects are themselves of considerable extent, and it is only quite recently that our knowledge has become sufficiently exact to make such an attempt. The author has certainly succeeded in collecting together the greater part of our reliable knowledge on these subjects, which is scattered through much scientific literature, and the information is on the whole remarkably accurate and trustworthy; and it may be only an attempt to make the subject readable that is the cause of some lapses from strict scientific accuracy. This is particularly noticeable in the section dealing with the chemistry of the cell, where, for instance, osmotic pressure is said to be proportional in dilute solutions to the number of *molecules* present in the given volume; and exception might be taken on certain grounds to the definition of fermentation given at the end of the section. The chapters on purely chemical subjects are well and clearly written; and if, perhaps, a little unnecessarily full for the purpose of the book, they give all the information necessary to understand the subject of enzyme action, though a concise statement of the law of mass action as bearing on catalysis in general, and the reasons for the departure of enzyme action from this law, and also as foreshadowing reversibility, would seem to be a useful addition. It is a little unfortunate that, in the section on the action of amylase on starch, general reactions of proteins are set down as general reactions for enzymes, as the impression is given that the two are quite similar—a statement which, although quite intelligible to the expert mind, might give a wrong impression to the student. There is rather a tendency in the latter chapters to compression, and as these chapters are the most important from a student's point of view, the freedom of treatment noticeable in the earlier chapters would have been welcome. For instance, in the section dealing with the nitrogen cycle, though all the reliable data are given, there is lacking that correlation of the various bacterial agencies which modern research justifies, and which makes this subject so interesting. The same is true of the chapter on sewage purification, which, excellent in itself, lacks that dogmatic treatment which one expects from such an author, and which helps the student from being overwhelmed with conflicting views. Though in such a work the author must be free to choose his subjects, it is a little surprising to see the enormous amount of work done on nitrogen fixation in soils by bacteria, apart from "nodule" fixation, completely ignored, especially when "cyanamide" is referred to. The only really weak section is that on bacteriological technique; and it would have been better to have referred the reader to works on this subject or to have amplified the section considerably. The work is singularly free from spelling mistakes, though some, such as "absorption" for "adsorption" on p. 1, are a little unfortunate. The constitutional formulæ in the chapter on the chemistry of the albumins would be clearer if the various groups were separated in the usual manner. Concise and exact methods for testing for various enzymes, etc., placed at the ends of the various chapters, instead of the rather vague details scattered through the text, would probably render the work of greater use to the analytical chemist.

C. REVIS.

MODERN METHODS OF WATER PURIFICATION. By JOHN DON, F.I.C., A.M.I.Mech.E., and JOHN CHISHOLM, A.M.I.Mech.E. London: Edward Arnold. Pp. 368. Ninety-six illustrations. Price 15s. net.

The above volume may be confidently recommended to the attention of engineers and chemists interested in the question of water-supply, as a careful perusal shows it to be based on practical experience and a very thorough general study of the question.

Its value to the chemist will be found chiefly in the comprehensive outlook it affords on the practical side of the problem, and in the excellent summaries which are given of the present position of sundry important questions.

The subject of sand-filtration is treated with great care—in fact, it is possible that a discussion of the function of the filtering skin is somewhat over-elaborated; it, however, brings into relief the importance of the work of Director Pennink and his colleagues on the mechanical and biological phenomena of the sand-filter. It might have been of interest if a short account had been given of the actual experiments on which these views are founded, and which are described in a paper in *De Ingenieur* for July, 1905. An understanding of the true mechanism of sand-filtration is increasingly important in view of such developments as the non-submerged filters, operated by sprays in the same manner as sewage trickling filters. The work of Miquel and of Baudet on these lines is well described. With the exception of the experiments at Bedford some years ago, but little has been done in this country with filters of this type.

The chapters on mechanical filters and on water-softening processes are very complete, although some of the diagrams and descriptions are likely to be more readily understood by the mechanical engineer than by the general reader, interested chiefly in understanding quickly "how it works."

The important question of the use of ozone for water purification is very well handled, and is evidently the result of careful study. The advantage of the ozone treatment is, of course, that no added chemical is left in the purified water, and unless in the meantime considerable progress is made with the theoretically perfect process of sterilisation by ultra-violet rays, it is likely that more will be heard of the ozone method in this country.

The now classical researches of Houston on the effect of storage in eliminating the organisms of typhoid and cholera are very well summarised, as well as the same investigator's older studies on the important question of the action of different waters upon lead. In this section, again, it is evident that the authors have obtained first-hand information on the subject.

Methods of chemical and bacteriological examination of water are refered to, but in a somewhat sketchy manner, and the authors have evidently not set out to write for analytical chemists. Although practical methods for making rapid routine bacteriological examinations at waterworks are well described, it is singular that little or no reference is made to the importance of careful sampling, apart from which the results of chemical, and especially of bacteriological examination, may be of very little value. A useful account is given of the recently introduced method of testing a water-supply by determination of its electrical conductivity.

Of special interest, however, is the section on the microscopic examination of the "Plankton" life of waterworks, and it may be hoped that this will stimulate further inquiry in a very interesting field of research.

The authors are to be congratulated on having produced a living book on a subject of great importance to the wellbeing of modern communities.

G. J. Fowler.

INSTITUTE OF CHEMISTRY.

Pass List: March—April Examinations, 1911.

Of thirteen candidates who presented themselves for the Intermediate Examination, nine passed: L. E. Campbell, B.Sc. (Lond.), R. B. Croad, A. J. Hale, B.Sc. (Lond.), W. F. Hollely, W. G. Prescott, C. J. Regan, B.Sc. (Lond.), C. B. Roos, B.Sc. (Lond.), H. B. Stevens, and A. F. Sugget. Of nineteen candidates who presented themselves for the Final Examination, twelve passed. In the Branch of Mineral Chemistry: W. O. Andrews, A.R.C.S. (Lond.), C. D. V. Georgi, B.Sc. (Lond.), H. L. Lucking, Ph.D. (Heidelberg), and O. D. Roberts; in the Branch of Metallurgical Chemistry: Gordon Wells, B.Sc. (Lond.), A.R.S.M., A.R.C.S.; in the Branch of Organic Chemistry: E. de Barry Barnett, B.Sc. (Lond.), G. E. Pool, B.Sc. (Lond.), and G. E. Slim; in the Branch of the Chemistry of Food and Drugs and of Water: S. W. Bridge, A. A. Eldridge, B.Sc. (Lond.), C. H. Hampshire, B.Sc. (Lond.), and H. M. Mason.

JUNE, 1911. Vol. XXXVI., No. 423.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE Ordinary Meeting of the Society was held on Wednesday evening, May 3, in the Chemical Society's rooms, Burlington House. The President, Mr. E. W. Voelcker, A.R.S.M., F.I.C., occupied the chair.

The minutes of the previous Ordinary Meeting were read and confirmed.

A certificate of proposal for election to membership in favour of Mr. A. D. Heywood, A.I.C., was read for the second time; and a certificate in favour of Mr. Horace C. Huish, 26, Westbourne Park Villas, Bayswater, W., chief assistant analyst to the Aylesbury Dairy Co., Ltd., was read for the first time.

Messrs. H. G. Battye, G. D. Elsdon, B.Sc., N. Evers, B.Sc., A.I.C., and A. W. Knapp, B.Sc., F.I.C., were elected members of the Society.

The following papers were read: "The Evaluation of Certain Spices used in Veterinary Medicine," by John C. Umney and Charles T. Bennett, B.Sc., F.I.C.; "The Detection of Traces of Hydrogen Cyanide," by G. Druce Lander, D.Sc., F.I.C., and A. E. Walden; "Note on the Composition of 'Bland's Pills,'" and "Note on the 'Pearl Coating' of Pills," by Albert E. Parkes, F.I.C., and John D. Roberts; and "A Reaction for Caulophyllin," by J. F. H. Gilbard, F.I.C.

* * * * *

NOTE ON ALMOND AND APRICOT KERNEL OILS.

BY RAYMOND ROSS, F.I.C., AND JOSEPH RACE, F.I.C.

(*Read at the Meeting, April* 5, 1911.)

IN a paper by Lewkowitsch (ANALYST, 1904, 29, 105), the characteristics of almond and allied oils are discussed, but the fatty acids were not fully examined.

By the kindness of Messrs. Stafford Allen and Sons we were placed in possession of a sample of almond oil and one of apricot kernel oil of undoubted authenticity, and the following are the analytical results obtained:

	Almond Oil.	Apricot Kernel Oil.
Iodine value	98·3	101·4
Saponification value	194·7	192·4
Zeiss butyro-refractometer reading at 40° C.	57·5	57·5
Refractive index at 20° C.:		
Nd	1·4717	1·4717
Nc	1·4691	1·4690
Nf	1·4782	1·4783
Ng	1·4837	1·4838
Reichert-Meissl value	2·6	2·6
Polenske number	0·6	0·8
Acetyl value (true)	9·67	12·28
Specific gravity 15·5/15·5° C.	0·9197	0·9198
Shrewsbury and Knapp figure	18·7	22·0

INSOLUBLE FATTY ACIDS.

	Almond Oil.	Apricot Kernel Oil.
Iodine value	99·2	103·4
Saponification value	201·6	199·8
Zeiss butyro-refractometer reading at 25° C.	58·0	59·0
Refractive index at 25° C.:		
Nd	1·4644	1·4645
Nc	1·4622	1·4622
Nf	1·4710	1·4711
Ng	1·4761	1·4762

DISTILLATION OF FATTY ACIDS AT 40 M.M. PRESSURE—ALMOND OIL.

Fraction.	Zeiss (25° C.).	Iodine Value.	Saponification Value.
1	44·0	82·9	205·1
2	45·0	84·7	—
3	47·0	88·0	—
4	48·5	89·9	—
5	51·0	91·2	—
6	55·5	96·7	—
Residue	82·0	119·3	194·6

APRICOT KERNEL OIL.

Fraction.	Zeiss (25° C.).	Iodine Value.	Saponification Value.
1	46·0	85·2	203·7
2	47·0	87·1	—
3	49·0	89·6	—
4	49·5	90·3	—
5	52·0	93·1	—
6	57·0	97·5	—
Residue	86·5	129·6	193·7

The Bieber reaction was given by the apricot kernel oil, and even after being subjected to steam distillation for some hours, the residue gave the reaction strongly but not the distillate.

This colour reaction is therefore not due to a volatile constituent. Further, after keeping for a year and then bubbling air through the warm oil for three days the reaction was still strong, and as little as 5 per cent. could be detected when mixed with almond oil.

This test, according to our experience, is the only reliable one. The results given above certainly seem to confirm the opinion expressed by some authorities—viz., that the two oils are so similar in composition that for practical purposes they may be considered as identical.

We are informed from an authentic source that peach kernel oils, as such, hardly ever come on the market. Apricot and peach kernels are, however, often used together, and the oil thus obtained cannot be distinguished from apricot kernel oil.

The following table gives the limits of the figures obtained from the analysis of four samples of almond and three samples of apricot kernel oil bought commercially, and also the figures for one sample sold as peach kernel oil:

	Limits of Four Samples of Almond Oil.	Limits of Three Samples of Apricot Kernel Oil.	Peach Kernel Oil.
Iodine value	97 to 102	100 to 106	101·6
Saponification value	183·3 to 207·6	184 to 192·4	191·7
Specific gravity, 15° C./15° C.	0·9178 to 0·9199	0·9198 to 0·9200	0·9167
Zeiss butyro-refractometer reading at 40° C.	57·5° to 58°	57° to 58·5°	55·5°
Bieber reaction	nil	strong	strong
FATTY ACIDS.			
Saponification value	200·4 to 207	197 to 202	201·6
Zeiss butyro-refractometer reading at 25° C.	56° to 58°	57° to 59°	53°

Mr. C. A. Hill writes:

"In my experience the iodine value of apricot kernel oil is distinctly higher than that of almond oil. A number of samples of each during the past three years have given

	Almond Oil.		Apricot Kernel Oil.
Iodine value	93 to 98	...	100 to 110

"Although the analytical data afforded by almond and peach kernel oils are very similar, and may even overlap, I cannot concur with the opinion that on this account the oils may be considered as identical.

"The authors give Zeiss readings at 40° and at 25° C., and refractive indices at 25° and at 20° C. I think it far preferable to have one standard temperature for refractive indices of fixed oils, and that this should be 40° C."

THE DETECTION OF TRACES OF HYDROGEN CYANIDE.

By G. DRUCE LANDER, D.Sc., F.I.C., and A. E. WALDEN.

(*Read at the Meeting, May* 3, 1911.)

SEVERAL important investigations relating to the detection and estimation of minute quantities of hydrogen cyanide have recently appeared. The colour reaction with alkali picrate has been most successfully employed by Guignard and by Armstrong in the study of enzymic action, whilst Waller (*Proc. Roy. Soc.*, B. 82, 1910, 574; ANALYST, 1910, 35, 406) has elaborated thereon a quantitative colorimetric process. The valuable work of Chapman (ANALYST, 1909, 34, 475, and 1910, 35, 469) elucidates the mechanism of the picrate reaction, showing it to be one of reduction, and therefore, being given by numerous other substances, to fail as a specific test for hydrogen cyanide. The papers of Berl and Delpy (ANALYST, 1910, 35, 362) and Lockemann (ANALYST, 1910, 25, 408) are concerned with the ferrocyanide test.

In view of the great sensitiveness of the picrate test, it appeared most desirable to make comparisons between it and the ferrocyanide reaction, having particularly in view the possibility of applying the latter specific reaction to such limiting cases as the detection of cyanide in the minimal quantities found in the brains of poisoned animals, as has been done with picrate by Waller.

Our experiments serve to show that, under regulated conditions, the ferrocyanide test is susceptible of equal, if not superior, refinement to the picrate, and that it may be applied with certainty and confidence to the above-named object.

As regards the limits of the various tests, Berl and Delpy have worked the ferrocyanide down to 0·00004 grm. hydrogen cyanide per c.c., and Chapman detects 0·00002 grm. with certainty by the picrate test. In Waller's numerous examples 0·00001 grm. appears to be the smallest amount actually estimated. Under defined conditions the ferrocyanide test recognises 0·00001 grm. with certainty, and definite positive results are obtainable with 0·000002 grm.

Berl and Delpy concentrate small quantities by extraction with ether, and subsequent resolution therefrom with a trace of alkali. This procedure is unnecessary, for we find that excessively dilute solutions can be boiled with alkali without change, as the following experiment shows: Ten c.c. of KCN solution required 18·8 c.c. $\frac{N}{100}$ I; after dilution to 150 c.c., addition of 6 drops of 10 per cent. caustic soda, and five minutes' boiling, the solution again required 18·8 c.c. of iodine. Since one almost invariably has to deal with distillates, this enables one to concentrate without risk of loss or the inconvenience of other dissolved solids.

In common with Berl and Delpy, we test in the cold, but we do not finally heat the alkali iron solution. No doubt many analysts have in their own experience noticed the advantage of working in the cold, but it is not the usual practice.

For quantities of less than 0·00002 grm. per c.c., we find the best method to be as follows: Add to the solution 2 drops of 10 per cent. caustic soda, and evaporate finally in a test-tube over the flame nearly to dryness; cool, add 1 drop of 2 per cent. ferrous sulphate, and leave in the cold for ten to fifteen minutes; add 2 to 3 drops of strong hydrochloric acid, warm gently, and cool. The liquid on careful dilution then shows a blue colour, the concentrated solution being generally blue-green. With a given concentration, better results are obtained thus than without evaporation.

With quantities of the order of 0·00002 grm. per c.c., boiling at once, after adding the alkali and iron, may give a negative result. Further, if a number of small distillates are separately taken and tested, or if a single large one is not evaporated, very appreciable quantities of cyanide may be entirely overlooked, and testing without evaporation will not give so good a result in any case as evaporation and subsequent dilution to the original volume.

The conditions governing the formation of sodium ferrocyanide from ferrous hydroxide and alkali cyanide are no doubt very complex. The reaction is not ionic, and the alterable character of the ferrous hydroxide further complicates the reaction.

The effect of concentration may be roughly gauged in its practical bearing from the following observations with 0·0025 per cent. hydrocyanic acid (as KCN), the tests being made without concentration:

Cyanide Solution.		Added Water.		Time.		Result.
(*a*) 1·0 c.c.	...	nil	...	10 minutes	...	good.
(*b*) 1·0 „	...	1·0 c.c.	..	10 „	...	positive.
(*c*) 1·0 „	...	2·0 „	...	10 „	...	blank.
(*d*) 0·5 „	...	0·5 „	...	10 „	...	blank.

The most remarkable factor is the apparent effect of the absolute quantity on the result of the test. Experiments (*b*) and (*d*) ought to have given the same result, the concentrations of cyanide being the same; and it may be mentioned that, as regards alkali and iron, these, in both instances, are in relatively enormous excess, the ferrous hydroxide further being a solid phase. We find similar effects with the picrate test. Quantities of 2 c.c., 1 c.c., and 0·5 c.c., of cyanide solution were mixed with equal volumes of Waller's reagent, sealed in tubes, and heated simultaneously at 37° C. for forty-eight hours. The 0·5 c.c. was distinctly less coloured than the 1 c.c. and 2 c.c. preparations. Considerations such as these serve to determine an absolute limit to microchemical tests.

The pale-coloured, weak alkali picrate of Waller will probably be preferred to the darker alkali hydroxide solution of Chapman, the colour of the latter tending to mask the dark yellow cyanide coloration. Thus, 0·000006 grm. KCN gave a definite result with 2 c.c. of Waller's reagent, but none with 2 c.c. of Chapman's reagent, whilst 0·000002 grm. gave a faint colour with 1 c.c. of Waller's reagent. The picrate test thus offers no advantage over the ferrocyanide in point of sensitiveness. Even if it did, there is less room for personal equation in the discrimination of pale yellow from blue-green, than of pale yellow from darker yellow.

Berl and Delpy have demonstrated that the ferrocyanide reaction affords excellent quantitative results. We do not place any reliance on the preparation of standard tints, being convinced that the excessive variations in quantity and concentration entirely vitiate results obtained by comparing an unknown quantity with an empirical standard. We recommend that, having obtained a certain result, it should be matched by taking known quantities of cyanide, evaporating, and treating in all respects exactly as was done in the original assay. In this way results, which in all such cases ought only to be regarded as approximations, are quickly obtained.

But such methods naturally need only be resorted to in limiting cases. For cyanide, we find that titration with $\frac{N}{500}$ iodine (freshly prepared) is useful; and since 1 c.c. of this equals 1 c.c. of $\frac{N}{1000}$ KCN (0·000025 grm.), it could be used for most of the cyanide determinations from blood and brain, such as are described below and by Waller.

That the ferrocyanide is equal to the picrate, if not superior, in toxicological work is shown by the following example: A dog, weighing 8·8 kilos, was destroyed by interthoracic injection of 3 c.c. of 8 per cent. KCN (equal to 0·1 grm. HCN). Ten c.c. of citrated blood, diluted with 30 c.c. of water, and acidified with tartaric acid, gave, on steam distillation, 15 c.c. of distillate, which yielded after concentration a ferrocyanide test amounting to the formation of a considerable precipitate, and equivalent approximately to 0·0001 grm.

An exactly corresponding picrate test gave excellent results. Ten grms. of brain similarly gave a good ferrocyanide result, equal to approximately 0·00002 grm., whilst the corresponding picrate test yielded results which were certainly positive, but not very well marked. The citrated blood was kept in a stoppered bottle for nine days, when 30 c.c., diluted with 50 c.c. of water, and acidified with tartaric acid, were slowly distilled in a current of steam, 10 c.c. being collected. Of this distillate, 5 c.c. required 6·8 $\frac{N}{500}$ iodine, corresponding to 0·00018 HCN, or 0·000036 HCN in 1 c.c. of distillate, or 3 c.c. of citrated blood. The ferrocyanide test was performed with 1 c.c. of distillate, and was matched by a comparison test from 1·7 c.c. of 0·002 per cent. HCN (as KCN), or by 0·000034 grm. HCN. This result is in sufficient agreement with the iodine estimation. In a second experiment, a dog was killed and its brain exposed eight days *post mortem*. Ten grms. treated as above gave an excellent result. The brain was left exposed to the air, and again tested after three and five days respectively. In both cases good positive tests were given, very much less than in the freshly opened specimen, but remarkably close to one another.

DISCUSSION.

Dr. WILLCOX said that he agreed with the authors that the Prussian blue test was more reliable than the picric acid test. In a recent instance in which he had compared the two methods, the picric acid test gave an excellent reaction, but unfortunately the colour soon faded; and it was afterwards found that the reaction was due, not to cyanides, but to sulphides, which would certainly be present in putrid viscera. Moreover, if it were necessary to prepare exhibits for production in court, the Prussian blue reaction was the more satisfactory one. When, however, the presence of hydrocyanic acid had been demonstrated, the picric acid method would be found useful for estimating the relative quantities present in different organs, provided they were not decomposed. He had found that the Prussian blue reaction was affected to some extent by an excess of ferrous sulphate, and he should like to hear whether the authors had found the addition of an excess of ferrous sulphate to be attended by any risk. It was, of course, necessary that the test should be carried out under constant conditions, and he felt sure that the authors were right in saying that, in making comparison tests with known amounts of cyanide, the complete process must be exactly followed, since the depth of the colour was considerably influenced by the conditions of working.

Mr. Chapman said that this paper was in a sense complementary to the paper which he had communicated to the Society recently, and in which he had called attention to the fact that the picric acid method was merely a very general reduction method, the red coloration being given by any substance capable of reducing picric acid in alkaline solution. From a diagnostic point of view the picric acid was on this account useless. The reaction was given not only by sulphuretted hydrogen, but by acetone, aldehyde, and a number of other substances which might quite conceivably be present in a toxicological distillate; so that, unless it were established that hydrogen cyanide was the only reducing agent present, no definite conclusion could be drawn from the results, and in toxicological work it would probably rarely, if ever, happen that one could be certain that no other reducing agent was present. The alkaline picrate method was undoubtedly useful in certain cases in which one required not so much absolute results as a series of comparative results. Under such circumstances the method had the advantage of being carried out even more quickly and easily than the Prussian blue method. The authors' results showed, however, that the Prussian blue test was actually more delicate than the picric acid method—a fact of which he (Mr. Chapman) was not aware at the time of the reading of his own paper. With regard to the method of titration with iodine, the same objection applied to this as to the picric acid method, since sulphuretted hydrogen and a number of other substances would react in the same way as hydrocyanic acid. He should like to ask the authors with what degree of certainty the Prussian blue method could be used—*i.e.*, whether one could always rely upon obtaining the same intensity of colour from a given quantity of hydrogen cyanide. With the picric acid method approximately the same amount of colour could always be obtained. He should also like to hear whether the Prussian blue standards were sufficiently stable. One advantage of the picric acid method was that the standards were easy to make, and could be kept for a reasonable time.

Dr. Lessing asked whether the authors were quite satisfied that no hydrocyanic acid was lost after boiling the liquid down to the required degree of concentration. It seemed possible that some of the cyanide might be converted into cyanate, and if this were so it might be the cause of the discrepant results obtained from the different absolute quantities in a bulk of 1 c.c. and 0·5 c.c. respectively. It would be interesting to know by what method the authors determined the absolute amounts of cyanide before starting and after concentrating, and suggested that it might be advantageous to use equivalent solutions of ferrocyanide as a standard, which would allow a conclusion as to the absolute quantities of cyanogen present.

Dr. Lander, in reply, said that in almost any case the proportion of precipitated iron hydroxide to cyanide in solution was very large. This was one of the complicated features of the reaction, and the physical mechanism of the production of ferrocyanide in solutions was not understood. Ferrous hydroxide was known to be slightly soluble, but, on the whole, the iron hydroxide in this reaction must be looked upon as a solid phase. Apart, however, from the slight coloration which it might impart to the final liquid, he did not think that the quantity of iron used was to be regarded as of very serious importance. He clearly recognised that the objections to the picrate process would apply equally to the iodine process. In both cases it was, of course, equally necessary first to ascertain that no reducing agent except hydrogen cyanide was present. He had suspected that cyanate might possibly be formed, but in experiments made by briskly boiling very dilute solutions no serious loss of cyanide was shown. Even supposing, however, that any formation of cyanate did occur—*e.g.*, by hydrolysis—during the evaporation, the results would still be comparable if the conditions of working were always the same.

A REACTION FOR CAULOPHYLLIN.

By J. F. H. GILBARD, F.I.C.

(*Read at the Meeting, May* 3, 1911.)

Caulophyllin is a brownish-grey powder prepared from the Blue Cohosh (*Caulophyllum thalictroides*), the rhizome and roots of which were formerly included in the United States Pharmacopœia. It is prepared by precipitating the resins from an alcoholic tincture with water, and collecting and drying the precipitate. It is used chiefly by homeopathists and herbalists. According to Squire's "Companion to the British Pharmacopœia" (1908 edition, p. 349), caulophyllin has been recommended as an emmenagogue, sedative, diuretic and anthelmintic, and is best given in the form of a pill in doses of from 1 to 4 grains. It is also reputed to be used as an abortifacient (see Taylor's "Principles and Practice of Medical Jurisprudence," 5th edition, vol. ii., p. 167). A sample of caulophyllin which I examined contained:

Moisture (loss at 100° C.)	8·0
Matters soluble in 80 per cent. alcohol	72·5
Matters insoluble in 80 per cent. alcohol ...	19·5
	100·0
Total matter soluble in cold water	51·5

In the course of an investigation, in which I assisted Dr. Dyer, into the composition of certain pills which were stated to contain this drug, it became important to find, if possible, some specific test for caulophyllin, no distinctive test for its recognition having, apparently, been hitherto recorded. After several unsuccessful attempts the following test was arrived at: Five c.c. of an alcoholic extract, obtained by digesting 0·1 grm. of caulophyllin in 25 c.c. of 80 per cent. alcohol and filtering, are evaporated to dryness on the water-bath in a flat porcelain capsule. The residue is taken up with

1 c.c. of water, and broken up with a flat-headed rod. Two c.c. of concentrated sulphuric acid are then slowly added, and the mixture well stirred. An intense purple-blue colour is produced within five minutes. (With some specimens of caulophyllin the colour is more inclined to reddish purple.) When testing a mixture of drugs (as, for example, a compound pill), 0·1 grm. of the pill is repeatedly extracted with 80 per cent. alcohol, filtered, and the filtrate evaporated in a porcelain capsule. The residue is broken up with 1 c.c. of water, and 2 c.c. of concentrated sulphuric acid are added. If caulophyllin be present, a distinct blue colour will be shown at the edges after a few minutes. The reaction is best seen by daylight, or by the light of burning magnesium.

The reaction appears to be characteristic of this resin, or of some constituent of it. The resins of many other drugs which were tested at the same time did not give the reaction.

DISCUSSION.

Dr. WILLCOX congratulated the author on the discovery of this reaction. The colour was very characteristic, and was produced quite definitely in the case of a mixture. He thought that the reaction might possibly be produced by other substances, and he did not imagine that the author would claim for it that it was characteristic of caulophyllin and of nothing else. In the case referred to, however—in which he (Dr. Willcox) had also been concerned—the test afforded valuable aid, for while the reaction was not given by the pills in question, it was given with certainty by pills made up according to the formula which was stated to have been followed, this formula containing caulophyllin with other drugs.

SULPHUR DIOXIDE IN COMMERCIAL GELATINS.

By HENRY LEFFMANN AND CHARLES H. LaWALL.

THE enforcement of the Federal Food Act, and similar acts, in most of the States of America has caused attention to be directed to the use of sulphur dioxide in certain classes of articles which have been treated with sulphur dioxide for antiseptic or bleaching purposes. Amongst such materials is gelatin, and considerable attention has been given to the occurrence of sulphur dioxide in this substance, and to the methods of determining it. It is recognised that simple methods of titrating with iodine solution may be misleading.

We have recently examined a number of commercial gelatins by the following method. A known weight of the sample was dissolved in water and distilled with phosphoric acid in an atmosphere of carbon dioxide, the distillate being received in an excess of iodine; the resulting sulphuric acid was then precipitated and weighed as barium sulphate.

It is evident from our results that with care in the selection and treatment of stock the manufacturer can keep the content of sulphur dioxide so low as to be negligible. Thus, of eighty-six samples from one factory, only two contained more than 50 parts of SO_2 per million, and six of the remainder not over 15 parts per million. Eighteen contained but traces, and most of the remainder less than 10 parts. From another factory, three samples were tested, all containing less than 10 parts per million. From a third source two samples, inferior in appearance and somewhat offensive in odour, contained respectively 305 and 331 parts per million.

The most striking results were obtained in the test of two samples of gelatin imported especially for bacteriological use, being the brand recommended by American bacteriologists. These samples contained 265 and 835 parts per million respectively of sulphur dioxide. It is obvious that an agent having so powerful a restraining action on micro-organisms will be particularly objectionable in a culture medium. It will be necessary, we think, for bacteriologists to establish a strict standard for gelatin.

It has been stated that gelatins low in sulphur dioxide are apt to be contaminated with bacteria, but this, if true, will have but little significance for the bacteriologist, as all media are sterilised.

PHILADELPHIA, U.S.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Examination of Absinthe and its Imitations. F. Schaffer and E. Philippe. (*Mitt. Lebensmittelunters. u. Hyg.*, 1911, 1, 1-13; *Chem. Zentralbl.*, 1911, 1, 1160-1161.)—According to the authors, the estimation of the "cloudiness coefficient" by dilution with water is not of much account, since it depends on the alcoholic strength, and the quantity and nature of the essential oils. In the detection of the poisonous thujone by Legal's reaction, the authors state that the test can be made sharper by adding the nitroprusside and sodium hydroxide and shaking, then waiting for half a minute before adding the acetic acid. Absinthe itself will barely show Legal's reaction; it is necessary to test a fraction rich in thujone, which occurs in the case of highly alcoholic liqueurs in the last fractions poor in alcohol, and in the case of weakly alcoholic liqueurs in the first fractions. A high percentage of alcohol weakens the thujone reaction. With pure thujone, working with fractional distillation of 100 c.c. of thujone solution, this body could be detected at dilutions of 1 in 50,000. The harmless carvone may also give a red coloration by Legal's test, likewise marc-brandy and denatured spirits. It is doubtful whether a really conclusive test for thujone has been found, and even then the presence of thujone would not afford conclusive evidence that wormwood has been employed in the preparation of the liqueur, since that ketone occurs in other plants. An essential oil prepared from the "great wormwood" gave Legal's reaction more strongly than one prepared from the "little wormwood" (*cf.* ANALYST, 1911, 12). J. F. B.

Colour Reactions of Aromatic Aldehydes and their Applicability in the Analysis of Spirits. T. von Fellenberg. (*Mitt. Lebensmitteluntersuch. u. Hyg.*, 1911, **1**, 311-350; through *Chem. Zentralbl.*, 1911, **1**, 1254-1255.)—The author has further investigated the reaction which takes place between the higher alcohols and a mixture of sulphuric acid and salicylic aldehyde (ANALYST, 1910, **35**, 403), and finds that this colour reaction is given by all unsaturated substances and by compounds which are converted into unsaturated substances by heating with sulphuric acid, unsaturated acids, in which the carboxyl group is next to the double bond, being exceptions. The reaction is also given by aldehydes and phenols, in which the para position is free; these phenols form colours of the type of rosolic acid. Although all aromatic aldehydes give the reaction, salicylic aldehyde has the advantage that it does not give a coloration with methyl or ethyl alcohol. Of the substances other than the higher alcohols, present in brandy and rum, only the terpenes, aldehyde, and acetal, give the coloration when treated with salicylic aldehyde and sulphuric acid. These three substances may be destroyed by boiling the spirit with silver oxide.

W. P. S.

Simplified Method for the Estimation of Arsenic in Atoxyl and Arsacetin. E. Rupp and F. Lehmann. (*Apoth. Zeit.*, 1911, **26**, 203-204; *Chem. Zentralbl.*, 1911, **1**, 1082-1083.)—The authors propose a simplified modification of the method of the German Pharmacopœia: 0·2 grm. of the substance is heated in a 200 c.c. flask with 10 c.c. of concentrated sulphuric acid at 70° C.; then 1 grm. of crystalline potassium permanganate is added in small portions, whilst the contents of the flask are rotated; 5 to 10 c.c. of officinal hydrogen peroxide are next added, drop by drop, until the liquid is colourless. It is then diluted with 20 c.c. of water, boiled for ten minutes, and further diluted with 50 c.c. of water. After cooling, 2 grms. of potassium iodide are added, the solution is allowed to stand for an hour, and then titrated with $\frac{N}{10}$ thiosulphate without an indicator. The authors quote examples showing that the results are in concordance with those of the official method.

J. F. B.

Preparation and Constitution of Caramel and its Estimation in Sugar Juices and Syrups. F. Ehrlich. (*Seventh Inter. Cong. App. Chem.*, 1909, Section V., 92-93.)—The author has succeeded in preparing a chemically homogeneous product of caramelisation by heating sucrose *in vacuo* in the oil-bath at 200° C., extracting the product with boiling methyl alcohol until colourless extracts were obtained, dissolving the residue in water, filtering and evaporating *in vacuo*. The product, amounting to 20 per cent., was "saccharan," having the formula $C_{[illegible]}H_{[illegible]}O_{[illegible]}$. It is the most intensely coloured "caramel" which has hitherto been prepared. It is therefore recommended as a standard for the colorimetric estimation of caramel, by dissolving 0·1 grm. in 100 c.c. of water and making observations in a 20 mm. cell. In this way the colouring power of any sample may be expressed numerically in terms of saccharan. The saccharan itself may also be determined by precipitating the other colouring matters by basic lead acetate, since saccharan is not precipitated by that reagent. Saccharan is a blackish-brown substance, existing in the form of lustrous scales; it is tasteless and non-hygroscopic. This substance may also be used as a standard in the colorimetric valuation of colour-malts and similar products, to which its shade approximates more closely than that of the iodine solution frequently employed. J. F. B.

Composition of Ripe and Unripe Bananas. K. Yoshimura. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, 21, 406-411.)—In order to ascertain the changes taking place in the composition of bananas during the ripening of the latter, analyses were made of the unripe fruit and of the same at intervals after it had been stored in a warm room; the results obtained were as follows:

	Unripe Fruit.	After One Week.	After Two Weeks.	After Three Weeks.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Water	70·13	70·31	71·47	70·72
	Per 100 Parts of the Dry Substance.			
Tannin	1·75	1·71	1·71	1·67
Starch	68·16	47·51	24·40	14·48
Reducing sugars	—	5·55	13·47	19·83
Cane Sugar (calculated as invert sugar ...)	—	14·92	28·61	30·12

As the quantity of tannin remains practically constant during the ripening process, it is probable that this constituent is without influence on the process. The conversion of starch into sugar proceeds fairly rapidly; it is at first changed into sucrose, but the latter is subsequently inverted by the action of the invertase which is present, so that there is no definite relation between the quantities of invert sugar and cane sugar formed. Sugars other than cane and invert sugar are not present in ripe bananas. W. P. S.

Analysis of Coca Leaves. A. W. K. de Jong. (*Arch. Pharm.*, 1911, 249, 209-214.)—In reply to certain statements of Bierling, Pape, and Viehöver upon the analysis of coca leaves (ANALYST, 1910, 35, 397) the author asserts that the persistent emulsion formed when petroleum spirit is used as the solvent may be resolved by expelling the petroleum spirit by means of a current of air. Comparative estimations have shown that somewhat higher results are obtained by the use of petroleum spirit instead of ether (*e.g.*, 1·47 as against 1·42 per cent.). Methods in which the alkaloid is extracted by shaking the leaves with the solvent never give correct results, and it is essential to use either percolation or extraction in a Soxhlet apparatus. The statement that the amount of water added in De Jong's original method (ANALYST, 1909, 24, 99) prevents complete extraction of the cocaine by the ether, is shown to be incorrect, the addition of water actually causing a slight increase in the yield. Two extractions with ether are quite sufficient to extract the alkaloid, and a third extraction is unnecessary. Petroleum spirit removes also δ-isatropylcocaine, although only very slowly. In the author's experience titration, as advocated by Bierling and his co-workers, will not as a rule give accurate results, since the alkaloid is a mixture of bodies of different molecular weights. For instance, in the case of Java leaves the alkaloid consists, in the main, of cinnamylcocaine and isatropylcocaine, the factor for which is not 0·00303 but 0·00329. The results obtained by the gravimetric and volumetric methods will therefore differ. C. A. M.

Estimation of Husk in Cocoa Powder. W. L. Dubois and C. I. Lott. (*J. Ind. and Chem.*, 1911, 3, 251-252.)—The authors have investigated a process proposed by Goske (ANALYST, 1910, 35, 162) for the estimation of husk in cocoa powders, and find that the results obtained by the method are neither concordant nor accurate. The sediments yielded by thirteen samples of commercial husk varied from 21·26 to 52·2 per cent. of the dry, fat-free substance, the average quantity being 36·96 per cent. Goske found much lower quantities. Results of the analyses of mixtures of cocoa powder with known quantities of husk show that the method does not afford reliable indication of the addition of less than 5 per cent. of husk, or of the amount of added husk actually present. W. P. S.

Note on the Detection of Cocoanut Oil in Chocolate. M. J. Wauters. (*Seventh Inter. Cong. App. Chem.*, 1909, Section VIII.c, 194.)—The evaporation to dryness in a strong current of air of the ethereal extract from a chocolate gives a residue having quite a different appearance when cocoanut oil is present from that of true cocoa butter. The addition of 10 per cent. of the former can be thus detected. The critical temperature of dissolution of cocoa butter in absolute alcohol is 78° C., while the figure for cocoanut oil is 34° to 35° C. H. F. E. H.

Analysis of Cod-Liver Oil by Means of its Miscibility Curve. E. Louïse. (*J. Pharm. Chim.*, 1911, 3, 377-385.)—The author has shown previously that a curve plotted from the results obtained in determinations of the miscibility points of oils with acetone is of use in ascertaining the quality of various oils (ANALYST, 1907, 32, 365) and of turpentine oil (ANALYST, 1910, 35, 322), and he now records the results found on the application of the method to cod-liver oil. Fifteen samples of colourless cod-liver oil gave almost parallel curves lying close together; the miscibility points of these oils, for quantities varying from 3 to 20 grms., were always above 0° C. The curves obtained with brown oils were of somewhat different form, and the miscibility points were all below 0° C., whilst the curves of light and amber-coloured oils lay between those of the colourless and brown oils. The miscibility curves indicate differences in the qualities of the oils more plainly than do the usual analytical constants. W. P. S.

Detection of Resin in Glazed Coffee. T. von Fellenberg. (*Mitt. Lebensmitteluntersuch. u. Hyg.*, 1911, 1, 301-302; through *Chem. Zentralbl.*, 1911, 1, 1253.)—The presence of resin on glazed coffee-berries cannot be detected directly by means of Storch's reaction (coloration with acetic anhydride and sulphuric acid), as coffee-berry oil itself gives a similar violet coloration. As, however, the substance in the coffee-berry oil which yields the reaction is an indifferent compound, whilst the resin reaction is due to the presence of abietic acid, the test may be used as follows: 10 grms. of the coffee are treated for a few minutes with 20 c.c. of ether, and the filtered ethereal extract is shaken with 3 c.c. of 5 per cent. sodium hydroxide solution. The aqueous solution will now contain the abietic acid, the acids of the coffee-berries, and traces of coffee-berry oil. The latter is removed by extracting the solution several times with ether, the solution being then acidified with hydrochloric acid, extracted with ether, the ethereal solution evaporated, and Storch's test applied to the residue obtained. Whilst pure shellac does not yield a coloration with the test, shellac glazes on coffee-berries will usually give a positive reaction, as the commercial shellac used for this purpose is almost invariably adulterated with resin (colophony). W. P. S.

Analysis of Commercial Dextrins. C. A. Browne and A. H. Bryan. (*Seventh Inter. Cong. App. Chem.*, 1909, Section V., 337-342.)—According to the method proposed by the authors, the percentages of dextrin and dextrose are calculated from the rotation and cupric-reducing power of the cold-water extract, taking the specific rotation of pure dextrin as 186, and the difference between the sum of these percentages and the dry organic solids of the extract is expressed as undetermined soluble organic matters. J. F. B.

Analysis of Honey. H. Witte. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 305-374.)—In continuation of a previous investigation on the composition and analysis of honey (ANALYST, 1910, **35**, 61) the results are now recorded of the analysis of forty-nine samples of pure honey, twenty-five samples of artificial honey, twelve samples of honey of doubtful purity, and nineteen samples of adulterated honey, these results, together with the behaviour of the samples towards various qualitative tests, being given in the form of eight separate tables. As the outcome of this investigation, the following limiting values for pure honey are suggested, and the reliability of certain tests is discussed: The quantity of water in honey should not exceed 20 per cent., and the acidity (calculated as formic acid) should lie between 0·06 and 1·2 per cent. The quantity of ash is generally from 0·1 to 0·35 per cent.; it may be as low as 0·065 per cent. The amounts of ash and acidity of a sample, however, afford little information as to the purity of the honey. The sucrose should not exceed 6 per cent., a larger quantity than this indicating that the honey is "unripe," that the bees have been fed on sucrose, or that the honey is adulterated. The author considers that "unripe" honey and that produced by sugar-feeding are not normal honeys. It may be mentioned that, at a suitable temperature, sucrose is inverted rapidly by certain honeys, and it is not possible to detect such inverted sugar by analysis. The quantity of nitrogenous substances in pure honey varies from 0·25 to 0·55 per cent., whilst artificial honey rarely contains more than 0·2 per cent. The catalase test and the *p*-phenylenediamine test proposed by Auzinger (ANALYST, 1910, **35**, 165, 259) do not always yield definite evidence as to the purity of a sample of honey, but, provided that the honey has not been strongly heated, the diastase test described by the same author is useful. Fiehe's reaction (ANALYST, 1908, **33**, 397) in conjunction with this diastase test is of great value in ascertaining the purity of a specimen of honey, but it must not be forgotten that artificial honeys occasionally give a negative reaction with Fiehe's test, and that honey which has been heated for a long time will yield a positive reaction. The faint coloration sometimes given by honey which has only been heated in the usual manner during its preparation cannot be mistaken for the cherry-red coloration yielded by artificial honey (invert sugar). In conclusion, the author recommends that all the data obtained during the analysis of a sample of honey ought to be considered together before an opinion is expressed as to the character of the honey. W. S. P.

Analysis of Honey, with Special Reference to the Nitrogenous Constituents. R. Lund. (*Mitt. Lebensmittelsunters. u. Hyg.*, 1911, **1**, 38-58; *Chem. Zentralbl.*, 1911, **1**, 1158-1159.)—As the result of the examination of a large number of samples of honey, the author concludes that in genuine honey about one-half of the total nitrogen exists in the form of protein and one-half as amino nitrogen, the quantity of ammonia nitrogen being negligible. Samples of genuine honey showed from 0·31 to 0·45 per cent. of total nitrogen, whilst artificial honeys contained only 0·106 to 0·20 per cent. For the estimation of the protein in honey, the author recommends a solution of 2 grms. of phosphotungstic acid in 20 grms. of dilute sulphuric acid (1 : 4) and 80 c.c. of water. Five c.c. of this reagent are added to 20 c.c. of a filtered 10 per cent. solution of honey, the mixture being diluted to 40 c.c. and stirred. The precipitate separates better in this way than when tannic acid is used, and the results are equivalent. Precipitation is effected in the test-tubes employed by Barth for the estimation of tannin in wine. The volume of the precipitate is read off after twenty-four hours, and in the case of natural honey it ranges from 0·6 to 2·7 c.c. Artificial honey gives either no precipitate or less than 0·5 c.c. If proteins have been added to artificial honey, differentiating tests, such as Bräutigam's, Ley's, and Fiehe's reactions, may be applied. J. F. B.

Volatile Acids of Honey. A. Heiduschka and G. Kaufmann. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 375-378.)—The volatile acids occurring in honey do not consist wholly of formic acid; in some cases this acid constitutes only about one-half of the total volatile acids. The authors employed two methods for estimating the amount of formic acid in various samples of honey—namely, the mercuric chloride method (reduction to mercurous chloride), and the sulphuric acid method (measurement of the carbon monoxide produced). The former method yielded from 0·006 to 0·01 per cent. of formic acid, and the latter from 0·005 to 0·0073 per cent.; these results confirm the statements of other workers that the sulphuric acid method yields slightly lower results than does the mercuric chloride method. After saponification, larger quantities of volatile acids were obtained from the honeys, showing that a portion of these acids, including the formic acid, was present in the honeys in the form of esters. The total amount of formic acid (free and combined) found varied from 0·0118 to 0·0229 per cent. by the mercuric chloride method, and from 0·0096 to 0·0208 per cent. by the sulphuric acid method. W. P. S.

Notes on Linseed and other Oils. H. Ingle. (*J. Soc. Chem. Ind.*, 1911, **23**, 344.)—The author has examined the relationship between the iodine value (Wijs) specific gravity and the yield of hexabromides by Hehner and Mitchell's method (ANALYST, 1898, **23**, 310). One to 1·5 grms. are dissolved in a weighed flask in 40 c.c. of ether (sp. gr. 0·720) and 5 c.c. glacial acetic acid. Excess of bromine is run in, and after six hours the precipitate is collected on a tared paper, washed four times with 10 c.c. of ether, and the total weight of the precipitate determined after drying the residue still left in the flask, and that on the filter in the water oven. Samples of known purity gave values as follows:

Oil.	Iodine Value.	Sp. Gr. at 15° C.	Hexabromides. (1)	(2)	Melting-point °C.
Baltic oil	197·0	0·9357	48·1	47·5	140–5
Calcutta oil	185·0	0·9322	39·1	39·3	140–5
Dutch crushed ordinary ...	181·5	0·9322	36·9	—	140–3
English " " ...	185·0	0·9332	40·0	—	140–3
Plate oil	179·5	0·9315	35·3	33·7	140–5
Menhaden oil	182·0	0·9328	61·8	—	decomposes
Tung oil	168·0	—	nil		—

These results, with the exception of the melting-points, are not at all in agreement with Hehner and Mitchell (*loc. cit.*). The length of time of the stand with bromine and ether is immaterial. The following are some iodine values obtained: Baltic oils, 190 to 204 (good samples should not fall below 195); La Plata, 175 to 186 (the higher figure is now commoner than formerly); Black Sea oils, 176 to 182; North-American oils, 177 to 188 (very variable); Morocco, Dutch, and Turkish oils, 185 to 192. The Hübl method, modified by the author (ANALYST, 1902, 27, 279), gives similar values. Figures are given showing the lowering effect on the iodine and hexabromide values due to heating a sample of linseed oil for varying times at 195 to 200° C.

H. F. E. H.

Analyses of Evaporated Milk and Milk Products. E. Gudeman. (*Seventh Inter. Cong. App. Chem.*, 1909, Section VIII.c, 237.)—Butter fat in concentrated milk and in milk products is estimated as follows: 2·5 grms. of the milk product are dissolved or made into an emulsion with about 100 c.c. of water. Fat, proteins, and insoluble substances, such as starch, gums, fibre, etc., are precipitated with copper solution (Fehling), and the precipitate filtered, washed, and dried at a low temperature between filter paper. This is then extracted with ether, and the solution dried on the water-bath. The residue after ether extraction is used for the estimation of insoluble protein, the Kjeldahl digestion being complete in less than one hour. Sugar is determined in the filtrate from the copper sulphate precipitation. A preliminary extraction with ether is recommended for bodies rich in fat, such as milk chocolates and milk powders. Many substances containing sugars, starch, and cereals may be treated in this manner.

H. F. E. H.

Composition of Dried Milk Powders. A. Burr. (*Milchw. Zentralbl.*, 1911, 7, 118-113; through *Chem. Zentralbl.*, 1911, 1, 1234.)—The following results were obtained on the analysis of samples of dried milk preparations. For the estimation of the fat, the Rose-Gottlieb process, as modified by Richmond (ANALYST, 1908, 33, 389), and the Werner-Schmidt process, were found to be trustworthy, but the Adams process yielded low results. The factor 6·37 was employed for converting the nitrogen found by Kjeldahl's process into protein:

	Water.	Fat.	Proteins.	Lactose.	Ash.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Full-milk powder (37 samples) ...	1·20 to 10·04	22·89 to 32·41	23·79 to 34·09	31·63 to 45·13	5·48 to 7·54
Cream powder (22 samples) ...	0·92 „ 8·21	30·23 „ 53·52	—	—	—
Skimmed-milk powder (20 samples)	2·62 „ 13·88	0·63 „ 4·18	—	—	—
Whey powder (2 samples) ...	2·10 „ 2·20	1·63 „ 1·70	14·01 to 14·48	75·44 to 75·57	8·38 to 8·99

With the exception of the water, the figures are calculated on the dry substance. Only three of the so-called cream powders contained more than 50 per cent. of fat, and in many cases they did not differ essentially from full-milk powders. The author is of the opinion that a full-milk powder should contain not less than 25 per cent. of fat. Apart from the two whey powders, the preparations did not dissolve completely in water, and, as the powders undergo certain changes which affect their taste and solubility, the author considers that milk powders cannot be termed satisfactory preparations. The use of alkalis in the manufacture of the powders may be detected by testing their aqueous solution with litmus paper*; the test, however, is of use only when the powder is quite fresh, or has been kept out of contact with air, as the powder soon develops a high degree of acidity. W. P. S.

Polarimetric Estimation of Nicotine in Tobacco Extracts. J. von Degrazia. (*Fachl. Mitt. d. œsterr. Tabakregie*, 1910, 87–90; *Chem. Zentralbl.*, 1911, 1, 1085.)—The specific rotation of nicotine changes very appreciably with the temperature. According to the method proposed by the author, 30 grms. of tobacco extract are treated with 3·5 grms. of calcium oxide and 10 c.c. of water, and the mixture is distilled in a current of steam. When the distillate amounts to six times the quantity of tobacco extract taken, practically all the nicotine will have distilled over. The rotation of the distillate is then observed in a 200 mm. tube with a Lippich half-shadow polarimeter. The percentage of nicotine is calculated from the formula $P = \frac{a.G.f}{g}$, in which G = the weight of the distillate, g that of the tobacco extract, and f = a factor (the rotation constant) which varies according to the temperature and the rotation. Values of *f* determined for different temperatures and angles of rotation are given in the following table :

---

* NOTE.—The use of rosolic acid is much to be preferred.

Temperature.	0·5°	1°	2°	3°	4°	5°
10° C ...	0·6365	0·6394	0·6405	0·6414	0·6419	0·6414
15° C ...	0·6315	0·6340	0·6349	0·6355	0·6354	0·6352
20° C ...	0·6264	0·6286	0·6293	0·6295	0·6288	0·6289

J. F. B.

New Method for the Estimation of Nicotine in Tobacco. J. von Degrazia. (*Fachl. Mitt. d. œsterr. Tabakregie*, 1910, 149–152; *Chem. Zentralbl.*, 1911, **1**, 1085–1086.)—Twenty grms. of finely powdered tobacco are treated in a flask of 300 c.c. capacity with 7 c.c. of potassium hydroxide solution (1 : 1), a few grms. of sodium chloride, and 130 c.c. of boiling concentrated brine. About 45 c.c. are rapidly distilled over without the use of steam, and then distillation is further continued in a current of steam, until 100 c.c. of distillate are obtained. Only with tobaccos very rich in nicotine is it necessary to distil off more. After the introduction of the current of steam, the direct heating of the flask should be interrupted for a time, to allow of the dilution of the residue. The distillate is weighed and polarised, the percentage of nicotine being calculated by the formula given in the preceding abstract. The results agree very closely with those obtained by Kissling's method (*cf.* ANALYST, 1911, pp. 106 and 143). J. F. B.

Estimation of Starch Syrup in Jams, etc. K. Beck and P. Lehmann. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 393–405.)—Two processes are described, the first being intended for use in the case of jams, etc., which are not homogeneous, whilst the second is applicable to samples of a more uniform composition. The factors taken into account in the formulæ given are : The specific rotation of the inverted dry solids of starch syrup = +134·1°; the specific rotation of the inverted soluble substances of the jam = −21·5°; and starch syrup contains an average of 18 per cent. of water. The tables given in the official (German) methods for the analysis of wine are used for finding the quantity of soluble matters corresponding with the specific gravity of the jam solution.

Method I.—The amounts of soluble and insoluble substances are first estimated. One hundred grms. of the sample are mixed with 200 grms. of dilute alcohol (1 part of alcohol to 2 parts of water) of which the alcoholic strength, p, has been exactly found by taking the sp. gr. of its distillate, and the mixture is allowed to stand 24 hours, with occasional shaking. After filtering, 50 grms. of the filtrate are mixed with 25 c.c. of water, distilled, and the sp. gr. of this distillate is determined, giving the percentage quantity of alcohol now present, p_1; the percentages of alcohol, p and p_1, are expressed in parts by weight. The percentage quantity of insoluble substances, I, is then calculated from the formula

$$I = 100\left(3 - \frac{2p}{p_1}\right).$$

The residual solution in the distillation flask is now diluted to a volume of 50 c.c., its sp. gr. is determined, and the quantity of soluble substances is calculated from the sp. gr.; this quantity, multiplied by 3, gives the percentage quantity, t, of soluble substances in the sample. One-half the weight of the 50 c.c. of solution is now transferred to a 50 c.c. flask, 13 c.c. of water and 4 c.c. of 38 per cent. hydrochloric acid are added, and the mixture is heated to 68° C. After cooling, the solution is neutralised, 5 c.c. of basic lead acetate solution are added, the mixture is diluted to the mark with water, and filtered. Twenty-five c.c. of the filtrate are then treated with 2·5 c.c. of saturated sodium phosphate solution, filtered, and the rotation of the filtrate observed in a 220 mm. tube. The reading, when multiplied by 3, gives the specific rotation ($[\alpha]_D$) of the sample. The percentage quantity of starch syrup, y, is found from the formula

$$y = \tfrac{1}{6}(t + 4{\cdot}651\,[\alpha]_D).$$

Example.—Sp. gr. of the solution $= 1{\cdot}0502 = 13{\cdot}00$ grms. of soluble substances, and $13{\cdot}0 \times 3 = 39{\cdot}0$ per cent. of soluble substances (t). The observed rotation $= +2{\cdot}8°$; then $2{\cdot}8 \times 3 = 8{\cdot}4$, the specific rotation of the sample. By the above formula

$$y = \tfrac{1}{6}(39{\cdot}0 + 4{\cdot}651 \times 8{\cdot}4) = 13{\cdot}0 \text{ per cent. of starch syrup.}$$

This quantity is then multiplied by the factor $1 - (0{\cdot}0033 \times I)$, in order to correct it for the volume of the insoluble substances and to obtain the actual quantity of starch syrup present.

Method II.—Fifty grms. of the sample are mixed in a tared flask with 200 c.c. of 25 per cent. alcohol, 20 c.c. of basic lead acetate solution are added, and a further quantity of the dilute alcohol is added to make the total weight of the mixture 320 grms. After mixing and allowing to stand for 30 minutes, the mixture is filtered and the filtrate is collected in a weighed flask; the excess of lead is removed from the filtrate by treatment with hydrogen sulphide, and, if necessary, water is added to make up any loss in weight. After filtration, 50 c.c. of the filtrate are evaporated to expel the alcohol, the residual solution is diluted to a volume of 50 c.c., and its sp. gr. is determined, the corresponding quantity of soluble substances, E, being then calculated. Of this solution, 41·7 c.c. are transferred to a 50 c.c. flask, inverted as described above, and polarised in a 200 mm. tube (the treatment with sodium phosphate is not required). The percentage amount of starch syrup, y, is then found from the formula

$$y = E + 3P,$$

where P is the polarimeter reading.

Example.—Sp. gr. of the solution $= 1{\cdot}0271 = 7{\cdot}01$ E, and the rotation found $= +2{\cdot}6°$; then

$$y = 7{\cdot}01 + (3 \times 2{\cdot}6) = 14{\cdot}8 \text{ per cent. of starch syrup.}$$

This quantity may be corrected for the volume of the insoluble matters present as described previously.

W. P. S.

Detection of Prune Juice and Caramel in Vanilla Flavouring Extracts. W. Denis. (*J. Ind. Eng. Chem.*, 1911, 3, 254-255.)—The ordinary basic lead acetate test for caramel is quite worthless in the case of extracts containing more than 0·1 per cent. of vanillin; when more than this quantity is present, it is precipitated by the basic lead acetate, and carries down with it practically the whole of the caramel which may be in the extract. The following modification of the test has therefore been devised, and has been extended to include the detection of prune juice. Twenty-five c.c. of the extract are mixed with 50 c.c. of water, evaporated to a volume of about 20 c.c., and filtered. The filtrate, when cold, is extracted twice with ether, using 15 c.c. of the latter each time; the colour of the first ethereal extract should be noted, as the colouring matter of the vanilla bean is fairly soluble in ether, whilst caramel and prune juice are quite insoluble. The aqueous liquid is now transferred to a beaker, heated to remove dissolved ether, and treated, when cold, in a cylinder with 1 c.c. of basic lead acetate solution of sp. gr. 1·25. If caramel is present, the precipitate produced will be dark brown in colour, whilst the supernatant liquid will also be dark coloured. Five c.c. of glacial acetic acid are then added; in the presence of a pure extract, or of an extract coloured with caramel, the precipitate will be dissolved immediately. If prune juice has been used, a reddish-brown gelatinous mass will remain insoluble in the acetic acid. The colouring matter of sherry is said to be sometimes used to colour vanilla extract; this colouring matter gives a light-coloured precipitate with basic lead acetate, closely resembling in appearance the precipitate obtained from a pure vanilla extract, but differing from the latter in containing a body which is insoluble in acetic acid. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Germicidal Action of Arsenic and Antimony Compounds on Bacillus Typhosus. G. T. Morgan and E. A. Cooper. (*Seventh Int. Cong. App. Chem.*, 1909, Section IV A, 365-366.)—The Rideal-Walker test was used under standard conditions, employing a twenty-four hours' culture of the organism. The following are some of the results obtained:

Substance.	Co-efficient.	Dilutions Employed.
Phenol	1	1 in 100 killed in about 5 minutes.
Atoxyl (sodium salt)	Under 0·1	1 in 10 failed to kill in 15 minutes.
Potassium dicamphorylarsenate ...	0·25	1 in 75 ,, ,, ,,
Arrhenal	0·5	1 in 50 ,, ,, ,,
Potassium arsenate	0·2	1 in 20 ,, ,, ,,
Potassium arsenite	1·3 (approx.)	1 in 140 killed in about 5 minutes.
Diiodomethylarsenic acid	1·25	1 in 120 ,, ,, ,,
Triphenylantimonic hydroxynitrate	4·0 (approx.)	1 in 400 ,, ,, ,,

The quinquevalent arsenic compounds above, with one exception, are but feebly germicidal, and in that case the iodine confers the greater activity. In the presence of potassium arsenite the subcultures grew in an erratic manner, and the authors point out that mercuric chloride also behaves similarly unless a trace of sulphuretted hydrogen is added to combine with the carried-over salt, and so prevent the formation of a compound between the albumin of the germs and the mercury. It is

suggested that the toxicity of tervalent arsenic is due to a combination of this kind between the unsaturated arsenic and the organism, thus accounting for the irregularity in its action.
H. F. E. H.

Contribution to the Study of Chemical Disinfectants. Second Paper. S. Delépine. (*J. Soc. Chem. Ind.*, 1911, **23**, 334-343; *cf.* ANALYST, 1911, 69.)—The author reviews the work of the chief investigators concerning the action of chemical disinfectants, dealing first with Baxter on the action of various agents upon organic fluids that had undergone spontaneous putrefaction, and then with the same author's work on vaccine lymph, septic peritonitis, and glanders nodules. Of methods adopted since 1881, he describes Koch's use of pure cultures as test organisms acting in presence of large quantities of the disinfectant. This worker combined the use of the "thread" method with solid media, and was followed by Fraenkel and Behring, who substituted peptone bouillon for the solid medium in order to minimise the "carry over" danger. Krönig and Paul's "garnet" method is criticised, as are the modifications introduced by Sternberg, Wynter Blyth, and Rideal and Walker; and the author describes in detail the "suspension" and "thread" methods he has himself mostly employed.

The "suspension" method resembles in some respects that used by Baxter and Sternberg, and is used with such modifications as the occasion requires. Comparisons with phenol as the standard were almost always used, and in all cases it is easy to estimate accurately the proportion of bacteria, associated matter, and of disinfectant. No cotton-wool is employed, and the whole of the procedure is carried out in a small double-walled chamber, kept at 19° to 20° C. A mechanical rocker is employed (and illustrated) to keep the fluids in motion.

The Thread Method (*J. Roy. San. Inst.*, 1907, 28).—This differs from the former as regards the state of the test bacteria, and full details are given for the use of *B. coli communis* and *B. typhosus*. Unlike Rideal and Walker, the author does not express his results by means of a phenol co-efficient, but states exactly under what conditions the death of the test organisms occurred. In both the thread and suspension methods there is in each set of tests but one variant—the strength of the disinfecting solution; whereas Rideal and Walker have two—the degree of dilution and the time of exposure. The author gives various reasons for believing that either of his methods is preferable to the Rideal and Walker, and especially claims its superiority for testing disinfectants to be used on surfaces or articles contaminated with dry infectious products.

After discussing the objects of standardisation of disinfectants from the chemical and hygienic points of view, the author concludes: (1) That the use of naked bacteria is sometimes advantageous when the bactericidal powers of disinfectants, and not the actual hygienic practice, is under consideration, and that his suspension method is then preferable to the drop (or Rideal-Walker). (2) That the results obtained by these methods may be expressed by a figure indicating the bactericidal value of a disinfectant, carbolic acid being the standard; but that this figure indicates only a ratio obtained under conditions not necessarily occurring in practice, and that the term "co-efficient" should not be understood to indicate the hygienic value. (3) The hygienic value can be ascertained only by means of a series of tests in which practical conditions are represented as closely as possible. H. F. E. H.

Detection of Blood by Means of Leuco-Malachite Green. F. Michel. (*Chem. Zeit.*, 1911, **35**, 389-390.)—A reagent may be used for the peroxydase test in blood by dissolving 1 grm. of leuco-malachite green in 85 grms. of glacial acetic acid, and diluting the mixture with water to a volume of 250 c.c. One drop of the solution to be tested for blood is treated with 5 drops of the reagent and 2 drops of 1 per cent. hydrogen peroxide. If the drop of solution contains only as little as 0·002 mgrm. of blood, a green coloration will be obtained. W. P. S.

Estimation of Catalase in Milk. O. Laxa. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 417-420.)—An apparatus is described for measuring the quantity of oxygen liberated from hydrogen peroxide by the catalase present in milk. It consists of a graduated glass tube, the lower end of which is constricted to form a narrow jet, whilst the upper end is fitted with a tap. The capacity of the tube is 20 c.c. A mixture of the milk to be tested and hydrogen peroxide is prepared in the proportion of 15 c.c. of milk to 5 c.c. of 1 per cent. hydrogen peroxide solution, and the apparatus is filled with this mixture. After the lapse of a definite period of time, the volume of oxygen liberated by the action of the catalase is noted. Results of experiments with numerous samples of milk are given, showing that the apparatus yields concordant figures, and that the latter agree closely with those obtained by Koning's process (titration of the excess of hydrogen peroxide). The method described by Burri and Staub (ANALYST, 1909, **34**, 160) was found to yield unreliable results, probably owing to the liability of the agar cylinder to shrink and allow the gas to escape. W. P. S.

Estimation of Inorganic Phosphorus in Animal Tissues. A. C. Whittier. (*J. Ind. Eng. Chem.*, 1911, **3**, 248-250.)—The following method, due to Forbes (*Ohio Agr. Exp. Sta.*, *Bulletin* **215**, 481), is recommended: Extraction is accomplished by boiling the sample in ammonium sulphate solution, followed by repeated extractions with hot water. The determination is made by precipitating the inorganic phosphates with magnesia mixture and ammonia, followed by the regular gravimetric method for phosphorus on the dissolved magnesium precipitate. The method gives almost identical results with and without the application of heat to cold water extracts of flesh, and the results agree well with those obtained by the method of Emmet and Grindley (ANALYST, 1906, **31**, 159). Trowbridge and Stanley (ANALYST, 1910, **35**, 311) have pointed out that methods depending on the use of boiling water are faulty, because at this temperature organic compounds of phosphorus may be hydrolysed. The present author finds no evidence of this. Such hydrolysis as may occur on storage seems rather to depend on the action of enzymes and bacteria, and boiling arrests such action, and, in addition, gives rise to clear solutions, in which the subsequent precipitation is more complete. It is shown that Trowbridge and Stanley's determinations of organic phosphorus in uncoagulated extracts by the barium method are too high, and this is traced to the passage of barium phosphate through the filter. G. C. J.

Experiments on the Antiseptic Properties of Sulphurous Acid, Sulphites, and Complex Compounds of Sulphurous Acid. E. Hailer. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **36**, 297-340; through *Chem. Zentralbl.*, 1911, 1, 1309-1311.)—The relative concentrations of sulphurous acid necessary to destroy moulds, yeasts, and bacteria, were in the order 5, 4, and 1, respectively. The addition of dextrose to the media containing the organisms decreased the action of the sulphurous acid. The latter has a more powerful action at a temperature of 37° C. than it has at 22° C. Sodium sulphite, in the concentrations employed in the experiments, was without effect on the organisms, whilst sodium bisulphite was less effective than an equivalent quantity of sulphurous acid. All three kinds of organisms were equally resistant to the action of phenol, a $\frac{1}{35}$-molar solution being required to kill them, whilst moulds were destroyed by a $\frac{1}{150}$-molar solution of sulphur dioxide, yeasts by a $\frac{1}{186}$-molar solution, and bacteria by a $\frac{1}{750}$-molar solution. A much higher phenol concentration is, therefore, required to kill the organisms than is necessary in the case of sulphurous acid. The compounds of formaldehyde and acetaldehyde with sodium bisulphite, even in high concentrations, do not affect moulds, but the corresponding compounds of acetone and dextrose have some action. The dextrose compound has the most effect on bacteria, then follows the acetone compound, and next the acetaldehyde compound. The quantity of sulphurous acid necessary for the effective preservation of a substance depends to a great extent on the composition of the latter; and, without taking into account its physiological action, sulphurous acid, when used as a preservative, possesses the disadvantage that it is volatile and is also readily oxidisable. As regards its employment in the case of dried fruits, experiments showed that there was no need for its use when the fruits are properly dried. The alleged necessity for the use of sulphurous acid in certain classes of wine is being investigated. W. P. S.

Estimation of Hexamethylenetetramine (Urotropine) in Urine. F. Schröter. (*Archiv. exper. Pathol. Pharm.*, 1911, **64**, 161-166; through *Chem. Zentralbl.*, 1911, **1**, 1257.)—As inaccurate results are obtained by estimating the nitrogen in the mercuric chloride precipitate obtained from urine containing hexamethylenetetramine, owing to the occlusion of uric acid in the precipitate, the following method, in which the precipitate is treated for the removal of the uric acid, is recommended. One hundred c.c. of the urine are mixed with 10 c.c. of 25 per cent. acetic acid, and treated with 120 c.c. of saturated mercuric chloride solution. After the lapse of twelve hours, the precipitate is collected on a filter, then digested on the water-bath with 15 c.c. of concentrated sodium chloride solution, and again filtered; the hexamethylenetetramine-mercuric chloride compound dissolves in the sodium chloride solution, and, after the mercury has been removed by the addition of sodium hydroxide, the nitrogen in the solution is estimated by Kjeldahl's process. The amount of nitrogen found is then calculated into hexamethylenetetramine.

W. P. S.

Bacteriology of Water: Its Present Position. P. F. Frankland. (*J. Soc. Chem. Ind.*, 1911, **23**, 319-334.)—The author reviews the present position of the knowledge on this subject, special mention being made of his own work and the various recent reports of Houston to the Metropolitan Water Board. A short historical summary is followed by numerous tables dealing with the biochemical reactions of *B. typhosus*, *B. coli*, and streptococci, and the rate of disappearance of the former from raw river and stored waters. An account is given with tables of recent bacteriological methods as applied to testing the purity of waters which have been treated by processes other than storage and sand filtration. These include mechanical filters, Clarke's process of softening, lime and alumino-ferric, ozone, bleaching powder and ultra-violet light. Illustrating the extremely laborious nature of the work done by Houston, a description in detail is given of one investigation involving the examination of 156 samples of raw river water containing 135,687,500 bacteria. From these 7,329 selected colonies were subcultured and fully examined for behaviour characteristic of *B. typhosus*. Not one of all these colonies agreed in all respects with any of the thirty-two known strains of this organism which were simultaneously examined. In another series, out of 5,451 colonies selected for special study from raw river water, one consisted of bacteria which closely resembled the typhoid bacillus.

The work of McConkey and Hill and Savage on *B. coli communis* is reviewed, the labour expended on "this now classical microbe" having been of wider scientific interest than its mere hygienic significance. The position taken up as long ago as 1886 by the author is vindicated with regard to the storage of water as effecting its purification, for, notwithstanding the great advances in the technique of typhoid-testing, the results obtained recently by Houston are essentially similar to those obtained by the author fifteen years previously.

The author fully endorses all the advantages which Houston claims are secured by the storage of surface waters.

In the final conclusion it is stated that no very surprising novelties have been brought to light since 1895. By that date all the salient features in the bacteriology of water had been mapped out, and recent work has filled in details and confirmed previous results broadly established. The all-important questions for the water-examiner remain the same: (1) Has the water been contaminated with the excreta of man? and (2) if so contaminated, has the water been since subjected to conditions sufficient to insure the destruction or removal of the pathogenic organisms which may so have been introduced? No categorical answer is yet possible to the first of these questions, because no organism absolutely characteristic of human excreta is yet known. *B. coli communis* is characteristic of fæcal matter in general, and all surface water must be contaminated more or less with this organism.

The second question also requires a qualified answer. If the water is free from *B. coli* in a large volume, it may be concluded that *a fortiori* it is free from typhoid. But should *B. coli* be found in a small volume, it does not prove that the water may at any time be liable to contain typhoid bacilli, because the presence of *B. coli* does not prove that the water has been contaminated by man. It is easier to exculpate a water than to incriminate it, but even the absence of *B. coli* from a large volume does not prove its safety in view of the recent remarkable revelation as to people who are typhoid-carriers, and who by discharging typhoid bacilli in their urine may contaminate water without causing it at the same time to receive any *B. coli*. The author deprecates the adoption of any hard-and-fast standard of purity such as the now popular "no typical *B. coli* in 100 c.c.," and also the idea that the chemical examination of drinking water has been superseded by the bacteriological, and asserts that the latter, while more useful for following the variation in purity of a known water may, if used without chemical analysis in a water of unknown origin, lead to erroneous conclusions. H. F. E. H.

ORGANIC ANALYSIS.

Use of Metallic Potassium in the Estimation of Halogens in Benzene Derivatives. C. H. Maryott. (*Amer. J. Sci.*, 1910, **30**, 378-380; through *Chem. Zentralbl.*, 1911, **1**, 1246.)—From 0·1 to 0·4 grm. of the substance is placed in a flask, 15 c.c. of a mixture of 1 part of alcohol with 2 parts of thiophene-free benzene are added, the flask is attached to a reflux condenser, and about ten times the amount of potassium required by theory is introduced gradually. After the contents of the flask have been heated and the reaction is completed, a further quantity of 2 c.c. of alcohol is added, and the heating is continued until the whole of the potassium has disappeared. The halogen in the resulting solution is then estimated in the usual way. The method yielded trustworthy results in the case of such substances as chlorobenzene, bromobenzene, hexachlorobenzene, and *p*-chloraniline. When metallic sodium was used as recommended by Stepanow (ANALYST, 1907, **32**, 52), only 84 per cent. of the quantity of halogen present was obtained. W. P. S.

Caoutchouc Nitrosite and its Analytical Application. P. Alexander. (*Zeitsch. angew. Chem.*, 1911, **24**, 680-687.)—The author has previously recorded the production of carbon dioxide during the preparation of caoutchouc nitrosite and has analysed the products obtained, suggesting the formula $C_9H_{12}O_6N_2$, instead of Harries' formula $(C_{10}H_{15}O_7N_3)_2$ for the "nitrosite-c." In the present paper he confirms his observations and defends his views against certain criticisms which have been made. He admits that the amount of carbon dioxide formed varies with the conditions under which the nitrosite is prepared, depending especially on the time and temperature of the treatment; but if care be taken to collect all the carbon dioxide produced, a quantity representing 86 per cent. of that calculated for the splitting off of 1 molecule of carbon dioxide from a body of C_{10} constitution may be found. The greater portion of this is evolved by secondary oxidation changes during the later stages of the reaction, but in any case there is always sufficient evolution of carbon dioxide to exclude the possibility of simple nitrosite formation quantitatively with the production of a nitrosite of C_{10} formula. The author concedes, however, that with very different varieties of caoutchouc the quantity of crude nitrosite obtained by the full action of nitrous vapours corresponds very closely with that calculated from Harries' formula. But this in no way proves the correctness of that formula for a purified derivative, but merely that the loss of carbon dioxide is approximately compensated by the fixation of oxygen in the residue. Dealing with the question whether the nitrosite reaction may be legitimately used for the quantitative estimation of caoutchouc, the author decides that if the conditions prescribed by Harries be accurately followed, Harries' calculation-factor $\frac{136}{284}$ may certainly be accepted as an empirical value, not, however, expressing the actual quantitative production of his "nitrosite-*c*," for which it was originally intended. For the estimation of caoutchouc in vulcanised products, however, the author cannot recommend the nitrosite method unreservedly, although in many cases he uses it for the estimation of the coefficient of vulcanisation with satisfactory results. It possesses a great advantage in enabling the analyst to eliminate all mineral loading materials, by dissolving the nitrosite in acetone and filtering the solution (*cf.* ANALYST, 1911, 158). J. F. B.

Sources of Error in the Folin Method of Estimating Creatinine. A. E. Taylor. (*J. Biol. Chem.*, 1911, **9**, 19-20.)—Personal equation, the absence of a standard light, and the presence of urinary pigment and bile are disturbing factors in this estimation.

Study of the Velocity of Detonation. A. M. Comey. (*Seventh Inter. Cong. App. Chem.*, 1909, Section III, B, 28.)—The velocities of detonation of American "straight" dynamites—*i.e.*, nitroglycerol absorbed in an active dope, gelatine dynamites, "ammonia" dynamites, and nitroglycerol in tubes, are determined by Bichel's well-known method and by the method of Dautriche (*Comptes rend.*, **143**, 641, and **144**, 1030). By the Dautriche method, applied to a row of sticks of dynamite rolled in paper with their ends touching, and detonated at one end, it was found that the velocity was constant for high-grade dynamites (*e.g.*, 5,803 to 5,793 metres per second for dynamite containing 60 per cent. nitroglycerol), increased from the first to the last stick for intermediate grades (4,000 to 4,356 for 33 per cent.), and tended to uniformity again for the lowest grades (3,144 to 3,200 for 27 per cent.). With blasting gelatine the velocity increased rapidly from the point of detonation, reaching a maximum in about 4 inches. The velocity of transmission through air from one stick to another was found generally to vary inversely as the distance, up to a maximum, according to the size of the primer. O. E. M.

Estimation of Essential Oils. C. D. Howard. (*J. Ind. Eng. Chem.*, 1911, **3**, 252.)—It is admitted that the method described previously by the author (ANALYST, 1908, **33**, 236), sometimes gives inaccurate results in the case of certain oils, although it has proved to be of use with such oils as lemon, orange, wintergreen, and peppermint. A modification of the method, has, however, been found to be trustworthy for the analysis of most varieties of essential oil preparations; it involves the application of the principle that when an ethereal solution of an essential oil is evaporated rapidly there is no appreciable loss of oil. The procedure is as follows: Twenty c.c. of the essence in which the essential oil is to be estimated are mixed with 50 c.c. of water and 2 drops of concentrated hydrochloric acid, and shaken out with three successive quantities (15 c.c., 10 c.c., and 5 c.c. of ether). The combined ethereal extracts are washed once with 10 c.c. of water saturated with ether, and then transferred to an ordinary Babcock milk-bottle. The latter is immersed in hot water and the neck is connected with a filter-pump; when most of the ether has evaporated, the bottle is shaken violently and immersed for a few seconds in boiling water until the ether has been completely expelled. Cold water is then added, the contents of the bottle are submitted to centrifugal action, and the volume of the oil is read. W. P. S.

Essential Oil of "False Camphor-Wood"; The Occurrence of Myrtenal and d-Perilla Aldehyde in Nature. F. W. Semmler and B. Zaar. (*Ber.*, 1911, **44**, 815-819.)—"False camphor-wood," of unknown botanical origin, yielded 2.06 per cent. of an essential oil having the constants: $d_{15} = 0{\cdot}958$; $[n]_{D20^\circ} = 1{\cdot}49695$; $[\alpha]_D = +98^\circ 10'$, soluble in 2·5 vols., and over, of 70 per cent. alcohol. This oil, on extraction with sodium bisulphite, yielded up to 75 per cent. of an aldehyde, $C_{10}H_{14}O$. The authors have isolated from the oil two aldehydes of the above formula. The main constituent is extracted by means of sodium bisulphite and is the dextrorotatory isomeride of the perilla aldehyde previously described. The second aldehyde is extracted by means of sodium sulphite, and is identical with myrtenal, hitherto obtained only synthetically. The oil contains, in addition, *d*-limonene and considerable quantities of cineol. Perilla aldehyde has a monocyclic constitution, and myrtenal a bicyclic. They stand, to one another, in the same relationship as limonene stands to pinene. J. F. B.

Analysis of Gelatine. J. Herold. (*Chem. Zeit.*, 1911, **35**, 93-94.)—The melting-points are taken of a 20 per cent. jelly prepared from the sample and of a 20 per cent. jelly made from a mixture of equal parts of pure gelatine and glutose (prepared by heating gelatine and ammonia in a sealed tube at a temperature of 100° C.). The percentage of glutin (x) in the sample is then calculated from the equation $x = 68{\cdot}3a$, where a is the difference in the melting-point.

Glucoside Reactions: Convallarin and Convallamarin. C. Reichard. (*Pharm. Zentral.-h.*, 1911, **52**, 183-188.)—These two glucosides occur in the roots and leaves of *Convallaria majalis*; convallamarin has a similar physiological action to that of digitalin, whilst convallarin acts solely as a purgative. The most characteristic reaction for differentiating the two substances is that obtained with sodium iodate; a mixture of convallarin and sodium iodate when dried yields a white residue which is not affected by hydrochloric acid, whilst the residue obtained in the case of convallamarin consists of a moist amorphous mass which is coloured yellow on the addition of hydrochloric acid. Reactions with numerous other reagents are described.

Estimation of Glycerol. E. Probeck. (*J. Ind. Eng. Chem.*, 1911, **3**, 253-254.)—From his experience with the acetin process as applied to the estimation of glycerol in crude glycerol, the author is of the opinion that the results obtained are from 0·2 to 0·5 per cent. too low. The loss is not due to the presence of impurities, but to the manipulations introducing sources of error. The bichromate method is preferable in the absence of acrolein and other volatile aldehydes; if aldehydes are present, they must be removed before the addition of the bichromate. Instead of removing chlorine and proteins from the crude glycerol previous to the oxidation, the author prefers to apply the bichromate process directly to the glycerol and to make a correction for the amount of chloride, etc. For this purpose, a quantity of the glycerol is neutralised and evaporated at a temperature of 160° C., and the residue is oxidised with bichromate. The quantity of bichromate thus required is deducted from that used for the total oxidation.

W. P. S.

Estimation of Indigotin in the Presence of Starch. W. Thomson. (*J. Soc. Dyers*, 1911, **27**, 49-51.)—In the case of mixtures consisting of synthetic indigo and starch, Rawson's permanganate process (with salt precipitation of the sodium indigotindisulphonate) yields low results. After treating the sample with 4 per cent. hydrochloric acid in order to hydrolyse the starch, and washing away the sugars formed, the process gives better results. Bloxam's tetrasulphonate process yields uniform results.

Estimation of the Acidity of Fats and Oils, particularly Lubricating Oils. H. Loebell. (*Chem. Zeit.*, 1911, **35**, 276-277.)—A mixture of alcohol and benzene is recommended as a solvent for the oil, the end-point of the titration being thus rendered sharp.

Estimation of the Saponification Value of Oils, Fats, and Waxes. Use of Propyl Alcohol. L. W. Winkler. (*Zeitsch. angew. Chem.*, 1911, **24**, 636-638.)—The employment of propyl alcohol in place of ethyl alcohol is recommended in the preparation of the alcoholic potassium hydroxide solution used in estimating the saponification values of fats and waxes; it may also be used as the solvent for the fat or wax in the estimation of the acid value. Warm propyl alcohol is a better solvent for fats than is ethyl alcohol, and, on account of its relatively higher boiling-point, the saponification of even beeswax is completed after ten minutes' boiling.

W. P. S.

Some Constants of Mutton-Bird Oil. L. H. Smith. (*J. Soc. Chem. Ind.*, 1911, **30**, 405.)—The oil carried in the stomach of the mutton-bird (*Aestrelata lessoni*), a petrel peculiar to the Antarctic regions, has the following characters: Sp. gr., 0·8819 to 0·8858 at 15·5° C.; saponification value, 125·9; iodine value (Wijs), 71 per cent.; unsaponifiable matters (alcohols), 36·88 per cent.; m.-pt. of alcohols, 30·5° to 31·5° C. It yields no glycerol, and is therefore not a glyceride but a liquid wax. At 0° C. it solidifies to a translucent mass.

The body-fat of the bird is of a soft consistency and has the following characters: Free fatty acids, 3·5 to 4·3 per cent. (as oleic acid); iodine value (Wijs), 89·1 per cent.; unsaponifiable matter, 1·76 to 2·0 per cent.; sp. gr., 0·9351 to 0·9380 at 15·5° C.; titre test, 29·4° C.

A. R. T.

Detection of Animal Sizing in Paper. Differentiation of Gelatin and Casein. C. Levi. (*Papierfabr.*, 1911, **9**, 365-367; through *J. Soc. Chem. Ind.*, 1911, **30**, 484.)—For the detection of animal size in paper, whether gelatin or casein, the author recommends the biuret reaction. A fragment of the paper is steeped for a few minutes in a 2 per cent. solution of copper sulphate, and is then treated with a

5 per cent. solution of sodium hydroxide, the latter being preferably dropped on the paper. If gelatin or casein be present, a violet coloration is immediately produced. For distinguishing between gelatin and casein in a paper found to contain animal size, the author recommends the xanthoprotein reaction, which is shown by casein, but not by gelatin. A fragment of the paper is moistened with a drop of concentrated nitric acid, and if casein be present an intense yellow stain is produced. This stain turns brown with caustic soda and orange with ammonia. The presence of mechanical wood-fibre vitiates this test, since lignin is also stained with nitric acid. In the case of papers coated with casein the coating may be scraped off, or in cases where the paper cannot be tested direct the casein may be extracted with borax or alkali, precipitated with acetic acid, and the dried precipitate tested with nitric acid or Millon's reagent.

Lubricating Oils for Motor-Cars and Gas-Engines. F. Schwarz and H. Schlüter. (*Chem. Zeit.*, 1911, **35**, 413-415.)—Oils for lubricating the cylinders of explosion motors must not be too viscous, nor have too high an ignition point, and it is essential that the portion which is inevitably consumed in the explosion should not contain too much hydrocarbon to be burned up by the available oxygen. If any carbonaceous residue is left, the gases escaping from the motor cylinders will have a blue-grey colour and an unpleasant odour. For this reason, any admixture of fatty oils to cylinder oils is now, as a rule, avoided. Fractionation of a lubricating oil by means of acetone into lighter and heavier portions will probably afford a means of ascertaining the liability of a cylinder lubricating oil to emit malodorous vapours in use. Thus, by practical tests it was found that the fraction insoluble in acetone produced only grey-white vapour, with a faint, not unpleasant, odour, whereas the original oil and the portions soluble in acetone emitted dirty grey vapours, with the well-known unpleasant odour. The following results are typical of those thus obtained:

	Per Cent. by Weight.	Colour in 15-Mm. Tube.	Sp. Gr. at $\frac{15^\circ}{4^\circ}$ C.	Viscosity, Engler (Water at 20° C. = 1).		Ratio Viscosity, $\frac{20^\circ}{50^\circ}$ C.	Flash-Point (Open Test).	Ignition Point.	Insoluble in Petroleum Spirit after 50 Hours at 50° C.
				at 20° C.	at 50° C.		° C.	° C.	Per Cent.
Motor-car oil	—	Light brown	0·9159	37·7	5·9	6·4	208	259	0·31
Insoluble in acetone	66	Ditto, slightly turbid	0·8959	43·6	6·9	6·3	215	257	0·04
Soluble in acetone, first extract	14	Light brown	0·9657	48·4	6·3	7·7	198	high 241	1·45
Ditto, second extract	12	Ditto	0·9552	43·6	5·7	7·7	191	237	—
Ditto, third extract	8	Brownish-yellow	0·9471	40·1	5·5	7·3	196	246	—

The petroleum spirit used for the estimation of the substances insoluble in petroleum spirit had a sp. gr. of 0·6324 at 15° C., and 93 per cent. passed over between 30° and 50° C. In the author's opinion, the most suitable lubricants for the cylinders of motor-cars are pure mineral oils, with a viscosity of 6 to 13 Engler's degrees at 50° C. (seldom greater). The proportion of paraffin wax should also be low, so as to prevent congealing in winter. Results obtained with representative motor and gas-engine lubricating oils on the market are shown in the following table, the practical tests having been made with motors of different strength:

	Viscosity, Engler (Water at 20°=1).		Sp. Gr. at 15° C. (Water at 4°=1).	Cold Test.	Flash-Point (Pensky-Marten).	Composition.	Behaviour in Practice.
	20° C.	50° C.					
				° C.	° C.		
MOTOR-CAR OILS:							
(a) *Of consistency of machine oil*—							
1	25·0	5·1	0·9077	+5 to 0	193	Pure mineral oil	Satisfactory as cylinder oil
2	68·8	9·6	—	—	224	Ditto	Ditto
(b) *Of medium and high viscosity*—							
3	about 128·0	8·3	0·9078	+15 to +10	65	Ditto	Satisfactory
4	—	9·6	0·8889	—	206	Contained fat	Deposit formed in cylinder
5	—	15·9	0·8996	Semi-solid at 0°	215	Pure mineral oil	Good as cylinder oil
6	—	36·0	0·9011	Ditto	238	Contained fat	Deposit formed in cylinder
GAS-MOTOR OILS:							
7	12·4	3·44	0·9035	—	211	Fat present	Satisfactory
8	70·1	7·8	0·9050	0 to −2·8	202	Mineral oil +2% fat	Unsatisfactory

Gas-engine oils have similar properties to those of motor oils. In one instance a sample gave a residue in the cylinders of the gas-engine, although in other respects it agreed with samples that were satisfactory. The tar value and tar-forming value were low, and the cause was not detected. The formation of a residue, however, is not always to be attributed to the lubricating oil. Thus, the use of coke-furnace gas which has been insufficiently freed from tar oil may lead to the deposition of a tarry residue in the cylinders.

C. A. M.

"Hughes' Reaction" of Potassium Iodide on Paper, and its Bearing on the Question of Acidity. J. Strachan. (*Chem. News*, 1911, **103**, 193-195.)—The author has studied "Hughes' reaction," which is observed when sized paper is moistened with a 20 per cent. solution of potassium iodide and exposed to the action of air free from acid or ammonia vapours, for an hour. Iodine is liberated, which produces a stain (blue when starch is present), more or less intense. The author considers that the occurrence of this reaction is due to the action of the undecomposed alum in the paper, in virtue of its acidity, upon the potassium iodide, and he

considers the presence of sufficient alum to give an intense coloration, according to Hughes' reaction, to be undesirable from the point of view of the permanence of the paper.
J. F. B.

Researches on the Quantitative Analysis of Pentoses and Pentosans, and its Practical Applications. R. Adan. (*Seventh Inter. Cong. App. Chem.*, 1909, Sect. VIII.c, 194-204.)—The gravimetric method of estimating furfural as phenylhydrazone, in the author's hands gave results with pure furfural which are accurate when calculated as xylose or arabinose; but the process is difficult and tedious, and requires a slight but varying correction for solubility of the hydrazone in the washing water. The phloroglucide method was generally employed, and gave results showing a maximum error of 1·5 per cent. when working on pure furfural. The proportion of phloroglucinol to be added to the distillate is double that of the furfural expected. The total volume of the distillate is then made up to 400 c.c. with HCl (sp. gr. 1·6), stirred, allowed to stand until the following day, collected on an asbestos filter, washed with 150 c.c. water, and dried at 98° C. for four hours. A sliding-scale correction has to be employed for the calculation of the result, which is given by Tollens and Gröber. The author has tried a method of estimating the furfural by adding excess of phenylhydrazine, and then measuring the nitrogen evolved from the uncombined phenylhydrazine in presence of copper sulphate, and thus by difference determining the amount required to combine with the furfural; but this, though applicable to pure solutions of phenylhydrazine, does not work well in presence of sodium chloride, and had to be abandoned.

In order to investigate the percentage of shell in cocoa-powder, the pentosans in both nibs and shell were estimated, using the distillation method of Tollens, and precipitating the furfural with phloroglucinol as described by König, "Untersuchung Landwirthschaftliche u. Gewerbliche Stoffe," 3rd ed., 1906. Two to 2·5 grms. were finely powdered and defatted. It was found from the mean of all analyses that 100 grms. of entire cocoa-bean gave 45 grms. of dry fat-free material, or 75 grms. of cocoa with 30 per cent. fat.

AVERAGE ANALYSIS OF SHELLED COCOA GRAINS.

Moisture.	Fat.	Starch.	Ash.	Cellulose.	Pentosans.			
					Grains.		Shells.	
					Initial Substance.	Powder with 30% Fat.	Dry Substance.	Substance with 10% Moisture.
6·43	44·44	8·22	4·00	4·78	1·53	2·47	9·96	8·21

AVERAGE COMPOSITION OF SIX COCOA POWDERS.

Moisture.	Fat.	Ash.	Cellulose.	Pentosans.	
				Initial Substance.	Powder with 30% Fat.
0·88	53·86	3·33	2·95	1·61	3·40

The wide variation between the percentage of pentosans in cocoa grains and that in shells—viz., 1·53 and 9·96—can be made the basis of an estimation of the quantity of the latter present in the finished article. H. F. E. H.

Technical Analysis of Petroleum Asphalt. D. Lohmann. (*Chem. Zeit.*, 1911, **35**, 357-358.)—The author claims that the analytical side of the asphalt industry is more fully developed in America than in Europe, and gives a blank form of the determinations usually made in this connection. The "penetration" test is made with Dow's apparatus, in which the penetration of a standard needle loaded with a standard weight is measured in tenths of a mm. at different temperatures. The penetration is an indication of the hardness, and to a certain extent of the ductility. The fixed carbon is determined by driving off the volatile matters in a covered crucible of standard dimensions with a standard flame. The sulphur is estimated in the calorimetric bomb of Mahler with oxygen under a pressure of 25 atmospheres, by absorption of the gases of combustion. The ductility is measured in an apparatus devised by Dow and Smith. A piece of asphalt, cast in a mould, is tested at a temperature of 77° F. by fixing one end and drawing out the other horizontally until the thread breaks. The test is performed under water, the speed of drawing is 5 cm. per minute, and the length of the thread is measured in cm. The ductility and penetration tests are the most important factors in the technical valuation of asphalt. A material of moderate hardness and inferior ductility would be quite unsuitable for street paving, at any rate if used alone. An asphalt of high ductility generally shows the greatest differences in the penetration tests at different temperatures. It is generally insisted that a petroleum asphalt should consist of nearly pure bitumen, soluble in carbon bisulphide up to a fraction of 1 per cent., and soluble within a few per cent. in carbon tetrachloride; thus it differs considerably from most natural asphalts. The solubility in petroleum spirit of sp. gr. 0·700 affords an indication whether a petroleum asphalt has suffered considerable decomposition during distillation, decomposed samples being less soluble in this spirit. The solubility, for the same reason, also bears a relationship to the ductility and the alteration of hardness with temperature. The percentage of sulphur appears to have no influence on any of the technically valuable properties. J. F. B.

Action of Iodine on Phenols and their Volumetric Determination. (Part I.). J. M. Wilkie. (*J. Soc. Chem. Ind.*, 1911, **30**, 398-402.)—The author reviews the various methods which have been proposed for the determination of phenol, salicylic acid, and β-naphthol by means of standard bromine and iodine solutions. As regards Messinger and Vortmann's method (ANALYST, 1891, **16**, 75), it is pointed out that good results are only obtainable when the proper proportions of the phenol, alkali, and iodine are present, and details of the method of working are given. Sodium carbonate is recommended as the alkali (in the cases of phenol and salicylic acid) instead of caustic soda. In the case of phenol and salts of salicylic acid, again, it is shown that the products of the action of iodine are two—namely, tri-iodophenol after a short period (five minutes), and, on long standing in contact with the reagent, tetra-iodo-diphenoquinone. With β-naphthol, a practically quantitative yield of 1·2 iodo-oxy-naphthalene is obtained when its aqueous solution is treated with $\frac{N}{10}$ iodine in the cold. With more sodium hydroxide than is necessary to form the sodium salt, the crystalline product is not produced, but the green amorphous substance described by Messinger and Vortmann (*loc. cit.*).

A. R. T.

Sensitive Test for Phenol and Salicylic Acid. J. M. Wilkie. (*J. Soc. Chem. Ind.*, 1911, **30**, 402-403.)—Although the sensitiveness of the tribromophenol method for these substances is limited by the considerable solubility of this derivative, as pointed out by Allen ("Com. Org. Analysis," vol. ii., part 2, p. 244) and confirmed by the author, the tri-iodo-phenol precipitates are not so soluble, and they thus provide a more delicate test for the presence of phenol and salicylic acid. The limit of sensitiveness of the reaction in the case of bromine-water is about 1 in 60,000; while in the case of iodine solution a precipitate is produced after one hour with solutions of salicylic acid of about 1 in 870,000 dilution, and of about 1 in 1,250,000 for phenol. The substance to be tested is treated with $\frac{N}{10}$ iodine and $\frac{N}{10}$ sodium carbonate, and allowed to stand for five minutes, when a slight excess of $\frac{N}{1}$ sulphuric acid is added. Amounts of phenol equal to 2 and 4 parts per million show the crystalline precipitate within five minutes, and 1 per million in about one hour, after the addition of the acid. The acid should be added within an hour of the commencement of the reaction, or a negative result may be obtained in the presence of the substances sought.

A. R. T.

Stability Tests of Smokeless Powder. G. W. Patterson. (*Seventh Inter. Cong. App. Chem.*, 1909, Section III.B, 99.)—The paper relates entirely to single base powders. The author considers it impossible to predict the life of a powder; if it shows a present wide margin of safety it is relatively safe. He describes modified forms of the German 135° C., and Vieille 18·5° C. tests, and gives details of his surveillance test. This consists in heating a standard weight of powder, about 45 grms., in an 8-oz. glass-stoppered bottle at 65·5° C., until red fumes appear. The number of days required is the index of stability. At 80° C. the time required is roughly a quarter of that at 61·5°.

O. E. M.

Experiments on the Precipitation of Proteins. A. J. J. Vandevelde. (*Bull. Soc. Chim. Belg.*, 1911, **25**, 166-173.)—By fractionally precipitating the proteins of milk by means of varying quantities of acetone, methyl alcohol, and ethyl alcohol in the presence of acetic acid, and then estimating the amounts of proteins in solutions of the precipitates, the author shows that the treatment to some extent transforms the proteins from one form to the other. Similar results were obtained in the case of beef serum, egg albumin, etc.

Influence of Certain Compounds upon the Colour Reactions of Strychnine. E. Mameli. (*Gazz. Chim. Ital.*, 1911, **41**, 329-334.)—The characteristic colour reactions given by a sulphuric acid solution of strychnine with potassium bichromate and with ammonium vanadate are masked completely by certain substances which include phenol, anethol, phenetole, β-naphthol, β-naphthyl salicylate, benzonaphthol, and dulcine. Acetonylacetone and salol have the same effect upon the bichromate reaction, but only when present in considerable quantity do they interfere with the vanadate reaction, causing the coloration to become green. In the presence of a large excess of strychnine the colour is violet instead of green. Aniline, acetic acid, tartaric acid, stovaine, and urotropine do not interfere with the vanadate reaction, but weaken, and, if present in sufficient quantity, prevent the bichromate reaction. Zinc lactate and orthotoluidine inhibit the bichromate reaction and weaken the vanadate reaction, which is also rendered fugitive by the presence of quinoline and terpene. Otto's (bichromate) reaction is not materially affected by piperonal, lecithin, and papain, but the coloration in the vanadate reaction is modified and rendered fugitive by their presence. Antipyrin, aspirin, menthol, analgin, and salicylic acid mask the bichromate reaction when present in sufficient excess, whilst in the ammonium vanadate test they give a fugitive green coloration (stable in the case of salicylic acid). The characteristic strychnine reactions are modified or retarded by an excess of citric acid, pyperonylic acid, quinine, glucose and mannitol. On the other hand, the colorations given by the anilides (acetanilide, benzanilide, etc.) with potassium bichromate may be readily distinguished from the violet coloration given by strychnine, and do not mask the latter. Among the numerous therapeutic agents that do not mask the strychnine reactions are caffeine, salophen, theobromine, saccharin, saligenin, sulphonal, trional, tetronal, veronal, and antithermin. For the separation of strychnine from the various organic compounds the author makes use of the fact that it is nearly insoluble in cold water, absolute alcohol, and anhydrous ether, scarcely soluble in boiling water (1 : 2,500), sparingly soluble in 90 per cent. alcohol (1 : 107), in benzene (1 : 165), in carbon tetrachloride (1 : 155), in amyl alcohol (1 : 180), and in glycerol, petroleum spirit, and carbon bisulphide; whilst, on the other hand, it is readily soluble in chloroform (1 : 7). A good method is to extract the mixture with chloroform, to evaporate the extract, and to treat the dry residue with anhydrous ether, which will remove the bulk of the substances that would interfere with the test for strychnine. C. A. M.

Estimation of Sulphur by the Method of Carius. G. Anelli. (*Gazz. Chim. Ital.*, 1911, **41**, 334-341.)—Estimation of sulphur by the method of Carius, as used by Peratoner (*Chem. Zentralbl.*, 1909, **1**, 479)—viz., heating the sample at 180° to 200° C., for four to eight hours with fuming nitric acid in a sealed tube—is shown to give results invariably too high. Thus, estimations of the sulphur in samples of pure sulphur and mixtures of sulphur and bitumen gave results ranging from 101 to 106 per cent. of the theoretical amount. This was found to be due to the action of the sulphuric acid, formed in the reaction, upon the silica in the glass, and the subsequent precipitation of the silicic acid as barium silicate. This may be obviated by placing barium nitrate in the tube, so that the sulphuric acid is precipitated as soon as it is formed. C. A. M.

Estimation of Theobromine and Caffeine in the Presence of Each Other.

C. Monthulé. (*Ann. Chim. anal. appl.*, 1911, **16**, 137-138.)—When a mixture of theobromine and caffeine is extracted with petroleum spirit, it is often difficult to dissolve the whole of the caffeine, especially when alkalis are present. This difficulty may be obviated by the use of the following modification of Kunze's method, in which the ammoniacal solution of the alkaloids is neutralised with acetic acid, so as to obtain a gelatinous precipitate containing the whole of the theobromine, whilst the caffeine remains in solution. The weighed quantity (0·2 grm.) of the mixed alkaloids is dissolved in a little ammonia solution in a 100 c.c. flask, and the solution treated with 20 c.c. of $\frac{N}{10}$ silver nitrate solution, any precipitate that forms being dissolved by the addition of more ammonia. The liquid is diluted, neutralised with acetic acid (with phenolphthaleïn as indicator), made up to 100 c.c., and filtered. Half of the filtrate is titrated with $\frac{N}{10}$ thiocyanate solution by Volhard's method to obtain the amount of uncombined silver. The percentage weight of theobromine is calculated by means of the formula $(10 - n) \times 16·6$, where n represents the number of c.c. of thiocyanate solution. Obviously the method is not applicable in the presence of chlorides, bromides, iodides, etc. The amount of caffeine may be found by evaporating another portion of the filtrate upon the water-bath in the presence of sodium chloride, and extracting the residue with chloroform. C. A. M.

Use of Temperature Corrections in the Polarisation of Raw Sugars and Other Products upon Quartz Wedge Saccharimeters.

C. A. Browne. (*Seventh Inter. Cong. App. Chem.*, 1909, Section V., 115-141.)—As the result of a great number of determinations, and from theoretical consideration of the effect of temperature on the specific rotation of sucrose and lævulose, and on the polarisation of mixtures of sucrose and sugar cane molasses, the author concludes that no temperature correction can be applied which will be of satisfactorily general significance for all types of commercial sugar products. Any temperature correction which is embodied in the adjustment of the saccharimeter—*e.g.*, to make an instrument adjusted at 20° C. give the same results as one adjusted at 30° C., when both are used at their specified temperatures—can only be valid for solutions of approximately pure sucrose. No such correction can take into account the influence of temperature on the specific rotation of the impurities, varied in their nature and amount, present in all types of raw products. Even if a correction table were drawn up for a certain type of raw sugar, its indications would be false for other sugars equally impure but varying from the average type. If temperature corrections are to be legitimately applied, it will be necessary to correct for changes in the specific rotations of all the ingredients present in the sample. Consequently for accurately comparative work, all sugar laboratories should be provided with means for warming or cooling the solutions to be examined to a standard uniform temperature throughout the year. J. F. B.

Estimation of Ash in Sugar and Syrups by the Determination of Electrical Conductivity. H. Main. (*Seventh Inter. Cong. App. Chem.*, 1909, Section V., 66-68.) — Considering sugar as a non-electrolyte, the electrical conductivity of its solutions may be regarded as a quantitative function of the salts present. The author has based a method for the estimation of ash in sugar on measurements of the resistances of solutions by Kohlrausch's method. The cell in which the resistances are measured should be fitted up on the "continuous" principle, like the continuous polarisation tube. Resistances are measured with the aid of a resistance-box, a "bridge" and a telephone. Although theoretically the sugar has no conductivity, practically the concentration of the sugar solution has an influence which may be eliminated by examining solutions of approximately the same density. The method is standardised against the incineration method for various types of sugar products, on the assumption that the relations between the constituents of the ash are the same for samples of the same type. For sugars containing 2 to 5 per cent. of ash, 5 grms. are dissolved to 100 c.c.; in the case of molasses the syrup is diluted to a density of 33° B. and 2 grms. are dissolved to 100 c.c. The method is stated to give satisfactory results when the percentage of ash is calculated from the standardisation-factor for the corresponding type of sugar product. J. F. B.

Estimation of Reducing Sugars. S. R. Benedict. (*J. Biol. Chem.*, 1911, **9**, 57-59.)—The following solution is recommended for use in place of Fehling's solution in the volumetric estimation of reducing sugars: Copper sulphate, 18; sodium carbonate, 200; potassium thiocyanate, 125 grms.; 5 per cent. potassium ferrocyanide solution, 5 c.c.; and water up to 1 litre. Twenty-five c.c. of this solution are reduced by 0·05 grm. of dextrose or by 0·053 grm. of lævulose. The cuprous oxide is not precipitated owing to the presence of the ferrocyanide, and the disappearance of the blue colour indicates the end-point of the titration.

Methods for Testing Coal Tar and Refined Tars, Oils, and Pitches derived therefrom. S. R. Church. (*J. Ind. Eng. Chem.*, 1911, **3**, 227-233.)—Methods are described in detail, and all the apparatus is illustrated by drawings, many of which are drawn to scale. The methods cover the determination of the sp. gr. and viscosity of tar as well as the estimation in it of moisture, free carbon, fixed carbon, and ash. An additional sulphonation test for creosote oils is also described.

G. C. J.

Estimation of Tarry Substances in Dark Mineral Cylinder Oils. D. Holde and G. Meyerheim. (*Chem. Zeit.*, 1911, **35**, 369-370.) In estimating the tarry substances in dark mineral cylinder oils by treating the sample with a mixture of alcohol and ether, and subsequently removing the paraffin wax from the insoluble residue by means of alcohol, erroneous results are liable to be obtained unless the washing is continued for a very long period. This may be obviated by extracting the mixture of tarry substances and paraffin wax in a cartridge suspended in a flask beneath a reflux condenser. About 5 grms. of the well-mixed sample are dissolved in about 25 times the volume of ether, and the solution is treated, drop by drop with continual shaking, with 12·5 times the volume (calculated upon an oil of sp. gr. 0·91) of 96 per cent. alcohol. After a thorough shaking, and having stood for five hours in the closed flask at 15° C., the liquid is filtered, the insoluble residue washed with alcohol-ether (1 : 2) until the washings are free from oily particles, and dissolved in benzene, the solution evaporated, and the residue of tarry matters and paraffin wax dried for ten minutes at 105° C. and weighed. It is then dissolved in 10 c.c. of ether, the solution mixed with about 2 grms. of dry coarse pure bone charcoal (previously extracted with alcohol) and about 10 to 15 grms. of coarse ignited sand, and the ether evaporated. The mass is now introduced into an extraction cartridge, and extracted with boiling absolute alcohol (as described above) until paraffin wax is no longer extracted. The alcoholic extract is evaporated, the residue dried for ten minutes at 105° C., and the weight of the paraffin wax deducted from the combined weight of the paraffin wax and tarry matters previously obtained. C. A. M.

New Method of Estimating Tar and Tar Contituents in Gas. W. Feld. (*J. Gasbeleucht.*, 1911, **54**, 33-35; through *Chem. Zentralbl.*, 1911, **1**, 693.)—The gas, in which it is desired to estimate the amount of tarry substances which will be deposited from the gas at any given temperature, is passed through a series of U-tubes packed with cotton-wool, and previously dried and weighed. The tubes are supported in a water-bath at the required temperature during this part of the operation, and the tarry matters collected on the cotton-wool are then dried by passing the same gas through the tubes after this gas has been dried. As it is already saturated with tarry matters, the gas will now only remove water from the tubes.

W. P. S.

INORGANIC ANALYSIS.

Precipitation of Aluminium Hydroxide in Granular Form. W. E. Taylor. (*Chem. News*, 1911, **103**, 169.)—A recently-described method for obtaining a granular precipitate of alumina by the use of a potassium iodide and iodate mixture, is mentioned by the author, who, however, finds that the simplest and most satisfactory mode of operating is to precipitate the aluminium hydroxide by means of ammonia at a temperature of 66° C. The solution may subsequently be boiled before filtration, the precipitate being granular and filtering rapidly. A. R. T.

Volumetric Method for Antimony in Alloys. G. S. Jamieson. (*J. Ind. Eng. Chem.*, 1911, **3**, 250-251.)—The drillings are heated with 10 c.c. concentrated sulphuric acid until the alloy is decomposed. After the lead sulphate has become white, the solution is boiled for two minutes, and then cooled and diluted with 15 c.c. of water. When cool again, 15 c.c. of hydrochloric acid (1 : 1) are added, the mixture shaken well, and the lead sulphate filtered off on a Gooch crucible and washed with small quantities of hydrochloric acid (1 : 1). The filtrate is transferred to a 250 c.c.

stoppered bottle, and 5 c.c. chloroform, 15 c.c. of concentrated hydrochloric acid, and 5 c.c. of iodine monochloride solution, are added. The mixture is shaken, allowed to stand five minutes, and the liberated iodine then titrated with standard potassium iodate solution (*cf.* Andrews, ANALYST, 1903, **28**, 306) until the chloroform is just decolorised after thorough shaking, which should be repeated in about a minute to make sure of getting the true end-point. The iodine monochloride solution is prepared by dissolving 10 grms. potassium iodide and 6·44 grms. potassium iodate in 75 c.c. of water, adding 75 c.c. of concentrated hydrochloric acid and a drop of chloroform, and adjusting exactly to faint iodine colour by shaking and adding dilute potassium iodide or iodate, as the case may require. Neither copper nor iron interferes. The final titration must take place in acid of at least 15 per cent. strength, as shown by Andrews (*loc. cit.*). G. C. J.

Attempts to Prepare a Solid Hydride of Antimony. H. Reckleben and J. Scheiber. (*Zeitsch. anorg. Chem.*, 1911, **70**, 275-281.)—Attempts were made to prepare a solid hydride of antimony in the manner in which its preparation has been described by Ruhland (1815) and Marchand (1845), and by methods analogous to those which give rise to the solid hydride of arsenic. The products were analysed by a method similar to that employed by the same authors in the investigation of the solid hydride of arsenic (see next abstract), but using, instead of silver nitrate, iodine solution, which could not be used in the arsenic research because it did not dissolve the arsenic precipitates quickly enough. The products were in every case found to consist of nearly pure antimony, and no evidence was obtained which would justify the assumption that any solid hydride of antimony, analogous to that of arsenic, exists.

The so-called "explosive" antimony (a solid solution of antimony chloride in a metastable modification of metallic antimony) was investigated, as it has been suspected that this substance might contain a solid hydride, but the result was again negative. G. C. J.

Detection of the Solid Hydride of Arsenic. H. Reckleben and J. Scheiber. (*Zeitsch. anorg. Chem.*, 1911, **70**, 255-274.)—Though an alleged solid hydride of arsenic was described nearly 100 years ago, and has been the object of many researches since, its formula and even its existence have been a matter of doubt until the present research was undertaken. The formula As_2H_2 is that most often given in modern textbooks, but results have been published which seemed to point to the formula As_2H or AsH_2. The arsenic content of any of these compounds is so near 100 per cent. that the experimental error of an arsenic determination precludes it as a means of determining the formula. Oxidation of the compound followed by weighing the water formed is unsatisfactory, as the compound is usually the product of a reaction in aqueous solution, and all authors agree that it is difficult to obtain it dry without risk of decomposition. Liberation of the hydrogen followed by its measurement is also unconvincing, as the product is never free from elementary arsenic, which may conceivably reduce some water adhering to an imperfectly dried product. The present authors have made use of the reducing power of the compound compared with its arsenic content. The oxidising solution used was an ammoniacal solution of silver nitrate. One atom of arsenic reduces 5 atoms of silver, one molecule of AsH should reduce 6 atoms of silver, whilst one of AsH_2 should reduce 7 atoms of silver. In no case did the silver-arsenic ratio exceed 6 : 1, so that the formula AsH_2 seems excluded. On the other hand, in many preparations the ratio was notably less than 6 : 1, but never so low as 5·5 : 1, the ratio which would correspond to the formula As_2H. There was evidence that the material examined always contained some elementary arsenic, and the authors conclude that they are justified in assuming that their preparations were mixtures of AsH (or As_2H_2) with elementary arsenic, and in calculating the proportions of this binary mixture from its reducing power.

It is suggested that the method may be useful in the analysis of other mixtures of two, but not more than two, reducing substances of different reducing power.

G. C. J.

Proportion of Lead Arsenate in the Products of Vines treated with Arsenical Washes. L. Moreau and E. Vinet. (*Comptes rend.*, 1911, **152**, 1057-1060.)—In the case of vines treated before the flowering period with lead arsenate washes, the quantity of lead arsenate adhering to the grapes at the vintage period is very small, and a large proportion thereof is eliminated during the pressing and fermentation. Hence, only insignificant traces of lead and arsenic will be present in the wines, comparable with those found in wines from vines that have never been treated with arsenical washes. If, however, the vines are treated at a later period, a considerable proportion of lead arsenate will be taken up by the must, and will be found in the finished wine. Thus, in an experiment made by the authors, the vine was treated with the arsenic in August, and the following amounts of lead arsenate were found in the wine and various residues:

	Grapes.	Fresh Marcs.	Sediment after Fermentation.	Lees of First Racking.	Lees of Second Racking.	Wine from Second Racking.
Weight corresponding to 1 hl. of wine, kilos. ...	153·7	37·3	6·2	1·7	1·5	1 hl.
Lead arsenate, grms. ...	7·165	6·117	0·582	0·115	0·015	0·414

C. A. M.

Sulphite Method for Separating and Identifying Calcium and Strontium. J. I. D. Hinds. (*J. Amer. Chem. Soc.*, 1911, **33**, 510-514.)—When a saturated solution of sodium sulphite is added to a solution of strontium chloride made strongly acid with acetic acid and the mixture boiled, a distinct precipitate results if the strontium concentration exceeds 0·0015 normal. Calcium sulphite is not very soluble in water, but in solutions made strongly acid with acetic acid it is not precipitated until the concentration approximates 1·3 normal. Strontium sulphite is even less soluble in neutral or alkaline than in acetic acid solution, but the difference in solubility of strontium and calcium sulphites is most marked in solutions made strongly acid with acetic acid. G. C. J.

Estimation of Copper by Means of Hypophosphorous Acid. J. Hanůs and A. Soukup. (*Zeitsch. anorg. Chem.*, 1911, **70**, 282-293.)—The apparently accurate results obtained when the Mawrow-Muthmann method (*Zeitsch. anorg. Chem.*, 1896, **11**, 268) is applied under favourable conditions depend on an approximate compensation of errors which are individually large and which may be very far from being mutually compensating. The positive error is mainly due to the oxidation of the separated copper, the negative error to incomplete precipitation, and sometimes to re-solution of the separated and oxidised copper. The precipitation is never quantitative, and the quantity of copper remaining in solution depends on the concentration of hydrion, on the time of contact of the copper with air, and of the oxidised copper with the acid solution. The concentration of hydrion is conditioned by the reaction itself, the excess of hypophosphorous acid and its purity, and finally, when sodium or magnesium hypophosphite is used, by the amount of acid used to accelerate the reaction. Only by repeated, cautious neutralisation can satisfactory results be obtained. Prolonged boiling must also be avoided, otherwise some of the hypophosphorous acid will be oxidised. The use of sodium acetate or tartrate to reduce the concentration of hydrion is without measurable influence on the results. The method cannot be made exact, and is unsuited to the separation of copper from cadmium, zinc, and other metals. G. C. J.

Dangers connected with the Storage and Transport of Ferrosilicon. C. Göpner. (*Chemische Industrie*, 1911, **34**, 31-38 and 64-72.)—An abstract of Copeman's report to the Local Government Board. It has been stated by various observers that, when acted on by water or moist air, ferrosilicon may give rise to hydrogen, acetylene, and the hydrides of phosphorus and arsenic, as well as that of silicon. Hake, who analysed the gases from some seventy samples collected by Copeman, found no trace of acetylene or silicon hydride. Hydrogen, as non-poisonous, was not looked for. The hydrides of phosphorus and arsenic were estimated in every case in which a qualitative examination showed their presence. Of the sixteen samples with 35 per cent. or less silicon, only two gave rise to a detectable trace of phosphoretted hydrogen, and none of these samples yielded any arseniuretted hydrogen. Most of the samples with 42 per cent. or more silicon gave rise to quantities of phosphoretted hydrogen which could be estimated gravimetrically, and many of them to notable amounts of arseniuretted hydrogen. Since the ratio of the volume of the former gas to that of the latter was invariably of the order of 10 : 1, it may be assumed that the chief danger of ferrosilicon lies in the risk of evolution of phosphoretted hydrogen. It is well known that the explosions which have occasionally accompanied the transport of ferrosilicon have been in every case caused by material of medium (40 to 60 per cent.) silicon content, and it has been said that material with more or less silicon than 60 or 40 per cent. respectively is safe as regards evolution of poisonous gases. Hake's results tend to confirm the view that low-grade ferrosilicons are not a source of danger, but the same cannot be said of the very high-grade ones. It is, however, noteworthy that the largest quantities of poisonous gases were obtained from samples containing 42 to 52 per cent. of silicon. Hake's analytical methods are described. Phosphoretted hydrogen was estimated either by passing it through a 0·5 per cent. solution of gold chloride and weighing the reduced gold, or by passing it through a measured quantity of $\frac{N}{10}$ silver nitrate, and then proceeding in one of the following ways: either the solution was filtered from silver phosphide, and the excess of silver in the filtrate determined by Volhard's method, or the silver phosphide was oxidised by means of nitric acid, the nitric acid removed by evaporation, silver precipitated by means of hydrogen sulphide, and the phosphoric acid in the filtrate finally obtained as magnesium pyrophosphate. The three methods give concordant results, and the volumetric method alone was employed in many experiments. Arseniuretted hydrogen was estimated by leading the gases through a solution of silver nitrate, filtering from silver phosphide, and adding the filtrate to a Marsh apparatus. The paper ends with a literal translation of Copeman's recommendations, which include the suggestion that ferrosilicon should not be packed or despatched from the works of its origin until a month after breaking to the customary size, and the further suggestion that sufficient hay or other packing material be used to prevent any movement of the contents of the barrels. G. C. J.

Estimation of Fluorine. G. Starck. (*Zeitsch. anorg. Chem.*, 1911, **70**, 173-177.)—The method described depends on the comparative insolubility of the compound PbFCl in water, and its still more marked insolubility in solutions of lead chloride. It is more soluble in dilute acids than in water. A solution of a fluoride is therefore first neutralised, and then mixed with a large volume (200 c.c.) of a nearly saturated solution of lead chloride, and the mixture allowed to stand overnight. The precipitate, which weighs fourteen times as much as the fluorine contained in it, is filtered off on a Gooch crucible, well washed with lead chloride solution, and finally washed three or four times with a small quantity of water. It is dried at 140° to 150° C. for two hours and weighed. At 18° C., 100 c.c. of water dissolve 32 mgrms.; 100 c.c. of $\frac{N}{20}$ lead chloride solution dissolve 0·2 mgrm. Quantities like 0·03 grm. of fluorine, corresponding to about 0·4 grm. of the lead compound, can be estimated with an error not exceeding ± 1 per cent. G. C. J.

Quantitative Analysis of Gold with the Use of Ether. F. Mylius. (*Zeitsch. anorg. Chem.*, 1911, **70**, 203-231.)—The author proposes to take advantage of the solubility of gold chloride in ether as a means of separating gold from other metals. The aqueous solution of gold should be strongly acid with hydrochloric acid, as the gold then exists as $HAuCl_4$, which is more soluble in ether and less soluble in water than gold chloride. The presence of a little nitric acid is also an advantage, so that a solution of the metal in aqua regia, after dilution until the concentration of hydrogen chloride is about 10 per cent., may be submitted to extraction at once without the necessity for eliminating any of the acid. When the gold needs only to be estimated accurately to within ± 0·1 per cent., four or five extractions with ether complete the analysis. But it is shown that the method may be employed to increase the accuracy as well as to diminish the tediousness of the most accurate class of work required at a mint. In such cases the ether process is made use of to separate the bulk of the gold from all the other metals. These and traces of gold are then recovered from the acid-aqueous solution by the usual methods. Special apparatus for conducting the ether extractions is described, and detailed directions are given for making a complete analysis of gold coinage. Test analyses of the gold coins of eight countries are given, and in every case, save two, the percentage of gold found was 90·000 per cent. The exceptions were English sovereigns and some old Russian coins which complied exactly with the English standard of 91·667 per cent.

Incidentally it is shown that the ether method affords the most ready means of preparing normal gold of the highest grade of purity. G. C. J.

The Influence of Pertitanic Acid on the Estimation of Iron in Minerals. E. Knecht and E. Hibbert. (*J. Soc. Chem. Ind.*, 1911, **30**, 396-397.)—The direct volumetric estimation of ferric iron in presence of titanic salts presents no difficulty if any of the usual reduction methods are employed, but if a fusion, in the case of refractory minerals, has been made, erroneous results may be obtained. Thus, minerals like rutile and ilmenite are only slowly attacked by fusion mixture, though they are readily and completely resolved by fusing for ten minutes with potassium hydroxide in a nickel crucible; if then the melt be taken up with water and the solution strongly acidified with hydrochloric or sulphuric acid, both the iron and titanium pass into solution, and an orange coloration of the liquid is produced, due to the presence of pertitanic acid (TiO_3). This pertitanic acid, if not first destroyed, causes high results in the titration of the iron. Larger amounts of pertitanic acid are produced in the case of nickel vessels than when silver vessels are used. The authors propose to overcome this interference with the method by running into the sulphuric acid solution permanganate solution till a faint permanent pink coloration is obtained. Pertitanic acid then acts like hydrogen peroxide, being completely reduced to titanic oxide, with evolution of oxygen. The titration of the iron in the solution, in presence of potassium sulphocyanide, by means of titanous chloride is then proceeded with as usual. The amount of pertitanic acid formed in these fusions is very considerable, nearly 15 per cent. of pertitanic acid, calculated on the titanic oxide present, being produced in one case. Its formation is independent of the presence of iron. A. R. T.

Method for Testing Galvanised Iron to Replace the Preece Test. W. A. Patrick and W. H. Walker. (*J. Ind. Eng. Chem.*, 1911, **3**, 239-242.)—The so-called Preece test consists in placing the test piece of galvanised iron in a solution of copper sulphate under standard conditions, and observing the number of one-minute immersions which can be made before copper in a bright adherent form will plate out on the article. It assumes that the galvanised coating is homogeneous, and that no bright copper will be seen until the iron base is uncovered. Neither of these assumptions is justified. Galvanised coatings usually include a well-defined layer of iron-zinc alloy between the iron base and the outer layer of pure zinc. The rate of solution of this alloy is very different from that of zinc, and under certain conditions bright copper may be deposited on the alloy long before the iron base is exposed. Moreover, the ratio of the thickness of the alloy to that of the whole coating may vary within wide limits. In some wet galvanised (electro-deposited) sheet the alloy may be represented by an insignificant film. In other sheets made by the same process, and in all "Sherardised" plate, the alloy forms a comparatively thick and well-defined layer. In hot-dipped sheet it forms a well-defined but usually thin layer.

The following method is recommended in substitution for the Preece test: The test piece is immersed for three minutes in a solution of basic lead acetate. The adherent lead is removed by a stiff brush, avoiding any burnishing action, and the immersion and brushing repeated until a bright surface of iron is exposed. Four immersions of three minutes each usually suffice. The coating is determined either from the loss in weight of the test piece or from the weight of reduced lead, which is either weighed as such or dissolved and estimated by a volumetric method. Since as much as 10 per cent. of the coating may be iron alloyed with zinc, the iron passing into solution as acetate should be estimated. Samples of weathered galvanised goods must be cleaned in dilute hydrochloric acid before testing. The basic lead acetate solution is made by shaking together 400 grms. lead acetate, 4 grms. litharge, and 1,000 c.c. water. The clear solution is decanted from any insoluble residue and diluted to a sp. gr. of 1,275. Such a solution dissolves zinc-iron alloys, but does not attack iron. G. C. J.

Estimation of Manganese by the Bismuthate Method. P. H. M. P. Brinton. (*J. Ind. Eng. Chem.*, 1911, **3**, 237-239.)—The conclusion of other workers is confirmed that, for the estimation of small amounts of manganese, the bismuthate method is the most accurate known. When the permanganate is standardised against oxalate or iron, manganese is sensibly underestimated. A gravimetrically standardised solution of manganese sulphate is the correct primary standard; but, as this method is less convenient than the sodium oxalate method, it is suggested that pure Sörensen sodium oxalate be used, and that the calculated manganese titer be corrected in accordance with the results published in the present paper. The theoretical value of the ratio 5 $Na_2C_2O_4$: 2 Mn is 1 : 0·16024. It is shown that the empirical factor 0·1656 is to be preferred in calculating the manganese titer of the permanganate. G. C. J.

Estimation of Soluble Mercuric Salts at Great Dilutions. H. R. Procter and R. A. Seymour-Jones. (*J. Soc. Chem. Ind.*, 1911, **30**, 404.)—The method was devised for the determination of quantities of mercuric chloride as small as 1 part in 100,000 of water, and takes advantage of the fact that certain organic acids (such as formic and citric) prevent the precipitation of mercuric sulphide, this compound remaining in the coloured colloidal form in solution on treatment with hydrogen sulphide. The coloration produced is perfectly definite for prescribed concentrations of the mercuric chloride and acid if the liquid has been saturated with hydrogen sulphide, and is directly proportional to the concentration of the original mercuric chloride solution. Thus, when certain thicknesses of liquid are examined and compared with a standard, using a Schmidt and Haensch "dipping colorimeter" (*J. Soc. Chem. Ind.*, 1910, **29**, 663), a solution of half the strength will require to be twice the thickness to produce the same colour. A standard solution containing 1 part of mercuric chloride by weight in 10,000 of water, and 1 per cent. by weight of formic acid, is saturated with hydrogen sulphide gas and placed in a standard 1 c.c. cell on the upper platform of the colorimeter. Against this standard colour all solutions of lower concentration may be matched. The mercuric solution of unknown strength is made into a 1 per cent. formic acid solution, similarly treated with hydrogen sulphide and run into the dipping cylinder of the colorimeter. The dipping stage is then adjusted till the field of view in the telescope is of a uniform colour, when the depth of solution is read off and its strength calculated, the depth of the standard liquid being 10 mm. It is possible to distinguish by this method between 76 and 77 parts of mercuric salt per 100,000. Small quantities of arsenic and lead may be similarly determined, suitable standards being prepared. Lovibond standard glasses may be used instead of a liquid standard, the glasses being matched with the prepared standard in the usual way. A. R. T.

Quantitative Analysis of Mixtures by Differences in the Specific Gravities of their Components. H. Friedenthal. (*Ber.*, 1911, **44**, 904-909.)—In many cases, especially in physiological analysis—*e.g.*, of blood, milk, wine, gall, etc.—a quantitative separation of the constituents may be effected by evaporating the substances to dryness, reducing to a fine powder, and separating the components by the differences between their specific gravities. With mixtures of bromoform, sp. gr. 2·90, and xylene, sp. gr. 0·70, a suspension liquid of any density desired between these limits is readily obtained. In simple cases, separation is effected in an ordinary separating funnel; in other cases a centrifugal tube having a stopcock of full bore in the middle may have to be employed. The stopcock has no projecting handle liable to fracture, but is operated by a key. As a simple example, the author quotes the quantitative separation of small quantities of potassium chloride (sp. gr. 1·98) from sodium chloride (sp. gr. 2·10) by means of a suspension liquid of sp. gr. 2·04. The author is engaged in the study of a more complicated phase of the same question: the separation of dissolved and colloidal bodies by the application of extremely high centrifugal forces. Special machines have been constructed making 10,000 revolutions per minute, and plans for a machine giving 100,000 revolutions are under consideration. The machine has to be very accurately balanced and well protected. With these fast machines, the casein can be separated from the lactalbumin of milk; the fat can be separated into liquid and solid fractions. Combination with iodine or bromine has the effect of greatly accentuating the differences in the specific gravities of various organic substances. For the separation of solid substances, the material should first be freed from fat, the residue should be dried *in vacuo*, and then powdered in an electrically-operated agate grinding machine; the condition of the grinding may be controlled without appreciable loss by microscopic examination J. F. B.

Rapid Determination of Nickel and Cobalt by Means of the Gauze Cathode and Stationary Anode. R. C. Benner and W. H. Ross. (*J. Amer. Chem. Soc.*, 1911, **33**, 493-504.)—It is shown that the rapid estimation of nickel and of cobalt by means of the gauze electrode and stationary anode is perfectly satisfactory with most of the electrolytes in common use. The rate at which they are precipitated is practically the same for all the electrolytes which can be used in ammoniacal solution, and is little affected by the amount of ammonia added. In acid solution the rate of precipitation is not quite as great as in ammoniacal solution, and decreases slightly as the amount of acid is increased. Although the rate of precipitation of these elements on the gauze electrode is not quite equal to the rate at which they are precipitated by means of the same current when the electrolyte is agitated by mechanical means, it is rapid enough for practical purposes. In addition to its simplicity, the apparatus has the advantage that it can, when desired, be used without any alteration with the small currents, which alone were used formerly and which it is still sometimes convenient to employ. G. C. J.

New Method of Estimating Nitrites. E. Rupp and F. Lehmann. (*Arch. Pharm.*, 1911, **249**, 214-217.)—The method depends upon the oxidation of the nitrous acid to nitric acid by means of bromine, the excess of which is estimated iodometrically. In practice it is better to use nascent bromine liberated from an acid solution of potassium bromate and bromide. In estimating—*e.g.*, sodium nitrite—2·5 grms. of the sample are dissolved in 500 c.c. of water, and 10 c.c. of the solution mixed in a stoppered flask with 50 c.c. each of $\frac{N}{100}$ potassium bromate solution and potassium bromide solution (6 grms. of the dry salt per litre), and 10 c.c. of dilute sulphuric acid. The flask is then well shaken and allowed to stand for thirty minutes in the dark, after which 0·5 grm. of potassium iodide is introduced, the flask again shaken, and after two minutes the liberated iodine titrated with $\frac{N}{10}$ sodium thiosulphate solution. The number of c.c. required is deducted from 30 c.c. (the quantity corresponding to the bromate solution taken), and the difference multiplied by the factor 0·00345 gives the quantity of sodium nitrite present.

C. A. M.

Colorimetric Method of Estimating Phosphoric Acid. N. Passerini. (*Gazz. Chim. Ital.*, 1911, **41**, 182-186.)—A colorimetric method of estimating phosphoric acid is based upon the coloration given by molybdic acid with gallic acid, the colour being yellow, orange, or red, according to the amount of gallic acid. A similar coloration is obtained with gallotannic acid, but that substance is less suitable for the purpose, since it is usually more or less coloured. The phosphoric acid is dissolved from the rock, etc., by means of nitric acid, and precipitated from an aliquot portion of the solution with the usual molybdic reagent. After twenty-four hours, the precipitate is collected, washed with water containing 1 per cent. of nitric acid until the filtrate no longer gives a yellow coloration with gallic acid, and dissolved in the smallest possible quantity of dilute (1 : 4) ammonia solution. The liquid is boiled until it no longer smells of ammonia, and is then cooled and made up to 100 c.c. For the colorimetric estimation 15 c.c. of water and 2 c.c. of a freshly-prepared saturated solution of gallic acid are placed in each of two glass cylinders of equal diameter. Into one of these tubes is introduced 1, 1·5, or at most 2 c.c., of the standard solution of phosphoric acid, whilst the solution under examination is run drop by drop from a burette, with continual shaking, until the colours of the two liquids match. The standard solution (1 c.c. = 0·01 mgrm. of P_2O_5) may be prepared from any phosphate of known composition. Thus, 1·9153 grms. of pure dicalcium phosphate are dissolved in 1 litre of water acidified with 1 per cent. of nitric acid, and 10 c.c. of the solution (= 0·01 grm. of P_2O_5) are treated with 2 c.c. of a 75 per cent. solution of ammonium nitrate, and with 25 c.c. of nitro-molybdic reagent, and the precipitate allowed to stand for twenty-four hours, washed with 1 per cent. nitric acid, and dissolved in ammonia solution. The liquid is filtered, and the filtrate and washings made up to a litre. This slightly ammoniacal solution will keep unchanged for a long time. When required for an analysis, a portion of it is boiled to remove the bulk of the free ammonia, and made up to its original volume. The tabulated results quoted show that the method gives results in close agreement with those obtained by the gravimetric method, whilst, in the case of materials containing only very small quantities of phosphoric acid, it is somewhat more accurate.

C. A. M.

Volumetric Estimation of Phosphoric Acid Soluble in 2 Per Cent. Citric Acid Solution. L. Wuyts. (*Ann. Chim. anal. appl.*, 1911, **16**, 134-137.)—The following method is recommended as giving results in close agreement with those obtained by the nitro-molybdate method: Ten c.c. of the solution (5 grms. of the sample to 500 c.c. of 2 per cent. citric acid solution) are treated with a few drops of hydrochloric acid and evaporated to dryness, and the residue taken up with 3 to 4 drops of nitric acid and a few c.c. of water. The solution is treated with 10 c.c. of nitric acid (sp. gr. 1·40) and 15 c.c. of a saturated solution of ammonium nitrate and heated to the boiling-point. It is next allowed to stand for two or three minutes and treated with 25 c.c. of ammonium molybdate solution (90 grms. per litre), and the resulting precipitate stirred up, allowed to settle again for about twelve minutes, collected, and washed free from acid with cold water. It is then dissolved in standard potassium hydroxide solution (326·5 c.c. of $\frac{N}{1}$ solution diluted to a litre; 1 c.c. = 1 mgrm. of phosphoric acid), an excess of 1 or 2 c.c. being added, and the solution treated with 0·5 c.c. of phenolphthaleïn solution (1 grm. in 100 c.c. of 60 per cent. alcohol) and about 50 c.c. of water, and titrated with standard sulphuric acid equivalent to the potassium hydroxide solution. The number of c.c. used, less the quantity required to neutralise the excess of alkali, gives directly the percentage of phosphoric acid.

C. A. M.

Estimation of Silver by Electrolysis of an Ammoniacal Solution of its Oxalate. F. A. Gooch and J. P. Feiser. (*Zeitsch. anorg. Chem.*, 1911, **70**, 294-296.)—Silver may be deposited from an ammoniacal solution of its oxalate in a state of purity, and suitable for its quantitative estimation. Ammonium nitrate or chloride may be present. The cathode surface should preferably be relatively large and the current density low, the exact value necessarily depending on the form of cathode, of which several were tried, and in every case rotated about 400 to 500 times a minute. Half a grm. of silver may be deposited in half an hour. There being no non-volatile substance in the exhausted solution, the results are never high, but may be as much as 0·7 mgrm. low. G. C. J.

"Perhydrol" for the Estimation of Total Sulphur in Coal-Gas. M. Dickert. (*J. f. Gasbeleucht.*, 1911, **54**, 182-183; *Chem. Zentralbl.*, 1911, **1**, 1154.)—Seventy-five c.c. of sodium hydroxide solution of 30° B. are mixed with 10 c.c. of "perhydrol," the mass of crystals which form is broken up by stirring, and the reagent is placed in a Drehschmidt's gas-washing bottle, through which a current of the gas to be analysed is passed at a rate of up to 100 litres per hour. The contents of the bottle are subsequently washed into a beaker, acidified with hydrochloric acid, and boiled, and the sulphuric acid is either precipitated as barium sulphate or titrated according to Holliger's method. Thiophen appears to escape oxidation by this method, but the quantity of this substance in coal-gas is so small that its presence may be neglected. J. F. B.

Estimation of Sulphur in Coal-Gas and of Ammonium Sulphate. H. Blair. (*J. Soc. Chem. Ind.*, 1911, **30**, 397-398.)—The method depends upon the reaction between formaldehyde and an ammonium compound, hexamethylenetetramine being formed: $4NH_4Cl + 6CH_2O = N_4(CH_2)_6 + 4HCl + 6H_2O$. The acid may be titrated with alkali and phenolphthaleïn.

For Sulphur in Coal-Gas.—The liquid obtained in the "Referee's Test" is diluted to 500 c.c., and 50 c.c. boiled for two or three minutes to expel carbon dioxide. Ten c.c. of neutral formaldehyde solution (about 30 per cent.) are then added to the hot solution, and the liquid at once titrated with $\frac{N}{10}$ potassium hydroxide solution. One c.c. = 0·0247 grain of sulphur. The alkali should be standardised against a standard solution of ammonium sulphate, containing a little ammonium carbonate. Concordant results, slightly higher than are obtained by the barium sulphate method, are obtained. By this method a small quantity of gas (1 or 2 cubic feet) may be examined.

For Ammonium Sulphate.—The solution, always slightly acid, is neutralised by potassium hydroxide, boiled for a few minutes, and treated with 10 c.c. of neutral formaldehyde solution. After continuing the boiling for a few seconds, phenolphthaleïn is added, and the liquid titrated as before. One c.c. = ·0066 grm. $(NH_4)_2SO_4$. The results obtained agree with those given by the barium sulphate method. A. R. T.

Simple Method of Decomposing Refractory Tin Ores. H. Y. Loram. (*Proc. Chem. Soc.*, 1911, **27**, 60.)—The mineral (2 grms., or more if desired), crushed to a sixty-hole powder, is fused for about an hour in a covered silver crucible at a temperature well below its melting-point, with about six or seven times its weight of potassium hydroxide, to which is added potassium cyanide equal to the weight of tin ore taken.

The mass, on cooling, is extracted with water, when the whole will dissolve in dilute hydrochloric acid, and, after boiling to destroy any cyanide still remaining, the tin can be estimated by any of the usual methods.

Sensitiveness of the Colorimetric Estimation of Titanium. R. C. Wells. (*J. Amer. Chem. Soc.*, 1911, **33**, 504-506.)—The object of the experiments described in this paper was to establish the range of suitable concentrations for the colorimetric estimation of titanium. The solutions contained 3 per cent. of sulphuric acid and 2 per cent. of hydrogen peroxide. It is found that titanium may be estimated with equal accuracy over a rather wide range of concentrations—namely, from 1·5 to 20 mgrms. titanium dioxide per 100 c.c. Within these limits of concentration the determination may be made with an error of certainly less than 3 per cent. Most observers will find it easy, with a suitable colorimeter, to keep the mean error of their observations below 2 per cent. G. C. J.

Use of Methyl Orange in the Colorimetric Estimation of Titanium. A. Gautier. (*Rev. Generale Chim.*, 1911, **14**, 16-17; through *Chem. Zentralbl.*, 1911, **1**, 843.)—Methyl orange solutions may be used as comparison solutions in the colorimetric estimation of titanium; these solutions keep well, and their colour is not altered by exposure to the air. The concentrations of helianthin and titanium solutions of equal depth and tint are given in tabular form in the original paper.

W. P. S.

Indirect Method for the Estimation of Tantalum and Columbium. H. W. Foote and R. W. Langley. (*Amer. J. Sci.*, 1910, **30**, 393-400; through *Chem. Zentralbl.*, 1911, **1**, 1249.)—The method depends on the difference between the densities of the oxides of tantalum (8·716) and columbium (4·552). In the case of such a mineral as stibiotantalite, a quantity of the sample is treated with hydrofluoric acid, the solution is diluted with water, and the antimony and bismuth are removed by means of hydrogen sulphide. The solution containing the tantalum and columbium is then evaporated to dryness, the residue is heated with sulphuric acid to remove hydrofluoric acid, the hydroxides are precipitated from the diluted solution with ammonia, collected on a filter, washed, ignited over a blast-lamp, and weighed. The sp. gr. of the mixed ignited oxides is then determined, and the quantity of each present is calculated from the figure obtained (*cf.* ANALYST, 1911, 239).

W. P. S.

Estimation of Tungsten by Means of Stannous Chloride. B. Mdivani. (*Ann. Chim. anal. appl.*, 1911, **16**, 132-134.)—A method of estimating tungsten is based upon the fact that it may be precipitated by means of an excess of stannous chloride solution in the form of the oxide, W_2O_5. For example, the solution of 0·1 grm. of tungstic acid in 50 c.c. of dilute ammonia solution is treated with 20 c.c. of a freshly prepared solution of stannous chloride (50 grms.) in 200 c.c. of concentrated hydrochloric acid, and the mixture boiled for one or two minutes and allowed to stand. The precipitate is washed several times by decantation, and is finally collected, ignited, and weighed as tungsten trioxide. In the test experiments described the amounts of tungstic acid found ranged from 0·0995 to 0·1005 grm. The precipitate was quite free from tin, and it was proved that the presence of iron had no influence upon the results. C. A. M.

Estimation of the Salinity of Sea Water by Means of the Refractometer.

A. Berget. (*Comptes rend.*, 1911, **152**, 984-986.)—A series of determinations of the refractive indices, by means of Féry's refractometer, of solutions of sodium chloride have shown that they increase proportionately with the increase in the amount of salt. Thus the following results were obtained:

		0·010	0·015	0·020	0·025	0·030	0·035	0·040	0·045
Refractive index $[n]_{D\ 16^\circ C.}$	1·333804	1·33453	1·33536	1·33622	1·33712	1·33789	1·33875	1·33968	1·34050

In like manner a sample of sea water from Monaco gave the following results: Original water, 1·33929; diluted to half its salinity, 1·33576; and diluted to one-fourth, 1·33400 at 22·7° C. As in the case of the salt solutions, these results, when plotted graphically, formed a straight line. The method thus gives results quite as accurate as those calculated from the specific gravity. C. A. M.

Estimation of Silicon in Vanadium and Molybdenum and in their Iron Alloys.

W. Trautmann. (*Zeitsch. angew. Chem.*, 1911, **24**, 635-636.)—When the metals vanadium and molybdenum or their iron alloys are dissolved in the usual way, and the insoluble silica is collected on a filter, it is usually found that the silica has a green colour, owing to its being contaminated with traces of compounds of vanadium or molybdenum. The latter tend to form immediately after the acid solution has been decanted through the filter and the washing process is commenced. To remove these traces of impurities from the silica, it is recommended that, after the diluted acid solution of the metal has been decanted, the residue of silica should be washed twice with water, and then extracted with hot 10 per cent. hydrochloric acid until it is colourless. The silica is finally washed with water, dried, ignited, and weighed. In the case of molybdenum it is better to extract the silica with hot concentrated hydrochloric acid containing a little nitric acid. W. P. S.

Estimation of the Hardness of Water: the Wartha-Pfeiffer Method and its Modification.

J. M. Silber. (*Arch. f. Hyg.*, 1911, **73**, 171-182; *Chem. Zentralbl.*, 1911, **1**, 1081-1082.)—According to the original Wartha-Pfeiffer method (*Zeitsch. angew. Chem.*, 1902, **15**, 193), the temporary hardness in many cases is found to exceed the total hardness. The author describes the following modification, the solutions used being a 0·2 per cent. solution of methyl orange, $\frac{N}{10}$ hydrochloric acid, and a $\frac{N}{10}$ solution of a mixture of equal parts of sodium hydroxide and carbonate; 100 c.c. of the water are treated with 2 to 3 drops of the indicator, and titrated cold with $\frac{N}{10}$ hydrochloric acid to the red point.

The number of c.c. required is called *A*. The neutralised water is heated to boiling, treated with an excess of the $\frac{N}{10}$ alkali mixture, and further boiled for five minutes.

The liquid and precipitate are transferred quantitatively to a graduated stoppered cylinder, cooled, diluted to 200 c.c., and filtered; 100 c.c. of the filtrate are titrated back with $\frac{N}{10}$ acid; the number of c.c. is multiplied by 2 and subtracted from the number of c.c. of alkali added. The result, *B*, multiplied by 2·8, gives the total hardness (German degrees). Next, 100 c.c. of the original water are boiled for half an hour, keeping the volume constant, in order to decompose the bicarbonates. The filtrate is titrated with $\frac{N}{10}$ acid, and the number of c.c. of acid used, *C*, is subtracted from the original alkalinity of the water, *A*; and when the difference is multiplied by 2·8, the result is the temporary hardness. For the direct estimation of temporary hardness, 100 c.c. of the water are boiled in the usual way, filtered, and the precipitate is washed. The filter and precipitate are returned to the boiling-flask, treated with excess of $\frac{N}{10}$ hydrochloric acid, and the excess of acid is titrated back.

J. F. B.

APPARATUS, ETC.

Device for Accurately Reading a Burette. J. Milbauer. (*Chem. Zeit.*, 1911, **35**, 419.)—The principle of the Schnellbach burette may be applied to the reading of an ordinary burette. A sharp line, about 2 mm. in breadth, is drawn in red or blue ink upon a piece of cardboard, which is then cut with two slits, and placed over the burette, so as to form a background to the level of the liquid.

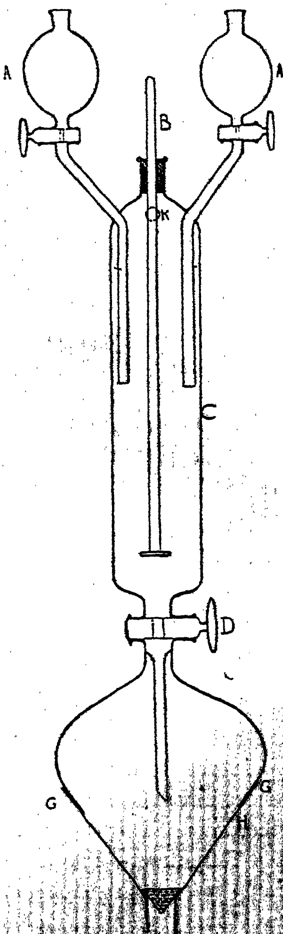
C. A. M.

Recording Thermo-Electric Calorimeter. C. Féry. (*Seventh Inter. Cong. App. Chem.*, 1909, Sect. X., 69.)—An apparatus is described which can be used continuously for checking the value of the gas produced in a gas works or producer plant. The gas is burnt at a constant rate in a special burner consuming from 5 to 10 litres per hour. The flame heats a recuperative thermopile, of which the cold junction is traversed by the air used for the combustion, and the hot junction is heated by the products of combustion. The pile contains fifteen junctions, enabling a P.D. of 0·2 volt to be maintained. The resistance being very low, the energy produced is sufficient to obtain a trace with a recording instrument similar to that in the Richard recording thermometers and barometers. For laboratory work this form is not so suitable as for everyday work on a gas of approximately uniform density, and the author has modified it by connecting the thermopile of the calorimeter to an electric meter which measures the energy developed by it, while the gas consumed is measured by a laboratory meter. As soon as a steady regime is set up, the ratio of the readings of the electric and gas meters gives the calorific power. It is advisable to regulate the consumption, so that the thermopile is in the same condition for different gases. With ordinary town gas a variation of 50 per cent. in the rate of consumption produced an error of proportionality of 3·5 per cent. With acetylene the variation was 1 per cent., and with gases of such different calorific powers as hydrogen and acetylene the proportionality is good, as can be seen by comparing the figures obtained with the bomb calorimeter. With liquid fuels the electric meter must be employed to measure the total heat production. By weighing at the beginning and at the end of a test the weight of fuel consumed is obtained.

H. F. E. H.

Apparatus for Precipitating, Filtering, and Drying in an Inert Gas. J. B. Firth and J. E. Myers.

(*Proc. Chem. Soc.*, 1911, **27**, 96.)—The apparatus designed for the above purpose is shown in the accompanying sketch.



The reacting liquids are placed in the funnels A, A, and the remainder of the apparatus is evacuated through a Büchner flask fitted to the filter-funnel H. The apparatus is then filled with the inert gas through a side-tube at K. The tap D being closed, the reacting liquids are run into the precipitating tube C, and are mixed by means of the stirrer B, which slides in a rubber stopper lubricated with rubber grease. When the reaction is complete, the tap D, which has a wide bore, is opened, and the precipitate filtered off in the funnel H. The washing and drying are carried out by drawing suitable liquids through the precipitate, and finally aspirating a stream of the inert gas to remove the liquids used for drying. There is a ground glass joint at G, by means of which the funnel is prepared for filtration and the precipitate is removed. This apparatus can be used with satisfactory results in the preparation of copper hydride.

Adaptation of the Tap-Funnel to Rapid Electro-Analysis with Stationary Electrodes. T. S. Price and A. W. T. Hyde.

(*J. Soc. Chem. Ind.*, 1911, **30**, 391-396.) — The tap-funnel may be adapted for use with stationary electrode in the deposition of copper, nickel, and zinc. The type of stationary electrode used was a cylindrical cathode of sand-blasted gauze, 45 mm. long and 32 mm. in diameter, with 4 meshes to the sq. mm., its weight being about 15 grms. The anode was a cylinder of similar gauze, 44 mm. long and 22 mm. in diameter. With this equipment a concentration of less than 1 c.c. of nitric acid per 70 c.c. of electrolyte is inadvisable, while a concentration of 2 c.c. may be used with advantage. With a sufficient amount of nitric acid previous heating of the electrolyte is unnecessary, but a final temperature of 60° to 70° C. does not prevent the deposition of the copper with 2 c.c. of nitric acid per 70 c.c. of electrolyte. Zinc may be deposited satisfactorily from the sodium sulphate, sodium acetate, acetic acid electrolyte, about 65 c.c. of glacial acetic acid per 70 c.c. of electrolyte giving the most favourable results.

After an extended experience of both stationary and rotating electrodes, the authors are still of the opinion, previously expressed by Price and Humphreys (ANALYST, 1910, **35**, 274), that rotating electrodes are to be preferred in actual practice.

G. C. J.

Sensitiveness Tests by the Impact Machine (Drop Hammer). H. Kast. (*Seventh Inter. Cong. App. Chem.*, 1909, Section III.B, **23**.) — In the author's apparatus (D.R.G.M. 281,313), made by E. A. Lentz, Berlin, the explosive is placed between the faces of two hard steel plungers of ½ sq. cm. cross-sectional area sliding in a hard steel sleeve. The arrangement is centred upright on the anvil of the impact machine, so that the weight falls truly on the upper plunger. The chief advantage of this arrangement over allowing the hammer to fall directly on the explosive is that it maintains constant the area struck. It is claimed that the apparatus meets the conditions to be fulfilled by a satisfactory impact machine, which are stated. Details of the method of using it are given. O. E. M.

* * * * *

REPORTS, ETC.

Analysis of Crude Glycerol. (International Standard Methods, 1911.)—The valuation of crude glycerol has in recent years assumed greater commercial importance owing to the increased value of the commodity. The want of uniformity in the methods and processes of analyses, together with the irregularity of the results obtained, emphasised the desirability for the standardisation of crude glycerol analysis; so, with this object in view, committees were formed in America, France, Germany, and Great Britain. These committees worked, in the first instance, independently, but were ultimately brought together, and after a series of conferences the conclusions arrived at by the various committees were summarised and drawn up in the form in which they are now presented. The methods detailed in this report have the unanimous support of each of the above committees, and are strongly recommended by them as International Standards.

SAMPLING.—The most satisfactory method available for sampling crude glycerol liable to contain suspended matter, or which is liable to deposit salt on settling, is to have the glycerol sampled by a mutually approved sampler as soon as possible after it is filled into drums, but in any case before any separation of salts has taken place. In such cases he shall sample with a sectional sampler (a suitable sampling apparatus is described in an appendix to the report), then seal the drums, brand them with a number for identification, and keep a record of the brand number. The presence of any visible salt or other suspended matter is to be noted by the sampler, and a report of same made in his certificate, together with the temperature of the glycerol. Each drum must be sampled. Glycerol which has deposited salt or other matters cannot be accurately sampled from the drums, but an approximate sample can be obtained by means of the sectional sampler, which will allow a complete vertical section of the glycerol to be taken, including any deposit.

ANALYSIS.—1. *Determination of Free Caustic Alkali.*—Weigh 20 grms. of the sample into a 100 c.c. flask, dilute with approximately 50 c.c. of freshly-boiled distilled water, add an excess of neutral barium chloride solution, 1 c.c. of phenolphthaleïn solution, make up to the mark, and mix. Allow the precipitate to settle, draw off 50 c.c. of the clear liquid, and titrate with normal acid ($\frac{N}{1}$). Calculate to percentage of Na_2O existing as caustic alkali.

2.—*Determination of Ash and Total Alkalinity.*—Weigh 2 to 5 grms. of the sample in a platinum dish, burn off the glycerol over a luminous Argand burner or other source of heat giving a low flame temperature, the temperature being kept low to avoid volatilisation and the formation of sulphides. When the mass is charred to the point that water will not become coloured by soluble organic matter, lixiviate with hot distilled water, filter, wash and ignite the residue in the platinum dish. Return the filtrate and washings to the dish, evaporate, and carefully ignite without fusion. Weigh the ash.

Dissolve the ash in distilled water and titrate total alkalinity, using as indicator methyl orange cold or litmus boiling.

3. *Determination of Alkali present as Carbonate.*—Take 10 grms. of the sample, dilute with 50 c.c. distilled water, add sufficient $\frac{N}{1}$ acid to neutralise the total alkali found at (2), boil under a reflux condenser for fifteen to twenty minutes, wash down the condenser tube with distilled water, free from carbon dioxide, and titrate back with $\frac{N}{1}$ NaOH, using phenolphthaleïn as indicator. Calculate the percentage of Na_2O. Deduct the Na_2O found in (1). The difference is the percentage of Na_2O existing as carbonate.

4. *Alkali combined with Organic Acids.*—The sum of the percentages of Na_2O found at (1) and (3) deducted from the percentage found at (2) is a measure of the Na_2O or other alkali combined with organic acids.

5. *Determination of Acidity.*—Take 10 grms. of the sample, dilute with 50 c.c. of distilled water free from carbon dioxide, and titrate with $\frac{N}{1}$ NaOH and phenolphthaleïn. Express in terms of Na_2O required to neutralise 100 grms.

6. *Determination of Total Residue at* 160° *C.*—For this determination the crude glycerol should be slightly alkaline with Na_2CO_3, not exceeding the equivalent of 0·2 per cent. Na_2O, in order to prevent loss of organic acids. To avoid formation of polyglycerols, this alkalinity must not be exceeded.

Preparation of Glycerol.—Ten grms. of the sample are weighed into a 100 c.c. flask diluted with water, and the calculated quantity of $\frac{N}{1}$ HCl or Na_2CO_3 added to give the required degree of alkalinity. The flask is filled to 100 c.c., the contents mixed, and 10 c.c. measured into a weighed Petrie or similar dish 2·5 inches diameter and 0·5 inch deep, which should have a flat bottom. In the case of crude glycerols abnormally high in organic residue, a less quantity is to be evaporated, so that the weight of organic residue does not materially exceed 30 to 40 mgrms.

Evaporation of the Glycerol.—The dish is placed on a water-bath (the top of the 160° C. oven acts equally well) until most [illegible] the water has evaporated. From this point the evaporation is effected in the oven. Satisfactory results are obtained in an oven measuring 12 inches cube, having an iron plate $\frac{3}{4}$-inch thick lying on the bottom to distribute the heat. Strips of asbestos millboard are placed on a shelf halfway up the oven. On these strips the dish containing the glycerol is placed.

If the temperature of the oven has been adjusted to 160° C. with the door closed, a temperature of 130° to 140° C. can be readily maintained with the door partially open, and the glycerol, or most of it, should be evaporated off at this temperature. When only a slight vapour is seen to come off, the dish is removed and allowed to cool.

An addition of 0·5 to 1 c.c. of water is made, and by a rotary motion the residue brought wholly or nearly into solution. The dish is then allowed to remain on a water-bath or top of the oven until the excess water has evaporated and the residue is in such a condition that on returning to the oven at 160° C. it will not spit. The time taken up to this point cannot be given definitely, nor is it important. Usually two to three hours are required. From this point, however, the schedule of time must be strictly adhered to. The dish is allowed to remain in the oven, the temperature of which is carefully maintained at 160° C. for one hour, when it is removed, cooled, the residue treated with water, and the water evaporated as before. The residue is then subjected to a second baking of one hour, after which the dish is allowed to cool in a desiccator over sulphuric acid and weighed. The treatment with water, etc., is repeated until a constant loss of 1 to 1·5 mgrms. per hour is obtained.

Corrections to be Applied to the Weight of the Total Residue.—In the case of acid glycerol, a correction must be made for the alkali added. One c.c. $\frac{N}{1}$ alkali represents an addition of 0·022 grm. In the case of alkaline crudes a correction should be made for the acid added. Deduct the increase in weight due to the conversion of the $NaOH$ and Na_2CO_3 to $NaCl$. The corrected weight, multiplied by 100, gives the percentage of *total residue at* 160° *C.*

Preserve the total residue for the determination of the non-volatile acetylisable impurities.

7. *Organic Residue.*—Subtract the ash from the total residue at 160° C. Report as organic residue at 160° C. (*Note.*—It should be noted that alkaline salts of organic acids are converted to carbonates on ignition, and that the CO_3 radicle thus derived is not included in the organic residue.)

8. *Moisture.*—This test is based on the fact that glycerol can be completely freed from water by allowing it to stand *in vacuo* over sulphuric acid or phosphoric anhydride.

Two to three grms. of very pure bulky asbestos freed from acid soluble material which has been previously dried in a water-oven are placed in a small stoppered weighing-bottle of about 15 c.c. capacity. The weighing-bottle is kept in a vacuum desiccator furnished with a supply of concentrated sulphuric acid, under a pressure equivalent to 1 to 2 mm. of mercury, until constant in weight. From 1 to 1·5 grm. of the sample is then carefully dropped on the asbestos in such a way that it will be all absorbed. The weight is again taken, and the bottle replaced in the desiccator under 1 to 2 mm. pressure until constant in weight. At 15° C. the weight is constant in about forty-eight hours. At lower temperatures the test is prolonged.

The sulphuric acid in the desiccator must be frequently renewed.

Acetin Process for Glycerol Determination.—This process is the one agreed upon at a Conference of Delegates from the American, British, French, and German Committees, and has been confirmed by each of the above Committees as giving results nearer to the truth on crudes in general, and is the process to be used (if applicable) whenever only one method is employed. On pure glycerols the results are identical with those of the bichromate process. For the application of this process the crude glycerol should not contain over 50 per cent. water.

The following reagents are required:

1. *Best Acetic Anhydride.*—This should be carefully selected. A good sample must not require more than 0·1 c.c. normal NaOH for saponification of the impurities when a blank is run on 7·5 c.c. Only a slight colour should develop during digestion of the blank.

2. *Pure Fused Sodium Acetate.*—The purchased salt is again completely fused in a platinum, silica, or nickel dish, avoiding charring, powdered quickly, and kept in a stoppered bottle or in a desiccator. It is most important that the sodium acetate be anhydrous.

3. *A Solution of Sodium Hydroxide for Neutralising, of about* $\frac{N}{1}$ *Strength, Free from Carbonate.*—This can be readily made by dissolving pure sodium hydroxide in its own weight of water (preferably water free from carbon dioxide), and allowing to settle until clear, or filtering through an asbestos or paper filter. The clear solution is diluted with water free from carbon dioxide to the strength required.

4. $\frac{N}{1}$ *Sodium Hydroxide, Free from Carbonate.*—Prepared as above, and carefully standardised.

Some sodium hydroxide solutions show a marked diminution in strength after being boiled; such solutions should be rejected.

5. $\frac{N}{1}$ *Acid.*—Carefully standardised.

6. *Phenolphthaleïn Solution.*—0·5 per cent. phenolphthaleïn in alcohol and neutralise.

THE METHOD.—Into a narrow-mouthed flask (preferably round-bottomed) capacity about 120 c.c., which has been thoroughly cleaned and dried, weigh accurately and as rapidly as possible 1·25 to 1·5 grms. of the glycerol. Add first about 3 grms. of the anhydrous sodium acetate, then 7·5 c.c. of the acetic anhydride, and connect the flask with an upright Liebig condenser. For convenience the inner tube of this condenser should not be over 50 cm. long and 9 to 10 mm. inside.

The flask is connected to the condenser by either a ground glass joint (preferably) or a rubber stopper. If a rubber stopper is used, it should have had a preliminary treatment with hot acetic anhydride vapour.

Heat the contents and keep just boiling for one hour, taking precautions to prevent the salts drying on the sides of the flask.

Allow the flask to cool somewhat, and through the condenser tube add 50 c.c. of the carbon-dioxide-free distilled water, heated to about 80° C., taking care that the flask is not loosened from the condenser. The object of cooling is to avoid any sudden rush of vapours from the flask on adding the water, and to avoid breaking the flask. Time is saved by adding the water before the contents of the flask solidify, but the contents may be allowed to solidify and the test proceeded with the next day without detriment. The contents of the flask may be warmed to, but must not exceed, 80° C. until the solution is complete except a few dark flocks representing organic impurities in the crude. By giving the flask a rotatory motion, solution is more quickly effected. Cool the flask and contents without loosening from condenser. When quite cold wash down the inside of the condenser tube, detach the flask, wash off stopper or ground glass connection into the flask, and filter contents of flask through an acid-washed filter into a Jena glass flask of about 1 litre capacity. Wash thoroughly with cold distilled water free from carbon dioxide. Add 2 c.c. of phenolphthaleïn solution (F), then run in sodium hydroxide solution (C) or (D) until a faint pinkish-yellow colour appears throughout the solution. This neutralisation must be done most carefully. The alkali should be run down the sides of the flask, the contents of which are kept rapidly swirling with occasional agitation or change of motion until the solution is nearly neutralised, as indicated by the slower disappearance of the colour developed locally by the alkali running into the mixture. When this point is reached the sides of the flask are washed down with carbon-dioxide-free water and the alkali subsequently added drop by drop, mixing after each drop until the desired tint is obtained.

Now run in from a burette 50 c.c. or a calculated excess of $\frac{N}{1}$ NaOH (D), and note carefully the exact amount. Boil gently for fifteen minutes, the flask being fitted with a glass tube acting as a partial condenser; cool as quickly as possible, and titrate excess of NaOH with $\frac{N}{1}$ acid (E) until the pinkish-yellow or chosen end-point colour just remains. A further addition of the indicator at this point will cause a return of the pinkish colour; this must be neglected, and the first end-point taken.

From the $\frac{N}{1}$ NaOH consumed calculate the percentage of glycerol after making the correction for the blank test described below:

$$1 \text{ c.c. of } \tfrac{N}{1} \text{ NaOH} = 0{\cdot}03069 \text{ grm. of glycerol.}$$

The coefficient of expansion for normal solutions is approximately 0·00033 per c.c. for each degree C. A correction should be made on this account if necessary.

Blank Test.—As the acetic anhydride and sodium acetate may contain impurities which affect the result, it is necessary to make a blank test, using the same quantities of acetic anhydride and sodium acetate as in the analysis. After neutralising the acetic acid, it is not necessary to add more than 5 c.c. of the $\frac{N}{1}$ alkali (D), as that represents the excess of alkali usually left after saponification of the triacetin in the glycerol determination.

Determination of the Glycerol Value of the Acetylisable Impurities.—The total residue at 160° C. is dissolved in 1 or 2 c.c. of water, washed into a clean acetylising flask 120 c.c. capacity, and the water evaporated. Now add anhydrous sodium acetate, and proceed as in the glycerol determination before described. Calculate the result to glycerol.

Analysis of Acetic Anhydride.—Into a weighed stoppered vessel, containing 10 to 20 c.c. of water, run about 2 c.c. of the anhydride, replace stopper and weigh; allow to stand, with occasional shaking, for several hours, till all anhydride is hydrolysed; then dilute to about 200 c.c., add phenolphthaleïn, and titrate with $\frac{N}{1}$ NaOH. This gives the total acidity due to free acetic acid and acid formed from anhydride.

Into a stoppered weighing-bottle containing a known weight of recently distilled aniline (from 10 to 20 c.c.) measure about 2 c.c. of the sample, stopper, mix, allow to cool, and weigh. Wash contents into about 200 c.c. cold water, and titrate acidity as before. This yields the acidity due to the original, preformed, acetic acid plus one-half the acid due to anhydride (the other half having formed acetanilide); substract the second result from the first (both calculated for 100 grms.) and double result, obtaining c.c. $\frac{N}{1}$ NaOH per 100-grm. sample. One c.c. NaOH equals 0·0510 grm. of acetic anhydride.

Bichromate Process for Glycerol Determination. Reagents Required.—(*a*) *Pure Potassium Bichromate* powdered and dried in air free from dust or organic vapours, at 110° to 120° C. This is taken as the standard.

(*b*) *Dilute Bichromate Solution.*—7·4564 grms. of the above bichromate (*a*) are dissolved in distilled water and the solution made up to 1 litre at 15·5° C.

(*c*) *Ferrous Ammonium Sulphate.*—Dissolve 3·7282 grms. of potassium bichromate (*a*) in 50 c.c. of water. Add 50 c.c. of 50 per cent. (by volume) sulphuric acid, and to the cold undiluted solution add from a weighing bottle a moderate excess of the ferrous ammonium sulphate, and titrate back with the dilute bichromate (*b*). Calculate the value of the ferrous salt in terms of bichromate.

(*d*) *Silver Carbonate.*—This is prepared as required; for each test from 140 c.c. of 0·5 per cent. silver sulphate solution by precipitation with about 4·9 c.c. $\frac{N}{1}$ sodium carbonate solution (a little less than the calculated quantity of $\frac{N}{1}$ sodium carbonate should be used; any excess of alkali carbonate prevents rapid settling). Settle, decant, and wash once by decantation.

(*e*) *Subacetate of Lead.*—Boil a pure 10 per cent. lead acetate solution with an excess of litharge for one hour, keeping the volume constant, and filter while hot. Disregard any precipitate which subsequently forms. Preserve out of contact with carbon dioxide.

(*f*) *Potassium Ferricyanide.*—A very dilute solution containing about 0·1 per cent.

The Method.—Weigh 20 grms. of the glycerol, dilute to 250 c.c., and take 25 c.c. Add the silver carbonate, allow to stand, with occasional agitation, for about ten minutes, and add a slight excess (about 5 c.c. in most cases) of the basic lead acetate (*e*), allow to stand a few minutes, dilute with distilled water to 100 c.c., and then add 0·15 c.c. to compensate for the volume of the precipitate, mix thoroughly, filter through an air-dry filter into a suitable narrow-mouthed vessel, rejecting the first 10 c.c., and return filtrate if not clear and bright. Test a portion of the filtrate with a little basic lead acetate, which should produce no further precipitate. (In the great majority of cases 5 c.c. is ample.) Occasionally a crude glycerol will be found requiring more, and in this case another aliquot of 25 c.c. of the dilute glycerol should be taken and purified with 6 c.c. of the basic acetate. Care must be taken to avoid a marked excess of basic acetate.

Measure off 25 c.c. of the clear filtrate into a glass flask or beaker (previously cleaned with potassium bichromate and sulphuric acid). Add 12 drops of sulphuric acid (1 : 4) to precipitate the small excess of lead as sulphate. Add 3·7282 grms. of the powdered potassium bichromate (*a*). Rinse down the bichromate with 25 c.c. of water, and stand with occasional shaking until all the bichromate is dissolved (no reduction will take place).

Now add 50 c.c. of 50 per cent. sulphuric acid (by volume) and immerse the vessel in boiling water for two hours, and keep protected from dust and organic vapours, such as alcohol, until the titration is completed. Add from a weighing bottle a slight excess of the ferrous ammonium sulphate (C), making spot tests on a porcelain plate with the potassium ferricyanide (F). Titrate back with the dilute bichromate. From the amount of bichromate reduced calculate the percentage of glycerol.

1 grm. glycerol equals 7·4564 grms. bichromate.
1 ,, bichromate equals 0·13411 grm. glycerol.

Notes.—1. It is important that the concentration of acid in the oxidation mixture and the time of oxidation should be strictly adhered to.

2. Before the bichromate is added to the glycerol solution it is essential that the slight excess of lead be precipitated with sulphuric acid as stipulated in the process.

3. For "crudes" practically free from chlorides the quantity of silver carbonate may be reduced to one-fifth and the basic lead acetate to 0·5 c.c.

4. It is sometimes advisable to add a little potassium sulphate to insure a clear filtrate.

INSTRUCTIONS FOR CALCULATING ACTUAL GLYCEROL CONTENT.—1. Determine the apparent percentage of glycerol in the sample by the acetin process as described. The result will include acetylisable impurities, if any be present.

2. Determine the total residue at 160° C.

3. Determine the acetin value of the residue at (2) in terms of glycerol.

4. Deduct the result found at (3) from the percentage obtained at (1) and report this corrected figure as glycerol. If volatile acetylisable impurities are present, these are included in this figure.

NOTES AND RECOMMENDATIONS.—Experience has shown that in crude glycerol of good commercial quality the sum of water, total residue at 160° C. and corrected acetin result, comes to within 0·5 of 100. Further, in such "crudes" the bichromate result agrees with the uncorrected acetin result to within 1 per cent.

In the event of greater differences being found, impurities, such as polyglycerols or trimethylene glycol, are present. Trimethylene glycol is more volatile than glycerol; it can therefore be concentrated by fractional distillation. An approximation to the quantity can be obtained from the spread between the acetin and bichromate results of such distillates, trimethylene glycol showing by the former method 80·69 per cent., and by the latter 138·3 per cent., expressed as glycerol.

In valuing crude glycerol for certain purposes it is necessary to ascertain the approximate proportion of arsenic, sulphides, sulphites, and thiosulphates. The methods for detecting and determining these impurities have not formed the subject of this investigation.

J. L. BUCHANAN, *Hon. Secretary.*

RECOMMENDATIONS BY EXECUTIVE COMMITTEE.—If the non-volatile organic residue at 160° C. in the case of a soap lye "crude" be over 2·5 per cent.—*i.e.*, when not corrected for carbon dioxide in the ash—then the residue shall be examined by the acetin method, and any excess of glycerol found over 0·5 per cent. shall be deducted from the acetin figure.

In the case of saponification, distillation, and similar glycerol, the limit of organic residue which should be passed without further examination shall be fixed at 1 per cent. In the event of the sample containing more than 1 per cent., the organic residue must be acetylated, and any glycerol found (after making the deduction of 0·5 per cent.) shall be deducted from the percentage of glycerol found by the acetin test.

Composition of the Gases caused by Blasting in Mines. E. A. Mann. (*Report to the Government of Western Australia,* 1911.)—The operator, equipped with a Fleuss apparatus, took the samples at the face immediately after a blast. The sampling apparatus consisted of a box containing two 1,500 c.c. bottles, connected in parallel with a bellows fixed outside the box. Each bottle was fitted with two glass stop-cocks and a standard thermometer. Twelve compressions of the bellows (each 2,000 c.c.) were given. Carbon monoxide was determined by the iodine pentoxide method, carbon dioxide by the Haldane apparatus, described in his "Investigations of Mine Air," p. 100. Nitric oxide, hydrogen sulphide, and sulphur dioxide, were sometimes tested for by aspirating respectively through solutions of starch and potassium iodide, lead acetate, and bromine (weak). The sulphuric acid formed in the last case was determined as barium sulphate. The series of trials included the explosives commonly used in the district, and samples from South Africa, fired under various conditions. Carbon monoxide and nitric oxide were always found. The causes of their formation, and preventive measures, are discussed. O. E. M.

REVIEWS.

ARSENICAL GAS-POISONING. By JOHN GLAISTER, M.D. 1908. Edinburgh: E. and S. Livingstone. 1910. Price 5s. net.

This short work by Dr. Glaister is the outcome of an investigation into the literature of poisoning by arseniuretted hydrogen consequent on two cases which came within the experience of the author. A very careful and detailed account is given of these two cases, one of which was fatal. Both of these cases resulted from the cleaning out of a retort which had been used for the manufacture of chlorine. The "manganese mud" which lay in the retort was shovelled by means of an iron shovel into a zinc galvanised iron pail, the workman having in each case to enter the retort. The arsenic present in the "manganese mud," together with the acid also present, resulted in the production of arseniuretted hydrogen by their action on the shovel and pail. The late Sir Thomas Stevenson made an investigation on behalf of he Home Office, and found that the débris from the retort, when placed in contact vith either zinc or iron, or both together, caused the evolution of arseniuretted ıydrogen. Sir Thomas Stevenson also made a toxicological analysis of the viscera ›f the fatal case, and found arsenic present in amount corresponding to 0·37 grain of ırsenious acid in the whole body.

The author gives a very interesting account of the clinical symptoms presented by the fatal case, the important ones being continued vomiting, the passage of blood in the urine, and jaundice. In spite of the most careful treatment, the symptoms continued, and hiccough, delirium, and collapse supervened before death, which occurred six days after the exposure to the poisonous atmosphere.

The case which did not prove fatal, only showed clinically nausea with weakness and general feeling of illness. There was no passage of blood in the urine, and no jaundice, both of which symptoms always make the prognosis very grave.

Dealing in detail with the possible sources of arseniuretted hydrogen and the numerous ways in which accidental poisoning may occur from inadvertent exposure to a tainted atmosphere, the author gives a full list of scientific and industrial operations in which this is especially likely to occur.

He also gives a summary of the professions and occupations in which there may be risk of exposure to arseniuretted hydrogen.

A valuable account is given of the symptoms and pathological changes occurring in arsenical gas-poisoning, together with a detailed description of the poisonous effects on animals, whilst the synoptical account of the recorded cases is of great interest and very instructive.

It is to be regretted that the author makes no mention of the part played by arseniuretted hydrogen in the gas-poisoning resulting from the storage of ferro-silicon, several fatal cases of which have occurred in recent years.

In a detailed description of the analytical methods for the detection of arsenic in toxicological investigations, rather too much importance is attached to the Gutzeit test, since there are many risks of fallacy with this test which do not obtain in some of the other more reliable methods.

At the end of the book is a bibliography of the subject.

The work is a valuable contribution to the subject of arsenical gas-poisoning, and should be carefully studied by all interested in this branch of toxicology.

W. H. Willcox.

Fibres used in Textile and Allied Industries. By C. Ainsworth Mitchell, B.A. (Oxon), F.I.C., and R. Maxwell Prideaux, F.I.C. London: Scott, Greenwood and Son. 1911. Price 7s. 6d. net.

In this work the authors have produced a laboratory manual for the examination and identification of the principal textile fibres, or, as they express it, for want of a better term, of fibres in the "isolated" condition, thus excluding those used in furriery and paper-making.

The method of treatment is concise, rather in the form of laboratory notes. Such a method necessarily tends to be empirical, and first principles are perhaps too much left to be inferred, but nothing which is noted in the way of criticism in the present review must be taken as intended to minimise the value of this work to all analysts whose practice may include the occasional investigation of fibrous materials. The microscopical, chemical, and physical characters of the individual fibres are well and adequately described, and the sixty-six illustrations, specially drawn for this book, are beyond all praise. These illustrations are all on a uniform scale to facilitate ready comparison, which, however, makes the cross-sections rather small, and the diagrammatic or exaggerated representation of characteristic features has been expressly avoided. The scope of the work comprises the animal, vegetable, and "artificial" fibres. All these are admirably described from the analyst's point of view; but the correlation between the analytical facts and their commercial and industrial significance is not always sufficiently developed. The authors quote freely from the general and periodical literature of the subject, but without criticism, and in many cases, one cannot help feeling, without personal verification. The section dealing with wool, the animal fibres, and silk, appears to have been more carefully prepared than the section dealing with the cellulose fibres. In stating (p. 29) that in chlorinised wool there is apparently no direct combination with chlorine, the authors have evidently overlooked Cross and Bevan's work on the chloro-proteins. The omission of a chapter on the adulterations of wool—*e.g.*, by mercerised jute, and, above all, the omission of a scheme for the detection and estimation of shoddy and other forms of re-manufactured wool, one of the most important and most difficult tasks of the fibre-specialist, constitutes a serious gap in this section of the book. On p. 73 the statement that artificial silk is unattacked by cuprammonium solution calls for comment. Throughout the book typographical errors are more frequent than they should be (how do the authors finally decide to spell the word "coloration"?), and on p. 96 the misplacement of the decimals is responsible for the statement that raw Egyptian cotton contains 2·50-2·56 per cent. of nitrogen. Objection may be taken to the method prescribed for the preparation of the cuprammonium reagent (p. 97), hence the not very characteristic appearance of Fig. 37. A reagent sufficiently powerful for all the purposes of the microscopist can only be obtained by the direct action of the strongest ammonia on copper turnings. For the analysis of sized cotton goods the authors describe an old method used by Thomson in 1877, but omit to say how they themselves would undertake the operation in 1911; there is no reference to the use of diastase in this connection. On p. 117 Schwalbe's toluene-distillation method is quoted for the testing of hydrated mercerised cellulose, although Schwalbe himself abandoned this method soon after its publication. The iodine colour-tests for mercerised cotton described on pp. 119-121 are of little practical value. In the chapter on artificial silks the authors have evidently had to depend too much on outside sources of information. Theoretical principles expounding the relations between the different systems adopted for the formation and twisting of the threads and the contour of the cross sections, also between the methods of dissolving the cellulose and the modified chemical properties of the products, are neglected, and the chapter becomes a compilation of empirical facts. First principles should at once have suggested to the authors that Figs. 44 and 45 have been inadvertently transposed. No reference is made to the detection and estimation of combined formaldehyde in the semi-waterproofed ("sthenosed") silks and its influence on tensile strength.

The problem of differentiating between flax and hemp might have been more clearly developed and expounded from the authors' own experience. The application of the cuprammonium reagent should have been illustrated, also the characteristic cuticular residues left after this treatment. In the succeeding chapters the following corrections should be noted: (p. 136) "cottonised flax," in the form of yarns spun like cotton from carded flax tow, is still occasionally met with in commerce; (p. 156) flax yarns, even when fully bleached, nearly always contain residues of the cortical parenchymatous tissue; (p. 163) the value of 2·0 to 2·7 mm. for the length of the ultimate fibre of Manila hemp is far too small—6 mm. would be nearer the mark. This error is quoted from Wiesner, and the authors might easily have given instead the results of their own personal measurements; a description should also have been given of the characteristic cortical tissues ("sheave") found in Manila hemp. On p. 181 African piassava is described as a single ultimate fibre, whereas a single fibro-vascular bundle is intended. Lastly, the authors might have included in the scope of their subject the "artificial horsehairs" produced by coating textile yarns with a layer of dissolved cellulose, also the textile yarns manufactured from twisted paper.

J. F. Briggs.

A Course of Practical Work in Agricultural Chemistry for Senior Students. By T. B. Wood, M.A., Drapers Professor of Agriculture in the University of Cambridge. Cambridge: At the University Press. Price 2s. 6d. net.

The contents of this pamphlet are the outcome of seventeen years' experience in teaching a class of senior students in the University of Cambridge, and the hope is expressed by the author that it may be found useful to teachers in other institutions who are attempting to give their senior students some practical acquaintance with the modern developments of agricultural chemistry. To fulfil such ambitious objects within fifty-six pages of letter-press would be a difficult task, and a perusal of the text shows it to be devoted entirely to a description of methods of analysis of soils, manures, milk, carbohydrates, proteïns, oils, food, roots, cereals, etc. Of these the methods relating to agricultural chemistry are the best, though some of them are of such a rough-and-ready character—notably those for the qualitative examination of soil—that they appeal to the untrained agriculturist rather than to the senior student. As an example of the slovenly way in which the pamphlet is written, the paragraph dealing with the estimation of nitrates in soil may be cited: "Take 1 cc. of 'soil water' in a perfectly clean test tube, add about 3 c.c. of strong H_2SO_4, shake to mix, and cool. Add about 1 c.c. of carbazol solution, shake and leave to stand five minutes. Match this colour with a solution of KNO_3 containing 10 parts N in 1,000,000, *i.e.*, 0·072 grm. KNO_3 in 1000 c.c."

Under milk analysis it is stated that there are two ways of estimating fat in milk, chemically by the Werner-Schmid method, and mechanically by the Gerber method. As a general test for the carbohydrates, the author observes that all carbohydrates, except cellulose, when boiled for some time with dilute acid, and then neutralised, give sugars which reduce Fehling's solution. He contradicts this on the next page by stating that cellulose under these circumstances is converted into glucose. The remarks on the sugars and their estimation are in many instances misleading and inaccurate.

The writer much regrets having to pass such severe strictures on a work emanating from a University which has done so much to promote agricultural science.

ARTHUR R. LING.

THE SALE OF FOOD AND DRUGS ACTS. By Sir W. J. BELL, C. F. LLOYD, and R. A. ROBINSON. Pp. xxvi and 303. London: Butterworth and Co.; Shaw and Sons. 1910. Price 8s. 6d. net.

This, the fifth, edition of the book has been enlarged so as to include the Butter and Margarine Act, 1907, and the Butter Factories Registration Order, 1907. More than fifty decisions of the different superior courts of the United Kingdom have been reported since the publication of the last edition of the book, and these, together with a number of circular letters from the various Government departments, are also included. The book contains an immense amount of information for the use of those engaged in the working of the Acts relating to the Sale of Foods, Drugs, etc., every section of the various Acts being commented upon, and the legal decisions relating to proceedings taken under the sections are recorded concisely. The information given in the volume has been brought up to date, and deals with the whole of the laws on the subject, from the Adulteration of Coffee Act, 1718, to the Fertilisers and Feeding Stuffs Regulations, 1910. An alphabetical list of cases is given and an efficient index is provided. W. P. SKERTCHLY.

MODERN INDUSTRIAL CHEMISTRY. By H. BLÜCHER. Translated by J. P. MILLINGTON, M.A., B.Sc. London: The Gresham Publishing Company. 1911. Price 30s.

In the Publishers' Note it is stated that this book is designed to cover the whole range of subjects with which the chemist and manufacturer are usually concerned, and that it is intended to occupy a position between the textbook and the lexicon. When the whole field of chemical technology is covered in something under 800 pages, it will be readily understood that the various subjects cannot have been dealt with at all fully. As a matter of fact, it is somewhat difficult to understand the precise class of person to whom this work would be likely to appeal, since the information is in the great majority of cases too incomplete to be of any value to inquirers seeking really detailed information, whilst, on the other hand, the book is not one to which the ordinary scientific reader would be likely to be attracted. On the whole, the subject-matter seems to be accurate; but some of the articles appear to have been hastily compiled, and contain information which is neither correct nor up to date, whilst in other cases the processes (*e.g.*, brewing) dealt with have special reference to German procedure, and are, therefore, of less interest to the English reader. The list of firms given in connection with the various chemical products dealt with may sometimes be useful, but they have rather the appearance of advertisements, and in certain cases the firms mentioned are scarcely representative ones. The extent to which condensation has been carried out may be gathered from the fact that the technology of sodium and its various compounds are dealt with in some seventeen pages. The book is illustrated, and some of the illustrations are clear and well chosen, and the printing and general style of the book are good. A. CHASTON CHAPMAN.

NEW BOOKS.

ORGANIC CHEMISTRY FOR THE LABORATORY. By W. A. NOYES, Ph.D. 8vo. volume. The Chemical Publishing Company: Easton, Pa., United States of America. 1911. Price $2.

A second edition, revised and enlarged, contains 273 pages of subject-matter, with 41 illustrations, and an alphabetical index of subjects. The subject-matter is classified under the following heads: I. Analysis of Compounds of Carbon. II. General Operations. III. Hydrocarbons. IV. Alcohols and Phenols. V. Ethers. VI. Aldehydes, Ketones, and their Derivatives. VII. Acids. VIII. Derivatives of Acids. IX. Hydroxy- and Ketonic Acids. X. Carbohydrates. XI. Halogen Compounds. XII. Nitro Compounds. XIII. Amines. XIV. Diazo-, Hydrazo-, Nitroso-, and other Nitrogen Compounds. XV. Sulphur Compounds. XVI. Qualitative Examination of Carbon Compounds. Reagents.

YEAR-BOOK OF PHARMACY AND TRANSACTIONS OF THE BRITISH PHARMACEUTICAL CONFERENCE. Edited by J. O. BRAITHWAITE. 8vo. volume. London: J. and A. Churchill. 1910. Price 10s. net.

This year-book comprises abstracts of papers relating to Pharmacy, Materia Medica, and Chemistry, contributed to British and foreign journals from July, 1909, to June, 1910; and the Transactions of the British Pharmaceutical Conference, which was held at Cambridge in July, 1910.

JULY, 1911. Vol. XXXVI., No. 424.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The ordinary meeting of the Society was held on Wednesday evening, May 31, in the Chemical Society's Rooms, Burlington House. The President, Mr. E. W. Voelcker, A.R.S.M., F.I.C., occupied the chair.

The minutes of the previous ordinary meeting were read and confirmed.

A certificate of proposal for election to membership in favour of Mr. H. C. Huish was read for the second time; and certificates in favour of Messrs. Ronald Devereux Carty, A.R.C.Sc.I., A.I.C., The Laboratories, Survey Department, Public Works Ministry Gardens, Cairo, assistant in the Survey Department's Laboratory, Cairo; William Keighley Walton, "Beechwood," Upper Rushton Road, Thornbury, Bradford, assistant to Messrs. Richardson and Jaffé; and G. F. Wesley-Martin, Castle Park, Lancaster, chemist to Messrs. Maudsley and Son, were read for the first time.

Mr. A. D. Heywood, A.I.C., was elected a member of the Society.

The following papers were read: "Notes on the Analysis of Margarine," by Cecil H. Cribb, B.Sc., F.I.C., and P. A. Ellis Richards, F.I.C.; "Observations on Some Methods of estimating Cocoanut Oil and Butter in Butter and Margarine," by Cecil Revis and E. Richards Bolton; "The Composition of Milk," by H. Droop Richmond, F.I.C.; "The Estimation of Quinine as the Acid Citrate in Certain Organic Liquids," by T. Cockburn, F.I.C., and J. W. Black; "The Determination of the Amount of Dissolved Oxygen absorbed by Sewage Effluents containing Nitrite, and of the Amount of Nitrite in Sewage Effluents or Water," by R. W. Clarke, F.I.C.; and "Further Analyses of Ghee," by Cecil Revis and E. Richards Bolton.

NOTES ON THE ANALYSIS OF MARGARINE.

By CECIL H. CRIBB, B.Sc., F.I.C., and P. A. ELLIS RICHARDS, F.I.C.

(*Read at the Meeting, May* 31, 1911.)

The frequent occurrence of cocoanut oil in margarine mixtures (butter substitutes) at the present time has introduced a new factor into butter analysis. It is fully recognised that the simple method of examination by the official Reichert-Wollny process is no longer effective for determining whether margarine comes within the legal definition or not. Still less is it possible in the presence of cocoanut oil to arrive at the proportions in a mixture by this method.

Polenske's process and its modifications afford valuable assistance in this direction, more especially where only butter and cocoanut oil are present. Such mixtures, however, are the exception rather than the rule. Usually when margarine contains cocoanut oil it also contains animal fats other than butter, and it is precisely in cases such as these that difficulties arise.

Up to the present papers on the Polenske process and its modifications have largely dealt with the analysis of mixtures of two constituents, of which cocoanut oil is one. A number of processes, mostly modifications of the original Polenske, have been brought forward, but few, if any, of them offer any real advantage over the original method, and some at least greatly increase the time and trouble involved without materially improving the results. Ample illustration of this is afforded by Shrewsbury and Knapp (ANALYST, 1910, **35**, 385), and other authors, who show that the differences between the figures for cocoanut oil and butter-fat, upon which calculations are based, are not so great as in the Polenske process. The Polenske figure for cocoanut oil (17·5) is between five and six times that of butter (2 to 3·5), and, as far as we are aware, none of these other processes will improve on this ratio. It is obvious that the Wollny and Polenske processes together enable us to obtain figures from which it should be possible to calculate the percentages of butter and cocoanut oil in a mixture, leaving the third constituent, if present, to be calculated by difference, but no one has hitherto pointed out how this is to be done.

As the Wollny process is already in universal use, it would be very advantageous if a combination of the two were adopted as the basis of any new official method to be recommended by the Butter Committee. The initial procedure in both cases is practically identical, the Polenske being really an extension of the original Wollny method. To render the combined processes effective for the purposes we suggest, it is necessary to ascertain how far, if at all, the presence of one fat in a mixture affects the Wollny-Polenske figure of another.

It has been already shown by various workers that in mixtures consisting of *cocoanut oil and butter* ONLY, the proportion of the constituents can be determined with approximate accuracy by the simple Polenske process, and our experience confirms this; but the results obviously leave room for considerable improvement (see Table I., p. 331).[*]

The method of calculating the composition of the mixtures is as follows:

From the volatile insoluble acids we deduct one-tenth of the volatile soluble acids, assuming that this amount is derived from the butter present. This is not strictly correct, as a proportion of the soluble volatile acids is really due to the cocoanut oil. The residual volatile insoluble acids are calculated into terms of cocoanut oil on the assumption that genuine cocoanut oil yields 17·5 c.c. volatile insoluble acids. It is obvious from the table that the percentages of cocoanut oil obtained are low to the extent of from 2·5 to 9 per cent., the butter, if calculated by difference, being in excess to a corresponding extent. If any attempt be made to calculate the butter from the soluble volatile acids, the possible error is much greater owing to the wide variations in the soluble volatile acids of this fat. Even with cocoanut oil some disturbing influences are evidently at work, and it is to a consideration of these that our attention has been mainly directed.

---

[*] The figures in the table were obtained by saponifying 5 grms. of the fat with 20 c.c. of glycerol soda, employing the Wollny-Reichert process and apparatus throughout, but with powdered pumice (90 mesh). The distillate was cooled to 15 C. instead of 12 C., and the insoluble volatile acids collected as in the Polenske process.

In the first place the volatile soluble acids have to be corrected (*a*) for the proportion of soluble volatile acids due to the cocoanut oil, and (*b*) for the proportion of the insoluble volatile acids derived from the cocoanut oil becoming dissolved owing to the fact that while the volume of the distillate remains constant the volatile "insoluble" acids diminish directly with the cocoanut oil. In the second place the insoluble volatile acids have (*c*) to be increased by the amount that has been deducted from the soluble volatile acids, and (*d*) to be diminished by the amount of insoluble volatile acids due to the butter present.

In addition to the above, some experiments by Tatlock and Thomson (*J. Soc. Chem. Ind.*, 1909, **28**, 69-72; ANALYST, 1909, **34**, 223) suggest the necessity of a further correction—namely, for the retention of both soluble and insoluble volatile acids by the non-volatile fatty acids of butter, so that a portion of the volatile acids fails to reach the distillate.

We now propose to consider these various corrections in detail.

1. (*a*) *Correction of Volatile Soluble Acids for those due to Cocoanut Oil.*—The volatile soluble acid figure is derived both from the butter and the cocoanut oil. To ascertain the amount due to butter alone the number of c.c. due to cocoanut oil must, of course, be deducted. As cocoanut oil gives a fairly constant and small figure of 6·5 (for 5 grms. of fat) it is only necessary to know approximately the proportion of this fat in order to make the correction. For this purpose it is sufficient in the first instance to deduct from the volatile insoluble acids a number of c.c. equivalent to one-tenth of the volatile soluble figure, and to calculate the rest into cocoanut oil on the assumption that 17·5 c.c. corresponds to 100 per cent. of cocoanut oil. From the percentage thus obtained the soluble volatile acid figure for the cocoanut oil thus found is calculated and deducted from the total volatile soluble figure. The remainder, subject possibly to further correction, represents in c.c. the volatile soluble acids due to the butter present. As the matter is somewhat involved, a concrete example may be taken: 5 grms. of a mixture of butter-fat and cocoanut oil are found to give—

Soluble volatile acids, 25·2 c.c. Polenske figure, 5·4 c.c.

From the Polenske figure one-tenth of 25·2, *i.e.*, 2.5, is deducted. The remainder, 2·9, is equivalent to 16·5 per cent. of cocoanut oil, which should yield 1·07 c.c. of volatile soluble acids. This is then subtracted from 25·2, the result being 24·13 c.c. The volatile soluble figure for the butter employed in this mixture was 29·6, and calculating from this, the butter would be estimated at 81 per cent. The actual proportions taken were: Cocoanut oil, 20 parts; Butter-fat, 80 parts. Of course with a butter deviating more widely from the average, the figure for the butter would not be so good.

(*b*) *Correction for Solubility of So-called Insoluble Volatile Acids.*—Further corrections, however, as we have already suggested, must be made—namely, for the solubility in water of the so-called insoluble acids derived from the cocoanut oil.

From various experiments we have been led to adopt 0·8 c.c. as the figure to be deducted from the soluble acids and added to the insoluble acids. It must be borne in mind, however, that this figure is largely dependent on the temperature at which the distillate is filtered. In view of the great inconvenience of having to cool the latter to as low a temperature as 12° C., we have adopted 15° C., as it is only in the height of summer that the water-supply is likely to be warmer than this. If the correction be made, it becomes necessary to alter the figure for the cocoanut oil insoluble acids, on which the calculation of the percentage of the cocoanut oil is ultimately based, from 17·5 to 18·3 c.c. If this be done, the percentage of cocoanut oil becomes 20·2, as compared with 20 actually present. This correction also affects the percentage of butter, inasmuch as the soluble volatile acids from which this is calculated are further reduced. After the necessary allowance has been made, the proportion of butter becomes 79·9 instead of 80.

Table I. (p. 331) gives the results of the analyses of several mixtures of known composition, and shows also the effect of the various corrections. In view of the fact of the wide variations in the volatile soluble acids of different butters, it would be more satisfactory to calculate the butter by difference.

The presence of a third constituent seriously affects the complexity of the problem. It is hardly necessary to point out that the third fat will also contribute its quota of soluble and insoluble volatile fatty acids, and, for this, allowance must be made. In addition, other and less obvious effects are produced by the presence of the third constituent. Both butter-fat and margarine-fat exercise a retentive influence on the distillation of the soluble and insoluble volatile acids.

Of much more importance, however, is the fact that the whole process is an empirical one, and assumes a more or less definite ratio between the quantity of the volatile fatty acids and the volume of water distilled, and any departure from this alters the composition of the distillate. This has already been pointed out by Tatlock and Thomson (*loc. cit.*), but hitherto, so far as we are aware, the fact has not received any special attention.

Taking respectively 5 grms. and 1 grm. of cocoanut oil and distilling in each case in the usual way, there is a wide disproportion between the volume of the distillate and the weight of fatty acids distilled.

A series of experiments of our own illustrate this fact, and we found, as has been already demonstrated by Tatlock and Thomson, that in the case of both butter-fat and cocoanut oil, the soluble and insoluble volatile acids are quite out of proportion to the weights of the respective fat taken, increasing relatively as the quantity of the latter diminishes.

The retentive influence of the non-volatile fatty acids of margarine and butter upon the volatile acids of cocoanut oil and butter is shown by the results of some experiments given in Table II. (p. 332), in which the washed insoluble non-volatile acids from 5 grms. of certain fats were added to the liberated fatty acids of the same or other fats and distilled in the usual way.

In interpreting the figures, it should be borne in mind that the extra portion of insoluble acids added to the contents of the flask gives both soluble and insoluble acids as shown in Table III. (p. 332).

If allowance be made for this, the fact is obvious that the volatile acids are held back under these conditions. Thus, taking the Experiment 2, Table II., the figure for the volatile soluble acids is 28·75 for the butter-fat, and 0·2 for the margarine fatty acids added. The figure obtained was only 27·1—a loss of 1·85 c.c. In the case of the insoluble acids the calculated figure was 3·1, as compared with 2·0 actually found. To get the best results from the process in the case of a mixture of more than two fats, some correction must be made for these phenomena.

In Table IV. (p. 333) we have given the analytical results obtained by the examination of a series of known mixtures, the butter-fat content varying between 5 and 15 per cent.

We have not yet succeeded in working out a satisfactory method for correcting the figures obtained for the combined effect of the retention of volatile acid and the variation in the ratio between the water and the quantity of acids distilled, but a consideration of the figures in the table shows that an addition of 1·9 c.c. to the insoluble volatile acids, and a corresponding reduction of the same amount from the soluble volatile acids gives very fair results.

It will be observed that we have applied a different correction in the case of the three constituent mixtures from that used where butter and cocoanut oil only are present, and some justification for doing so is to be found in the fact that margarine fat appears to exert a much greater retentive influence on the volatile acids than does butter-fat (Table V., p. 333).

Although the suggestions put forward are only tentative ones, we trust that it may be of some assistance to the Butter Committee in the investigation upon which they are now engaged.

OBSERVATIONS ON SOME METHODS OF ESTIMATING COCOANUT OIL AND BUTTER IN BUTTER AND MARGARINE.

By CECIL REVIS AND E. RICHARDS BOLTON.

(Read at the Meeting, May 31, 1911.)

SINCE the day of Polenske's classical work on the estimation of cocoanut oil in butter, innumerable methods have been put forward for a similar purpose; it is, however, unfortunate that nearly all the later experimenters entirely fail to realise the fact which Polenske emphasised—namely, that there is no such thing as "average butter." The failure to recognise this practically renders all these later methods of no real value. The apparent reason for this diligent search for improvement can only be ascribed to a failure to realise the scrupulous attention to experimental details which the Polenske method necessitates, and at the outset we would strongly reiterate our conviction, which will be supported by all those who observe the necessary attention to detail, that the method fully justifies its claim, and is the only chemical method by which small quantities of cocoanut oil can be detected and approximately estimated in butter. Since the method was published we have applied it to a very large number of butters of known origin, and also to admixtures of these butters with known quantities of cocoanut oil, and have only once found cocoanut oil indicated when not present, and only once failed to find it when the percentage did not fall below five.

In the case of margarine, the increasing and almost universal use of cocoanut and palm kernel oil must be our sole apology for drawing attention again to the Polenske process, and the necessity for standard conditions.

These conditions as originally laid down by Polenske are complete except in one particular (to which Mr. Richmond drew our attention, and to whom our thanks are due for the suggestion). This particular is the temperature of the still-head during distillation, as undoubtedly the composition of the distillate varies with this temperature; we have therefore carefully investigated the effect of maintaining a constant temperature in the still-head, and compared it with our ordinary conditions of work.

For this purpose we employed an apparatus similar to that used by Richmond in his studies on Steam Distillation (ANALYST, 1908, **33**, 305), and as a result (see Table IV., p. 340) we find that, so long as reasonable care is taken to protect the still-head from draught, no error arises from this source ; and as the maintenance of a high temperature depresses both the Reichert-Meissl and Polenske values, there is no advantage in employing a specially protected high-temperature still-head, beyond the fact that time, and to a certain extent the type of distillation, become of less importance.

Besides the Polenske process, we have made use of the recently published method of Shrewsbury and Knapp (ANALYST, 1910, **35**, 385), and to a limited extent of the cadmium method of Paul and Amberger (*Zeitsch. Untersuch. Nahr. Genussm.*, 1909, **17**, 1), and also the method of Kirschner (*ibid.*, 1905, **9**, 65), as being representative of the different types of methods which have been put forward. The cadmium method, on account of its extreme laboriousness and questionable value (in our hands), was soon abandoned.

The method described by Shrewsbury and Knapp, is obviously open to several sources of error; and, in spite of the favourable results obtained by others, we found ourselves quite unable to obtain concordant results with the same samples: we therefore slightly modified the method, in order to avoid as far as possible these sources of error, though at the same time the time of operation was necessarily increased.

The method as modified by us is as follows: Five grms. of the fat are saponified in the usual manner, with glycerol soda. To the soap are added 150 c.c. of boiling water, and then 5 c.c. of sulphuric acid (1 in 5). The flask is closed with an india-rubber stopper, and the whole vigorously shaken for about half a minute, cooled by standing in a stream of running water, and the liquid poured off from the cake of fatty acids through a filter as completely as possible. To the fatty acids in the flask 20 c.c. of boiling water are added, and the whole well shaken. The flask is cooled, and the water poured off through the filter as before. The solid cake is then washed with 20 c.c. of cold water, which is poured on the filter and then with a final 10 c.c. The flask is inverted over the filter till the cake is thoroughly drained. The filter-paper is then dropped into the flask containing the cake of fatty acids, 100 c.c. of 60 per cent. alcohol (by volume) added, and the whole allowed to boil under a reflux condenser with occasional shaking for half an hour. The flask is removed, cooled rapidly by shaking under a water-tap, and finally allowed to stand in water at 60° F. for half an hour. The liquid is filtered off, and 50 c.c. titrated hot with $\frac{N}{10}$ soda. The number of c.c. so obtained constitutes the modified Shrewsbury and Knapp value.

The figures obtained by us for butters with this modified method show that the information given is not so reliable as with the Polenske process (see Table I., p. 338). In the case of margarines containing cocoanut oil, the values, generally speaking, are independent of the presence of butter-fat, but the results are of less value than those obtained by the Kirschner process.

It was soon apparent to us that, while Kirschner's extension of the Reichert-Meissl process offers little value over the Polenske method for cocoanut oil in butter, it is of decided value in the case of addition to butter of margarine mixtures containing cocoanut oil, and of unique value for the examination of margarines containing cocoanut oil with or without admixture with butter; and it is our conviction that it is the only published method at present available which will decide whether butter-fat is present in a margarine containing cocoanut oil, even if the amount be only 2 per cent. in conjunction with 75 per cent. or more of cocoanut oil.

We have examined by this process is a comprehensive series of margarines containing percentages of cocoanut oil from 5 to 75 per cent., with and without the addition of from 2 to 10 per cent. of butter-fat.

As, however, these values only apply when the Reichert-Meissl-Polenske-Kirschner process is carried out under the conditions which we employed, we append for convenience *exact* details of the methods: Five grms. of the fat and 20 grms. of glycerol are weighed with a 300 c.c. flask, and 2 c.c. of 50 per cent. sodium hydroxide solution added. The flask is heated over a flame with constant shaking till it clears suddenly, the soap is then cooled and 100 c.c. of recently well boiled distilled water is added, until solution of the soap is effected. 0·1 grm. of powdered pumice sieved through butter-muslin is added, and then 40 c.c. of sulphuric acid solution (20 to 25 c.c. of strong sulphuric acid diluted to 1,000 c.c., and the solution adjusted so that 35 c.c. neutralise 2 c.c. of the sodium hydroxide solution). The flask is at once connected with the condenser, and heated with a small flame till the insoluble acids are completely melted; the flame is then increased, and 110 c.c. distilled in nineteen to twenty-one minutes. The temperature of the condenser water should be from 18° to 20° C., and the dimensions of the apparatus are to be the same as given by Polenske. When 110 c.c. have distilled, the flame is removed, and a

25 c.c. cylinder placed under the condenser to catch any drops. The 110 c.c. flask and contents are stood in water at 10° to 15° C. for fifteen minutes. After mixing the contents of the 110 c.c. flask, they are filtered and 100 c.c. titrated with $\frac{N}{10}$ baryta, using 0·5 c.c. of a 1 per cent. solution of phenolphthaleïn as indicator. This number of c.c. increased by one-tenth, after subtraction of the blank (which must be determined in an exactly similar way, by using all the reagents except the fat), is the Reichert-Meissl value. The condenser, cylinder, and 110 c.c. receiver, are washed with 18 c.c. of cold water, which are then poured over the filter used to filter the distillate, and rejected. The condenser is washed out with four successive portions of 10 c.c. of neutral alcohol, which are received in the cylinder and poured over the filter into the 110 c.c. flask, the mixed alcohol solutions being then titrated with $\frac{N}{10}$ baryta, using phenolphthaleïn as an indicator. A blank value is obtained in a similar way. The number of c.c. of $\frac{N}{10}$ baryta used, less the number used for the blank, is the Polenske figure. Rather varying results have been obtained by various observers, but the following table will be found a very fair guide:

Reichert-Meissl Values.	New Butter Values (Polenske).
32	3·5
31	3·2
30	3·0
29	2·9
28	2·7
27	2·4
26	2·0
25	1·8
24	1·7
23	1·6

A "new butter value" (Polenske) exceeding by 0·5 c.c. the figure corresponding with the Reichert-Meissl value found indicates the presence of cocoanut or palm kernel oil or their products.

Kirschner's Extension.—To the 100 c.c. of the 110 c.c. distilled and titrated with baryta (care having been taken not to exceed the neutral point) is added 0·5 grm. of finely powdered silver sulphate, and the whole allowed to stand for an hour, with occasional shaking. The liquid is then filtered, 100 c.c. measured off, 35 c.c. of water and 10 c.c. of sulphuric acid (as previously employed) added, together with a long piece of aluminium wire, and 110 c.c. again distilled off in the standard Reichert-Polenske apparatus in twenty minutes; 100 c.c. are titrated, and the number of c.c. so obtained corrected for the blank, is calculated to the Kirschner value by the following formula:

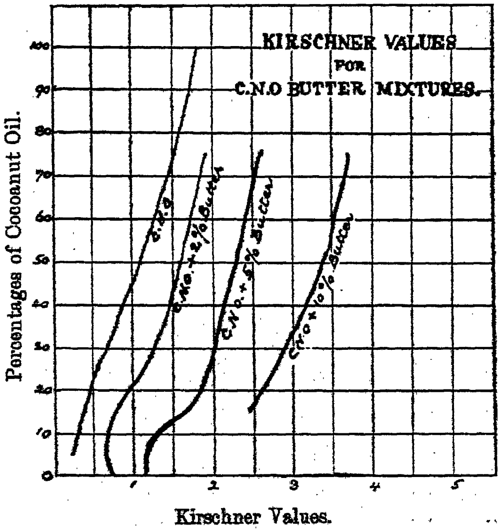
$$K = x \times \frac{121 \times (100 + y)}{10{,}000};$$

where x = the corrected Kirschner titration;
y = the number of c.c. of baryta used to neutralise 100 c.c. of the Reichert-Meissl distillate.

It will be seen on examination of Table I. (p. 338) that the variation between the Kirschner and Polenske values is greater than the variation between the

Polenske and the Reichert-Meissl values. The Kirschner value therefore assumes a certain amount of importance in the cocoanut oil butter mixtures; as will be seen, this importance is still further enhanced when the cocoanut oil is introduced into the butter as the constituent of a margarine.

This is due to the fact that the Kirschner value is practically a measure of the butyric acid content of the mixture, and is free from the difficulty which attaches to the value obtained by some of the other silver methods, in which the effect on the solubility of the silver salts of a common ion does not always seem to have been fully recognised. If the values given in Table II. are plotted, using percentages of cocoanut oil as ordinates and corresponding Kirschner values as abscissæ, it will be found that in the case of butter-free margarines containing cocoanut oil, practically a straight-line curve results, and that this curve lies wholly within that connecting the similar values obtained when 2 per cent. of butter-fat is present.



Objection may be made that constant values have been assumed for cocoanut oil, but in our experience the assumption is sufficient for the purpose. The variations of pure cocoanut oil and of the substances included under that designation are not great enough to invalidate the statements we have made. The curves for larger amounts of butter-fat lie still farther away. By means of these curves it can be at once determined from any Kirschner value, whether butter-fat is, or is not present, taking into account the corresponding Reichert-Meissl and Polenske figures. Further, for butter-free cocoanut oil margarines the Kirschner value is in complete agreement with the saponification and other values, usually concurrently determined, and so proving a most useful additional check.

Table III. (p. 340) gives the Shrewsbury and Knapp values for the same mixtures.

DISCUSSION.

The PRESIDENT, in inviting discussion, remarked that in these empirical methods it was important that the prescribed conditions of working should always be faithfully adhered to. Even the use of an upright instead of an inclined condenser, or of pumice of varying degrees of fineness, would cause the results to vary considerably.

Mr. RICHMOND said that, in attempting to ascertain the effect of different constituents on the proportion of soluble and insoluble volatile acids obtained on distillation, Messrs. Cribb and Richards had set themselves a very large problem, the distillation of butter-fat being one of the most complicated cases of steam distillation, since the water-soluble acids (which included both the soluble and insoluble volatile acids) were being distilled from a continually diminishing quantity of water, and were also soluble in a different ratio in the fatty acids, which latter were also slowly diminishing in quantity. The rate at which the soluble fatty acids were dissolved out from the insoluble fatty acids was also an important factor, depending upon the extent of the exposed surface of the fatty acids. In the Polenske process the exposure of surface was carried as far as possible to the limiting value by the use of a considerable quantity of very finely divided pumice, in order to approximate to a constant condition. He could not help thinking that the authors would have found the solution of the problem easier had they treated it mathematically. Messrs. Revis and Bolton had approached the matter in an entirely different way, and their combination of the Kirschner and Polenske methods seemed likely to give good results in the determination of the proportion of butter-fat in margarine. Their experience in regard to the use of a jacketed still-head in the Polenske process was much the same as his own. The only advantage of the jacketed still-head was that, except where the quantity of insoluble volatile acids was very large, it allowed of a greater latitude in regard to the time of distillation. In the ordinary Polenske process the limitation as to time of distillation was somewhat inconvenient, but when a jacketed still-head was used, it made practically no difference, with ordinary butter, whether the distillation was carried out in exactly twenty minutes, or continued for half an hour or even longer. When, however, large proportions of cocoanut oil were present, it was necessary always to distil for the exact time laid down, because, unless the boiling was very vigorous, the fatty acids were not mixed up, and the same surface of the insoluble fatty acids was not exposed to the aqueous portion.

Mr. T. Macara thought that the Polenske process should be included in any standard process of butter and margarine analysis that might be laid down, and that the inclusion of Messrs. Bolton and Revis's modification of the Kirschner method also would be additionally useful, particularly in the case of margarines containing cocoanut and similar oils. He had tried Messrs. Revis and Bolton's modification of Shrewsbury and Knapp's process, and had found it to be a great improvement.

Mr. E. Hinks, referring to Messrs. Revis and Bolton's statement that the presence of as little as 2 per cent. of butter-fat could be detected by means of the Kirschner process, asked if this held good when larger proportions of butter were present—*i.e.*, would the difference between, say, 10 per cent. and 12 per cent. of butter-fat be shown?

Mr. Cribb said that Mr. Richards and he had felt that the data they had so far obtained were not sufficient to permit of their treating the subject mathematically. They had brought their work forward merely as an attempt to open the way for the adoption of the combined Reichert and Polenske processes as a routine method, believing that, if an official process were to be laid down, it would be of advantage to choose one which was already familiar. Among the points in the official Reichert-Wollny method with regard to which they thought that modification was desirable was that of the temperature at which the distillate was filtered. It was inconvenient in warm weather to have to reduce the temperature to 12° C. by special means, and from this point of view 15° C. would be more satisfactory; but, on the other hand, the results were not so good as with the lower temperature. While pumice had been used in all the experiments recorded in their present paper, he should very much like to see it replaced by aluminium wire, which was first suggested to him by Mr. Stokes. The slow stream of hydrogen which the aluminium wire gave off most effectually prevented bumping; and when the wire was removed the residual fatty acids were available for further examination. The only objection that they had found to the use of aluminium wire was that the figures for soluble and insoluble volatile acids were altered, and a fresh basis for calculation would have to be worked out. He had been much interested in Messrs. Revis and Bolton's remarks about the Kirschner process, which appeared to supplement the Polenske process to a valuable degree just at the point where it was weakest—namely, in the determination of the proportion of butter present.

Mr. Revis agreed that the use of pumice was open to some objection, but he was afraid that it could not be satisfactorily replaced. Aluminium wire was, of course, much more convenient, and was satisfactory in the Kirschner process, where there was no layer of fatty acids to be kept boiling; but, in order to get the full Polenske value, the fatty acids must be kept boiling, and with aluminium wire the boiling could not be so satisfactorily maintained as with pumice. In some comparison experiments which Mr. Bolton and he had made, using pure cocoanut oil, a Polenske value of only 11·2 was obtained when aluminium wire was used, whereas the same sample yielded a Polenske value of 16·1 when pumice was used. He was not sure whether the Kirschner process would be capable of distinguishing between 10 per cent. of butter-fat and 12 per cent., but in practice it would scarcely be necessary to do this, and in any case he considered that the Kirschner value would allow of a nearer approximation to the truth than could be obtained in any other way.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Examination of Bismuth Salicylate. H. Caron and D. Raquet. (*Ann. Chim. anal. appl.*, 1911, **16**, 177-179.)—The authors use the diphenylamine test for bismuth subnitrate in the following manner: A little of the sample is dissolved in warm dilute (1 : 10) hydrochloric or sulphuric acid, the cold liquid filtered from the crystallised salicylic acid, and about 1 c.c. of the filtrate added to 2 c.c. of a solution of diphenylamine sulphate in dilute sulphuric acid (1 : 10). On now pouring about 3 parts by volume of pure sulphuric acid down the side of the tube a blue ring will be produced in the presence of traces of the subnitrate. Another test is to add to a little of the sample 1 c.c. of pure sulphuric acid to decompose the salicylate, and then to dilute the liquid, and add an excess of ammonia solution. Any nitric acid liberated by the sulphuric acid will react with the salicylic acid to form nitro-derivatives which will give a yellow coloration with the ammonia. This test can be made quantitative. C. A. M.

Testing of Camphor. W. Lenz. (*Arch. Pharm.*, 1911, **249**, 286-298.)—The author has made a comparative examination of samples of camphor obtained from East Africa, together with a standard sample of Asiatic camphor and one of synthetic camphor. The melting-point is regarded by the author as a most valuable means for indicating the purity of a sample of camphor. Absolutely pure camphor melts at 178° C. The estimation of the specific rotatory power is not adapted to the valuation of crude camphor, because the latter contains impurities which possess a stronger dextrorotatory power than pure camphor. It is, however, a means for ascertaining whether the sample consists of natural dextrorotatory camphor. The estimation of the residue from the evaporation of the camphor on the water-bath affords a useful measure of its purity, but it requires a very considerable time. The conversion of the camphor into the oxime has been effected by an improved method of the author so as to yield 93 per cent. of the theoretical quantity, instead of 75-85 per cent., as formerly. In the author's experiments the yield of oxime appears to be proportional to the percentage of pure camphor in the sample, but the deficiency is too great to allow the method to serve for the accurate valuation of the camphor. The colour reaction with vanillin and hydrochloric acid can at the best only serve for the recognition of natural camphor. This coloration is not so characteristic as the red coloration produced by pure hydrochloric acid, containing 38 per cent. of real acid, with natural camphor. The quantity of residue insoluble in 10 parts of this strong acid is a good measure of the impurities of commercial camphor, and might serve as the basis of an accurate method. No single test is able to afford an accurate valuation of any sample of camphor; conclusions must be drawn from the general results of all the tests. J. F. B.

Quantitative Estimation of Cantharidine in Cantharides and in Tinctures. A. Kneip, N. Ney, and F. Reimers. (*Arch. Pharm.*, 1911, **249**, 259-285.)—This is a prize essay composed for the Deutscher Apotheker Verein, and constitutes a complete survey of the methods which have been proposed for the estimation of cantharidine in the various forms of the drug. The methods investigated are twenty in number, and, in conclusion, each of the authors recommends a different modification of one of the older methods. The various methods may be classified as follows: Extraction with solvents without any addition; extraction with solvents with the addition of alkalis—*e.g.*, ammonia, magnesia, sodium carbonate, sodium hydroxide; extraction with solvents with the addition of acids—(*a*) with benzene, (*b*) with chloroform. Ney recommends a modification of the Panchaud-Seigfried method, extraction with chloroform in presence of nitric acid, evaporating the chloroform slowly, and washing the residue with limited quantities of petroleum spirit, alcohol, and ether successively, the two latter solvents being previously saturated with cantharidine. Reimers adopts the methods of Fromme and the Ph. Ger. with modifications: extraction with chloroform in presence of hydrochloric acid, distillation of the chloroform, and extraction of the residue with petroleum spirit, collecting the remainder on a tared filter. The whole is subsequently washed with water containing a trace of ammonium carbonate and dried at 40° C., the weight being corrected for losses by solubility. The cantharidine so obtained is not quite pure, and may be purified by dissolving in acetone. The process recommended by Kneip has the advantage of yielding a perfectly pure cantharidine, melting at 214° C. Fifteen grms. of powdered cantharides are moistened with 3 c.c. of absolute alcohol containing 25 per cent. of dry hydrogen chloride, the alcohol is evaporated off at a low temperature, and the substance is extracted in a Soxhlet's apparatus with a mixture of 30 c.c. of petroleum spirit (b.-p. 50°-75° C.) and 50 c.c. of benzene for two hours. To the extract, after the evaporation of the solvent, are added 5 c.c. of a mixture of 10 parts of alcohol and 90 parts of petroleum spirit to dissolve the green fat, and the liquid is decanted off through a tared filter previously dried at 60° C. The crystals are washed with successive portions of 5 c.c. of the same solvent. The fat is also washed out of the filter in the same way, and the flask and filter are dried at 60° C. and again weighed. The free cantharidine in the sample may be estimated by extraction without previous acidification. The results are fairly satisfactory. According to Kneip, Spanish flies should yield a minimum of 0·65 per cent. of cantharidine by this method. This author also describes a simplified modification of his method for the estimation of cantharidine in tinctures. For the details of the manipulation the original paper should be consulted. J. F. B.

Microscopical Examination of Gambier. H. Brumwell. (*J. Soc. Chem. Ind.*, 1911, **30**, 475-477.)—Gambier is the evaporated extract of the leaves and twigs of the climbing shrub *Nauclea* or *Uncaria Gambir*. The insoluble matter amounts generally to 10 to 15 per cent., but by more careful manufacture it might easily be reduced to 3 or 4 per cent.; the tanning matter amounts to about 40 per cent., and soluble non-tannins to about 30 per cent. The insoluble matter consists mainly of leaf-débris and plant-hairs, the latter in great abundance. The cuticles of the leaf may be separated for microscopic examination by boiling successively with 5 per cent. sulphuric acid, 5 per cent. sodium hydroxide, nitric acid sp. gr. 1·2, and nitric acid with the addition of small quantities of potassium chlorate. The upper cuticle of the leaf exhibits very distinct cells, fairly regularly disposed and no hairs or stomata. In the lower cuticle the stomata are large, very distinct, in great profusion, and are devoid of hairs. Sago flour is occasionally used to adulterate gambier. In the analysis of gambier, which is apt to be of irregular composition, it is advisable to weigh out a large portion of the sample—say 300 to 500 grms.—and dissolve in water, boiling if necessary, and to make up the syrup to a known weight for analysis. J. F. B.

Analysis of Gum Arabic Pastilles. R. Malenfant. (*J. Pharm. Chim.*, 1911, **3**, 484-489.)—A sample of so-called gum pastilles which had the taste of a gum arabic product of good quality was found to have the following approximate composition: Dextrose, 25; sucrose, 25; gelatin, 35; and tapioca, 15 per cent. It also contained a small quantity of calcium sulphate, but not a trace of gum arabic.

C. A. M.

Distribution of the Phosphoric Acid in Milk. F. Bordas and F. Touplain.

(*Ann. des Falsifications*, 1911, **4**, 229-231.)—Estimations of the total phosphoric acid in the ash, in the lactoserum separated after coagulation of the milk by trichloracetic acid, and in the coagulum (fat and casein) after oxidation with nitric acid and potassium permanganate, gave the following results: In total ash, 1·663 grms.; in lactoserum, 1·279 grms.; and in coagulum, 0·319 grm. per litre.

C. A. M.

Composition of the Seeds of Leguminous Plants grown in Togo and German East Africa. C. Grimme.

(*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 547-553.)—The seeds of the different plants in the following table are largely grown as food products in Togo and German East Africa:

C. A. M.

Cryoscopic Examination of Milk. L. Stœcklin.

(*Ann. des Falsifications*, 1911, **4**, 232-257.)—From the examination of about 2,500 samples of milk during four years the author concludes that a cryoscopic examination will distinguish between genuine and watered milk, notwithstanding differences of age or the addition of potassium bichromate to the former. The production of 1 grm. of lactic acid per litre increases the observed freezing-point of a milk from about 0·045° to 0·050° C., and the latter value may be accepted as the correction to be made in practice. In like manner 1 grm. of potassium bichromate increases the acidity by an amount equivalent to 0·614 grm. of lactic acid. The amount of lactic acid capable of influencing the PG in a bichromated milk may be found by means of the formula—

$$L = A - (1{\cdot}20 + Cr \times 0{\cdot}061),$$

where L represents the true lactic acid in grms. per litre, A the total acidity of the milk expressed in terms of lactic acid, and Cr the grms. of potassium bichromate per litre. The factor 1·20 for the "non-lactic acidity" is reduced to 1·08 in a milk containing 10 per cent. of water, to 0·96 for 20 per cent. of water, etc. The average of the estimations showed that 1 grm. of potassium bichromate increased the original freezing-point of the milk (PGI) by 0·018° C. The application of these calculations may be illustrated by the following results obtained with a milk containing 1·1 grms. of potassium bichromate per litre and 3·5 grms. of total acids expressed as lactic acid:

$$\text{Observed freezing-point} = -0{\cdot}490^\circ \text{ C.}$$

$$\text{True lactic acid, } 3{\cdot}5 - (1{\cdot}20 + 1{\cdot}1 \times 0{\cdot}61) = 1{\cdot}73.$$

$$\begin{array}{lr} \text{Correction for lactic acid, } 1{\cdot}73 \times 0{\cdot}050 = & -0{\cdot}0865^\circ \text{ C.} \\ \text{,, \quad ,, \quad bichromate, } 1{\cdot}1 \times 0{\cdot}018 = & -0{\cdot}0198^\circ \text{ C.} \\ \hline & 0{\cdot}106^\circ \text{ C.} \end{array}$$

$$\text{PGI} = 0{\cdot}490^\circ \text{ C.} - 0{\cdot}106^\circ \text{ C.} = 0{\cdot}384^\circ \text{ C.}$$

$$\text{Amount of water added to milk} = 100 - \frac{0{\cdot}384}{0{\cdot}550} \times 100 = 30 \text{ per cent.}$$

Whenever the PGI is lower than −0·530° C., the addition of water is certain, whereas in the case of a milk showing a PGI of 0·550 watering cannot be regarded as proved, whatever be the results of chemical analysis. The pathological occurrence of an excess of water in milk (physiological water) will show a normal PG (about 0·550° C.) accompanying chemical evidence of the addition of water. C. A. M.

Comparison of the Reductase Test with Other Hygienic Tests for Milk. C. Barthel. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 513-534.)—The author has made a comparative study of the results obtained with his reductase test (Analyst, 1908, **33**, 237) and with other hygienic tests for milk. In Auzinger's modification of the alcohol test (*Milchwirtsch. Zentralbl.*, 1909, **5**, 293) a definite quantity (5 c.c.) of the milk is shaken with an equal volume of 60 per cent. (by weight) alcohol, and a note taken whether any precipitation of casein occurs. If there is no trace of a precipitate the milk is fresh, whilst a fine flocculent precipitate is obtained with slightly sour milk and a coarse one with distinctly sour milk. The author's experiments with this test show that milk with an acidity of 21° (Thörner) begins to give the reaction, whilst in most cases milk with a lower degree of acidity gives a negative result. In three cases, however, a positive result was obtained in spite of the acidity being normal. One of these samples showed a reduction period of more than twelve hours, and contained 90,000 bacteria per c.c., and was thus satisfactory from the hygienic point of view. The second was a milk with a putrid odour, having a reduction period of eight minutes, catalase = 7·5 c.c., and bacteria 28,530,000 per c.c.; whilst the third was free from objectionable odour or taste, but had a reduction period of ten minutes, catalase = 6·6 c.c., and contained 12,090,000 bacteria per c.c. In the author's opinion, therefore, the alcohol test affords a sharp means of detecting incipient souring of the milk, but its hygienic significance is limited, and it affords no more information than the acid value. As regards the catalase test (Analyst, 1910, **35**, 256, 526), it was found that out of forty-eight samples of milk which fell within the normal limits for the test (0 to 2·5 c.c. of liberated oxygen), four contained more than 10,000,000 bacteria per c.c. When examined by the reductase method, however, these four samples all gave a shorter period of reduction than the normal period. Out of 102 samples examined, there were twenty in which there appeared to be no relationship between the number of bacteria and the catalytic activity. The experiments showed that 2·5 c.c. of oxygen cannot be accepted as the highest permissible limit for good milk, since samples of good quality relatively poor in bacteria gave results as high as 4·5 c.c. A catalase value above this limit, however, corresponded, as a rule, to bacteria in excess of 10,000,000 per c.c., and a very short decolorisation period in the reductase test. The chief value of the catalase test is to detect abnormal milk or that from diseased individual cows in a herd. In the reductase test a period of reduction of less than one hour corresponds to about 10,000,000 or more bacteria per c.c. In the case of milks containing 4,000,000 to 10,000,000 of bacteria per c.c., reduction took place within an hour in half the samples, whereas with a still smaller bacterial content the decolorisation period was almost invariably longer than three hours. Only in the case of one sample containing over 10,000 bacteria per c.c. did the decolorisation time exceed three hours. The number 10,000,000 may therefore be regarded as the extreme limit for the number of bacteria that may be estimated by the reductase test. Below that figure the number of bacteria does not stand in any direct relationship to the time of decolorisation. In milks containing 10,000,000 to 20,000,000 of bacteria per c.c. the decolorisation time varied from seven to thirty-five minutes, whilst in those containing over 20,000,000 it was nearly always less than fifteen minutes.

C. A. M.

Applicability of Recent Methods for the Examination of Milk. E. Philippe. (*Mitt. Lebensmittelunters. u. Hyg.*, 1911, **2**, 1-36; through *Chem. Zentralbl.*, 1911, I., 1447-1448.)—The author considers that a leucocyte count affords a valuable means of diagnosing disease of the udder (*cf.* Hewlett and others, ANALYST, 1910, **35**, 23), and that a high catalase number is a certain indication of disease (*cf.* Revis, ANALYST, 1910, **35**, 359). He agrees that no lower limit can be placed on this number, which he determines at 25° C. and calculates as c.c. of oxygen split off by 100 c.c. of milk. Of 200 samples tested in this manner, 114 were found to have a catalase number of less than 20, that of 51 lay between 20 and 30, that of 17 between 30 and 40, whilst 16 were found to have a catalase number exceeding 40.

The fermentation-reductase test, or M-reductase test of Sames (*Milchwirtschaftl. Zentralbl.*, 1910, **6**, 462), using methylene-blue solution free from formaldehyde, is said to be a certain means of determining whether milk is fresh or not; the reduction of the colour to its leuco-base is due to bacterial action. A milk which is not decolorised within three hours may be passed as normal. The reductase test, or M. reductase test of Sames (*loc. cit.*), in which methylene-blue solution containing formaldehyde is used, is of doubtful value (*cf.* also Römer and Sames, ANALYST, 1910, **35**, 407), but it is said that a normal milk should decolorise the reagent within ten minutes. The author attaches importance to the determination in milk samples of sediment, which should be effected by a gravimetric method. G. C. J.

Soluble Basic Constituents of the Mushroom. F. Kutscher. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 535-540.)—A sample of mushroom extract sold under the name of "hercynia" as a medicinal stimulant, was found to contain adenin, but no guanin or xanthin. There were also isolated arginin and a new base, $C_{19}H_{15}N_3O_2$, which could be regarded as histidin that had taken up three methyl groups. The hydrochloride of this base gave a strong diazo reaction and a white precipitate, but no coloration with Millon's reagent. With potassium mercuric iodide it yielded a copious precipitate soluble in excess; with iodine in potassium iodide solution a brown precipitate, and with saturated alcoholic mercuric chloride solution a crystalline white precipitate; its platinichloride separated in short transparent yellowish-red needles. Its aurichloride melted at 180° to 182° C. The mushroom extract also contained betain and cholin. Since the quantities of these bases and of the potassium present were insufficient to exert their specific activity, the author concludes that the good results obtained in the treatment of invalids with this extract must be attributed to the presence of substances not precipitated by phosphotungstic acid.

C. A. M.

Accurate Estimation of Nicotine in Tobacco and in Green Plants of Nicotiana Tabacum. R. Mellet. (*Schweiz. Wochensch. Chem. u. Pharm.*, 1911, **49**, 117-120; through *Chem. Zentralbl.*, 1911, I., 1561.)—Toth's process (ANALYST, 1902, **27**, 12) is very useful for the estimation of nicotine in solutions or extracts, but some further modification is required for its estimation in solid materials. According to the method now described, the finely cut material, 30 grms. in the case of dry tobacco and 250 grms. in the case of the green plant, is treated with boiling water in a well-closed flask, and after twenty-four hours the liquid is cooled and milk of lime added. The flask is again closed and allowed to stand for a further twenty-four hours with frequent agitation. The liberated nicotine is distilled off in a current of steam, in such a way that the volume of liquid in the flask is reduced. When the volume of distillate attains two to three times that of the original liquid the operation is stopped and the distillate is acidified with sulphuric acid. It is then evaporated to a small bulk with exclusion of air, and, after the addition of potassium hydroxide, the nicotine is extracted with ether. The ethereal solution, containing some ammonia, is concentrated until all the latter is eliminated. The remainder of the ether is evaporated at the ordinary temperature; the residue is dissolved in water and titrated with $\frac{N}{10}$ sulphuric acid. Estimations effected with known quantities of nicotine indicated that the total losses of the alkaloid amounted to 0·06 grm., which figure must be added to the values found. The accuracy of the process, taking the above correction into account, depends to a certain extent on the quantity of nicotine found—*e.g.*, about 0·5 grm.—and the error, calculated on the nicotine, is less than 1·5 per cent.; when calculated on dry tobacco it is, at the most, a few mgrms., and on green tobacco a few tenths of a mgrm.

J. F. B.

Estimation of Nicotine in Tobacco Extracts. W. Koenig. (*Chem. Zeit.*, 1911, **35**, 521-522.)—The author has obtained satisfactory results by Toth's method (ANALYST, 1902, **27**, 12), working in the following way: 6 grms. of the extract are treated in a dish with 10 c.c. of 20 per cent. sodium hydroxide solution, and then mixed gradually with sufficient gypsum to give a nearly dry powder. The mixture is shaken in a cylinder with 100 c.c. of a mixture of ether and light petroleum spirit; 25 c.c. of the clear solution are transferred to a flask with 50 c.c. of water and an excess of $\frac{N}{10}$ hydrochloric acid, and then titrated back with $\frac{N}{10}$ sodium hydroxide in presence of iodeosin as indicator. The method suffers, however, from the defect that the results include any other bases which may be present in addition to nicotine. The author has introduced a polarimetric modification of this method by substituting a less volatile solvent—*e.g.*, toluene—for the ether-petroleum mixture. As a preliminary he has determined the specific rotation of pure nicotine in toluene solution, which may be taken as $[\alpha]_D = -168°$—that is, 1 grm. of nicotine dissolved in toluene to 100 c.c. gives a rotation in the 2 dcm. tube of $-3{\cdot}36°$ at 20° C. The modified procedure is as follows: 20 grms. of tobacco extract are treated in a porcelain dish with ignited sea-sand and 4 c.c. of sodium hydroxide (1 : 1) rubbed down to a semi-dry mass, and then mixed with sufficient gypsum to form a free powder. This is ground in a mortar and transferred to a stoppered bottle, the mortar being wiped out with sand and gypsum; 100 c.c. of toluene are added to the mass, the bottle is well stoppered and shaken for one to three hours. After settling, 30 to 40 c.c. are filtered through a covered filter and polarised. The rotation in the 2 dcm. tube, divided by 3·36, gives the weight of nicotine in 100 c.c.; but, since nicotine dissolves in toluene without loss of volume, a correction must be applied, thus: $x = g.\ \frac{100+g}{100}$, where $g =$ the grms. of nicotine found per 100 c.c.; then x multiplied by 5 gives the percentage of nicotine in the extract. For the titration of the nicotine, 25 c.c. of the filtered solution are placed in a stoppered flask in which a measured excess of $\frac{N}{10}$ hydrochloric acid and 50 to 75 c.c. of water are present. After the addition of 25 c.c. of ether and a few drops of iodeosin, the liquid is shaken vigorously, and the excess of acid is titrated back. One c.c. of $\frac{N}{10}$ acid = 0·0162 grm. of nicotine; the result is corrected in the same manner as above. The results are concordant, and agree satisfactorily with those obtained by Kissling's method; the author considers that Ulex's method cannot give correct results. If the polarimetric method alone be relied on, the tobacco extract may be made alkaline and shaken out with toluene direct, but the presence of ammonia, in that case, precludes the confirmatory titration.

J. F. B.

Adulteration of Pepper Corns. L. Bussard and Andouard. (*Ann. des Falsifications*, 1911, **4**, 263-266.)—A sample of pepper examined by the authors was found to be adulterated with the seeds of a species of lentil (*Ervum ervilia*), the appearance of which had been disguised by maceration in pimento extract and subsequent slight roasting until they had turned black. The microscopical appearance of the starch cells was very characteristic, being irregular in form, either elliptical or kidney-shaped, and having concentric striations. They ranged from 35 to 60 μ in length and from 30 to 40 μ in breadth, and were thus about six times the size of pepper starch cells. The seeds separated from the sample gave the following analytical results: Starch, 41·60; nitrogenous substances, 25·00; cellulose, 14·70; mineral matter, 3·26; and alcoholic extract, 4·36 per cent. They thus differed from pepper in containing much more starch and nitrogenous substances, but much less cellulose and rather less ash. The alcoholic extract was greatly increased by the preliminary treatment of the seeds with the pimento extract, that from the normal seeds being very small. C. A. M.

Titration of "Salvarsan" with Iodine Solution. G. O. Gaebel. (*Arch. Pharm.*, 1911, **249**, 241-247.)—"Salvarsan"—*i.e.*, dihydroxydiaminoarsenobenzene hydrochloride—contains 31·6 per cent. of arsenic, and its formula may be written $C_{12}H_{12}N_2O_2As_2.2HCl + 2H_2O$. It is readily oxidised by iodine, giving the corresponding arsinic acid, and the end-point of the titration is sharp. Instead, however, of the theoretical 8 equivalents of iodine, only 7·5 equivalents are reduced per molecule of salvarsan, owing to the reversibility of the reaction. For the titration, a 0·2 to 0·8 per cent. solution of salvarsan is prepared, and a quantity corresponding to 0·1 grm. of substance is measured out. This is titrated with iodine, with or without the addition of starch. Towards the end-point the colour of the iodine disappears somewhat slowly, but there is no difficulty in recognising the point of permanent coloration. The results, when calculated by the empirical factor, 1 c.c. of $\frac{N}{10}$ iodine $= 0·006326$ grm. of salvarsan, are perfectly satisfactory. J. F. B.

Customs Examination of Rye and Wheat Bran. R. Woy. (*Zeitsch. öffentl. Chem.*, 1911, **17**, 101-109; through *Chem. Zentralbl.*, 1911, I., 1447.)—The classification of bran according to its ash content was irrational, and the more recent official German method, in which account is taken of the proportion which passes a fine sieve, is not much better. A starch estimation is the only rational basis of classification, and should be prescribed now that quick and sufficiently accurate methods are available. The author prefers the method of Ewers (*Zeitsch. öffentl. Chem.*, 1909, **15**, 8) to that of Lintner (*cf.* Thorne and Jeffers, Analyst, 1909, **34**, 332), because it avoids the use of concentrated acid. Using Ewers' method with 5 grm. substance, and polarising in a 200 mm. tube at 20° C., the author finds the correct factor (assuming the use of the Soleil-Ventzke scale) to be 1·892. It is suggested that some substance other than coal-dust might be prescribed for denaturing bran—some substance that would not detract so much from its commercial value, whilst attaining the object of the Customs authorities. G. C. J.

Detection of Invertase in Wine. F. Schaffer. (*Mitt. Lebensmittelunters. u. Hyg.*, 1911, **2**, 36-40; through *Chem. Zentralbl.*, 1911, I., 1450.)—Müller-Thurgau (*Landw. Jahrbb.*, 1885, 795) was unable to detect invertase in finished clarified wines, and suggested that their capacity to hydrolyse cane-sugar, which had been alleged by earlier authors, must be due to their acidity alone. He worked on two portions of wine, one of which was heated nearly to 100° C. to destroy invertase, before they were each mixed with an equal bulk of 20 per cent. cane-sugar solution and incubated. The heated sample served as a control, and only if the other gave rise to detectably more reducing sugar under identical conditions did he admit the presence of invertase. The method is not sufficiently delicate for the detection of traces of invertase. The author of the present paper dialyses the wine to be tested for two or three days, at the end of which time the portion which cannot penetrate the membrane is neutral and free from any trace of reducing sugar. It is then mixed with a 5 per cent. solution of cane-sugar and incubated at 50° C. Tested in this way, every sample of wine experimented with, whether genuine or admittedly artificial, showed the presence of traces of invertase. G. C. J.

Sulphurous Acid in White Wines. P. C. Mestre. (*Ann. des Falsifications*, 1911, 4, 266-276.)—A complete analysis is given of 103 samples of white wine made in Gironde during several years since 1893, and of 34 commercial samples. In estimating the amount of free and combined sulphurous acid, a correction of 14 mgrms. of sulphur dioxide per litre was made in each case, this figure corresponding to the average amount of iodine consumed by the musts produced in the South-West of France. The average results of some of these years are summarised in the following table:

Wine.	Origin.	Total Sulphur Dioxide Mgrms. per Litre.			Free Sulphur Dioxide Mgrms. per Litre.		
		Max.	Min.	Mean.	Max.	Min.	Mean.
Wine in bottles of 1901, 1902, 1903, 1904, 1905	Rive gauche	288	230	259	53·90	31·40	40·13
	Rive droit	345	310	327	76·80	23·00	51·60
	Graves	257	194	225	34·00	16·50	25·25
Wine in casks of 1906, 1907, 1908, 1909	Rive gauche	349	149	239·70	77·00	16·97	43·38
	Rive droit	395	182·75	290·25	61·00	36·25	48·50
	Graves	215	95·00	192·75	81·90	14·80	43·47
	Entre 2 Mers	294·75	126·00	215·00	72·90	16·33	43·50
Typical commercial samples	Rive gauche	362	203	307	84·00	23·00	61·00
	Rive droit	450	212	361	93·00	38·00	64·00
	Graves	446	288	388	89·60	39·40	68·20
	Entre 2 Mers	370	238	300	113·90	6·40	34·70
Wine in casks of 1906, 1907, 1908 (excluding 1909)	Rive gauche	404·6	180·5	282	87·60	17·90	47·50
	Rive droit	420·0	210·3	320	63·33	40·60	50·60
	Graves	273·0	118·6	247	105·30	17·13	54·81
	Entre 2 Mers	408·5	101·6	260	76·00	22·00	33·00

C. A. M.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Fungicidal Action of Bordeaux Mixtures. B. T. P. Barker and C. T. Gimingham. (*J. Agric. Sci.*, 1911, **4**, 76-94.)—It is uncertain how the mixture of copper sulphate and lime known as Bordeaux mixture, containing no soluble copper, acts as an efficient fungicide, and the three views generally held as to how the copper present is rendered soluble are—(1) The chemical action of the CO_2 in the air or rain-water; (2) the solvent action of the leaves of the host plant; (3) the solvent action of the fungus itself. Gimingham (*J. Agric. Sci.*, 1911, 4, 69) and both authors in the present paper give reasons for not accepting the first view, and describe experiments in connection with the second which go to prove that when healthy leaves are placed in ordinary Bordeaux mixture—*i.e.*, made with equal weights of copper sulphate and lime, and containing an excess of lime—no copper was found in solution. In the case of lime-water, Bordeaux precipitate, which is the basic sulphate (10 CuO, SO_3), containing no excess lime, very small amounts of copper, varying from 0·00014 to 0·0005 per cent., were brought into solution by the leaves, but this in all probability is due to an excretion of solvent juices from very small injuries on the leaves, and not to the action of the normal leaf-surface. As regards the action of the fungus itself, the authors describe many experiments with hanging-drop cultures of conidia of *Nectria*, spores of *Penicillium glaucum*, uredo-spores of *Puccinia hieracia*, etc., and, in the case of the first named, consider it proved that actual contact with particles of the insoluble copper compound is sufficient to cause death, although growth can occur in the immediate vicinity, provided the organism does not actually touch the copper. A solvent action on the part of the fungus thus occurs, which is not powerful enough, normally, to produce serious toxic effect, except when direct contact occurs, and does not result in the bringing into solution of sufficient copper to exercise a general fungicidal action over the whole leaf. Failure to demonstrate the presence of soluble copper in liquids containing simply the basic sulphate or carbonate of copper and the spores, cannot be held to prove the absence of a solvent action on the part of the fungus. The question of distance between the copper particles and the fungus is the critical matter. All the results obtained by previous workers can be explained according to the authors' view, which is briefly as follows: The cell wall is to be regarded as the most important factor. In an isolated cell an interchange of material between the cell and the surrounding medium is always proceeding through the cell-wall, which normally is readily permeable by a variety of substances, although such interchange is probably reduced to a minimum in the case of thick-walled resting spores. The typical primary cell-wall is always more or less saturated with aqueous solutions, containing such of the cell products as are allowed to pass through the parietal protoplasmic layer, and these are capable of exerting a solvent action on insoluble particles of the copper compounds with which they come into actual contact, the toxic action of the copper then being diffused throughout the cell contents. The authors consider that both the toxic action of the spray on fungus already present, and an indirect protective action on the foliage rendering it more or less immune to subsequent infection, occur, and they discuss the work of Massee in this connection. The importance of a fine state of division of the copper precipitate and of *thorough* spraying is emphasised, attention being drawn to the inadvisability of having too great an excess of lime present, and to the advantages of using a spray with good adhesive qualities. H. F. E. H.

Influence of Metals in Presence of Hydrogen Peroxide on Blood Reagents. F. Michel. (*Chem. Zeit.*, 1911, **35**, 471.)—It is found that clean iron or copper in presence of hydrogen peroxide will oxidise guaiacum, Adler's reagent, leuco-malachite green, etc. Since metallic particles may be present on clothing, especially that of metal-workers, this observation has an important bearing on the detection of blood in such cases. If to the oxidised (coloured) solution a few c.c. of a 1 per cent. colourless solution of 2·4 diaminophenol be added, no immediate change will be observed if the original colour was induced by the catalytic action of blood or pus. Only very slowly does a red or dirty brown colour, due to oxidation of the diaminophenol by the air, appear. If the original colour was due to the action of iron or copper or their oxides, addition of diaminophenol gives rise to an immediate red coloration (which contrasts best with that of malachite green) of the three reagents named.

This method of application of the diaminophenol confirmatory test only serves, however, to distinguish organic oxidising catalysts from such inorganic or organic oxidants as are reoxidised by hydrogen peroxide. Chlorine or permanganate, for example, would develop the colour of malachite green and be destroyed in the process, and so behave like blood and give rise to no red colour on the subsequent addition of the diaminophenol. The substance is therefore first tested with leuco-malachite green without the addition of hydrogen peroxide. The development of a green colour indicates the presence of an oxidising agent proper, such as ferric oxide or chlorine. If no coloration is produced, hydrogen peroxide is added. Whether any colour then produced is due to metallic iron or copper, or to blood or pus, is determined by means of diaminophenol. If paper transfers have to be examined, these are dipped in solutions of the appropriate reagents. G. C. J.

Bacteriological Study of Honey. A. Sartory and E. Moreau. (*Ann. des Falsifications*, 1911, **4**, 259-263.)—Bacteriological examination of samples of honey from different parts of France detected the following species of bacteria within the cells of the comb: *B. subtilis*, *B. megaterium*, *Sarcina lutea*, *B. aerophilus*, *Micrococcus radiatus*, and *Staphylococcus pyogenes*. The mould isolated included the following: *Penicillium glaucum*, *Rhizopus nigricans*, *Mucor racemosus*, *Aspergillus gracilis*, *Sterigmatocystes nigra*, and yeast. Among the bacteria was a yellow species which liquefied gelatin, and appeared to be intermediate between the *B. luteus* of Flugge and the *B. flavus* of Macé. The yellow pigment secreted by this bacillus was soluble in absolute alcohol. It was produced most abundantly at the optimum temperature (30° C.) for the growth of the organism. C. A. M.

ORGANIC ANALYSIS.

Asphaltum from Mexican Petroleum. D. Lohmann. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 107-108.)—A sample of asphaltum prepared from crude petroleum oil derived from two Mexican oil-fields was examined by the methods of Marcusson and Eickmann (ANALYST, 1911, 225). The original oil had a sp. gr. of 0·890 to 0·900 at 15° C., and yielded about 10 per cent. of petroleum spirit (benzine), 20 per cent. of lamp oil (kerosene), and 20 per cent. of asphaltum residue, together with lubricating oils, etc. The asphaltum gave the following results. Sp. gr. at

15° C., 1·07 to 1·12; total bitumen soluble in carbon bisulphide, 99·2 per cent.; soluble in normal benzine, 74 per cent.; volatile hydrocarbons, 76·5; carbon, 23·3; ash, 0·2; and sulphur, 5·5 per cent. Asphaltum of this type is exported in considerable quantities to Europe. Other samples contained from 2 to 6·2 per cent. of sulphur. Hence the proportion of sulphur affords no certain means of distinguishing between natural asphaltum and petroleum asphaltum. The proportion of ash in the Mexican petroleum products ranges from 0·1 to 0·9 per cent. There are also some kinds of natural asphaltum (*e.g.*, gilsonite) containing only 0·5 per cent. of ash. The amount of oil separated from the first sample by the method of Marcusson and Eickmann (*loc. cit.*) was 32·2 per cent. It was dark brown and of the consistence of cylinder oil, but was quite free from vaseline-like particles. It contained 2·2 per cent. of paraffin wax, estimated by the method of Holde. The acid value of the first distillate of 15 c.c. from 100 grms. of the asphaltum was 0·9 (after washing with water), whilst the second fraction of sp. gr. 0·8196, had an acid value of 0·42. The acid values of these distillates were therefore in accordance with the statement of Marcusson that the first fraction should have an acid value of less than one, and the second fraction a very small value. Both the value and the amount of paraffin wax, however, are so close to the limits given by Holde and Marcusson for petroleum asphaltum (paraffin wax, minimum, 2 per cent.; acid value, maximum, 1), that the latter should only be accepted with caution. C. A. M.

Wet Method for the Estimation of Carbon in Organic Substances. F. Tangl and G. v. Kereszty. (*Biochem. Zeitsch.*, 1911, **32**, 266-273.)—In the method described the organic substance is heated in a small flask with potassium bichromate and sulphuric acid until completely decomposed. The gases evolved are conducted from the flask through a combustion tube filled with copper oxide and heated to redness, and then through a tube filled with lead peroxide heated to a temperature of 150° to 180° C. From the latter tube the gases are conducted through an absorption vessel containing barium hydroxide solution, and, at the end of the experiment, the resulting barium carbonate is titrated in the usual way. A condenser is fitted in the neck of the decomposition flask, so that excess of moisture does not pass into the combustion tube, and the whole apparatus is so arranged that a current of dry air free from carbon dioxide may be passed through it before and after the organic substance has been decomposed; a specially-devised funnel fitted into the neck of the flask allows the substance and the sulphuric acid to be added after the current of pure air has been passed through the apparatus for some time. The method yields trustworthy results, even with substances containing nitrogen, sulphur, and chlorine. W. P. S.

Precipitation of Cocaine Solutions with Platinum Chloride. M. Nyman and R. Bjorksten. (*Pharm. Zentralbl.*, 1911, **52**, 71-74; through *Chem. Zentralbl.*, 1911, I., 1451.)—Cocaine, in not too dilute solution, may be estimated by precipitation with 2 c.c. of a solution of platinum chloride in hydrochloric acid (sp. gr. 1·125) followed by addition of 3 volumes of alcohol. As cocaine platinichloride is soluble to the extent of 0·012 per cent. in absolute alcohol, 0·022 per cent. in 70 per cent. alcohol, and 0·030 per cent. in 50 per cent. alcohol, a proper correction must be applied to the weight found. The method serves well for the control of sterilised cocaine solutions. The presence of boric acid has but little influence on the results, but the presence of sodium chloride renders precipitation incomplete, and the method is useless for the estimation of cocaine in presence of atropine. G. C. J.

Estimation of Free Fatty Acids in Fats. E. Bödtker. (*Chem. Zeit.*, 1911, **35**, 548.)—The author refers to Loebell's method for estimating the acid value of fats (*Chem. Zeit.*, 1911, **35**, 276). From 5 to 15 grms. of the fat (melted if required) are thoroughly shaken with 25 c.c. of alcohol, after which 50 c.c. of water and 2 to 3 drops of 1 per cent. phenolphthaleïn solution are added, and the mixture titrated with $\frac{N}{10}$ sodium hydroxide solution until the colour ceases to disappear when the flask is vigorously shaken, and then with $\frac{N}{10}$ hydrochloric acid until colourless. The method is advantageous in the case of coloured fats, since the dyestuffs are insoluble in water. C. A. M.

Estimation of Fatty Acids in Soaps. T. Budde. (*Verröffentl. a. d. Gebiete des Militärsanitätswesens*, Heft 5; *Arbb. a. d. hyg.-Chem. Unters.-Stellen*, 1911, **4**, 86-99; through *Chem. Zentralbl.*, 1911, I., 1449-1450.)—The soap is dissolved in absolute alcohol, the solution filtered from insoluble matter, any free alkali neutralised, and after neutralisation evaporated to dryness. The residue is dissolved in water and the solution made up to a known volume. Of this, 25 c.c. (corresponding to 0·5 to 0·8 grm. soap) is precipitated by the addition of 25 c.c. of a sufficiently strong solution of copper sulphate, and the mixture boiled. When cold, the copper salt of the fatty acids is filtered off, washed, dried at 103° C., and weighed. Assuming the copper salt to contain 10 per cent. of copper, its weight, less 9·7 per cent., should give the weight of fatty acids in the quantity of soap taken for precipitation. The results thus obtained are usually 1 per cent. above the truth, but never 2 per cent.

G. C. J.

Simplified Process for Estimation of Acid and Saponification Values in Wax. (*Pharm. Zentralbl.*, 1911, **52**, 363-367; through *Chem. Zentralbl.*, 1911, I., 1380.)—One grm. of the wax is heated for five minutes with 10 c.c. of absolute alcohol in a closed 100 c.c. bottle, which is suspended in a Nyman steriliser (*Chem. Zentralbl.*, 1910, I., 1402), and frequently agitated. After cooling for three minutes, the mixture is titrated with $\frac{N}{2}$ potash, using phenolphthaleïn as indicator; a further 20 c.c. of $\frac{N}{2}$ potash is then added, and the bottle closed, and heated for twenty-five minutes. It is then allowed to cool for three minutes, when the excess of potash is determined in the usual manner. G. C. J.

Estimation of Formic Acid. H. Franzen and F. Egger. (*J. prakt. Chem.*, 1911, **83**, 323-325; through *Chem. Zentralbl.*, 1911, I., 1529.)—The following improvement of the method of Franzen and Greve (ANALYST, 1909, **34**, 110; 1910, **35**, 29) is recommended: To each 0·5 grm. of the formic acid are added 50 c.c. of a clear solution of 200 grms. of mercuric chloride, 300 grms. of sodium acetate, and

80 grms. of sodium chloride, in a litre of water, and the mixture is heated for three and a half hours on the water-bath; the separated mercurous chloride is then estimated as described in the previous paper. It is essential that the concentration of the formic acid should not exceed 0·5 grm. per litre of liquid. C. A. M.

Detection of Graphite in Lubricants. J. Marcusson and G. Meyerhelm. (*Chem. Zeit.*, 1911, **35**, 461-462.)—The graphite which is incorporated with lubricating greases may generally be separated by treatment with benzene. Some greases are mixtures of fat and lime soaps; in such cases a mixture of 90 parts of benzene and 10 of alcohol by volume is a good solvent both for oil and soap. The graphite may be filtered off together with the mineral impurities, which are mostly soluble in hot hydrochloric acid; the graphite is estimated by combustion. In the case of mixtures of graphite with tars and pitches, the separation is more difficult, since these materials frequently contain carbon and black insoluble hydrocarbons not easily distinguished from graphite, especially if mixed with talc or similar mineral matters. In such cases a separation of the graphite from the amorphous forms of carbon may generally be effected by fusion with sodium hydroxide: One grm. of the residue insoluble in benzene is added in small portions at a time to 15 grms. of fused sodium hydroxide in a nickel crucible, and heated for fifteen minutes over a burner, and for a few minutes longer over the blowpipe flame. The amorphous carbon is oxidised by this treatment more rapidly than graphite. The melt is dissolved in water, the insoluble matter is washed by decantation, then on a filter; it is treated with hot dilute hydrochloric acid to remove iron and nickel hydroxides, and is finally dried at 105° C. Different varieties of graphite possess different degrees of resistance to oxidation, so the method is not absolutely reliable. The authors have been able to detect the presence of 20 per cent. of graphite mixed with the insoluble carbonaceous matters of pitches. In practice, however, the proportion of graphite, if present in sufficient quantity to have any appreciable lubricating value, will be considerably more than 20 per cent. of the insoluble carbon of the pitch. J. F. B.

Gum from Bombax Malabricum. P. P. Phillips. (*J. Soc. Chem. Ind.*, 1911, **30**, 469-471.)—The *Bombax malabricum* (vern., *semul*), the red, silk-cotton tree order *Malvaceæ*, yields a gum which exudes only from those portions of the bark which have been injured by decay or the attacks of insects (chiefly termites), but not from incisions in the healthy bark. The gum, known as *mocherus*, is sold in the form of brittle, mahogany-coloured tears, hollow in the centre. When powdered and treated with water, it swells up and yields a reddish-brown liquor, from which alcohol precipitates a little gum; the main bulk of the material is, however, insoluble in water. The gum leaves on incineration about 8 to 9 per cent. of ash. An extract obtained by boiling the gum for four hours with water gave many of the characteristic reactions of tannin. It gives a green coloration with ferric chloride, changing to purple on the addition of very dilute ammonia. It precipitates gelatin, and bromine water produces a copious yellow precipitate. The powdered gum dissolves almost completely in solutions of caustic alkalis. From its reactions, it is evident that the gum contains a considerable proportion of tannin, having the properties of a catechol tannin. On dry distillation of the gum, catechol could be detected in the distillate. During distillation, a pinewood shaving, moistened with hydrochloric acid and placed near the mouth of the receiver, was instantly coloured violet. On hydrolysis of the gum with boiling dilute hydrochloric acid, a red-coloured solution is obtained, with an insoluble residue having the colour of crimson lake. This colouring matter is only moderately soluble in alcohol; it does not possess the solubility generally attributed to the phlobaphenes. After removal of the tannins by lead acetate, the hydrolysed extract reduces Fehling's solution.

J. F. B.

Hydrargyrometric Analyses. L. Rosenthaler. (*Arch. Pharm.*, 1911, **249**, 253-259.)—Since mercuric nitrate gives a large number of reactions which yield undissociated or insoluble mercury compounds, it may be employed for volumetric analyses in many cases in preference to silver nitrate, using Volhard's method. The solutions required are: $\frac{N}{10}$ mercuric nitrate, $\frac{N}{10}$ ammonium thiocyanate, ferric ammonium sulphate, and concentrated nitric acid free from nitrous acid. An excess of mercuric nitrate is added to the liquid to be titrated, the mixture is shaken, and 2 c.c. of saturated ferric ammonium sulphate solution are added, together with sufficient nitric acid to produce perfect decolorisation. The liquid is then titrated back with thiocyanate until the red colour is established. The changes are not quite so sharp as in titrations of silver nitrate, but may be made sharper by saturating with sodium or potassium nitrate free from chlorides. Good results are obtainable in the estimation of hydrocyanic acid and cyanides, bromides, iodides (*e.g.*, ferric iodide in pharmaceutical preparations). The method is available for the estimation of hydrocyanic acid in presence of benzaldehydecyanhydrin, but not for the estimation of the combined hydrocyanic acid in the latter; it also cannot be used for the estimation of chlorides, since mercuric chloride is dissociated to a considerable extent in solution. J. F. B.

Oil from Seeds of the Ash-Tree. W. Bach. (*Chem. Zeit.*, 1911, **35**, 478.)—The crushed seeds of the ash-tree yielded, on extraction with ether, 9·7 per cent. of a brownish-yellow thick oil with an odour recalling that of tea. It formed a semi-solid mass in the elaidin reaction, and in its drying properties resembled sunflower and soya bean oils. A film exposed on glass at the ordinary temperature was not completely dry after fourteen days. The filtered oil became turbid at 27·1° C., and gave the following values: Sp. gr., 0·9181; saponification value, 168·5; iodine value, 129·5; Reichert-Meissl value, 1·68; insoluble fatty acids, 85·1 per cent.; unsaponifiable matter, 5·5 per cent. *Fatty acids:* Neutralisation value, 181·7; iodine value, 125·8; melting-point, 36·8° C.; and solidification-point, 28·6. The fresh oil contained 1·71 per cent. of free fatty acids (calculated as oleic acid). C. A. M.

Rice Oil. M. Tsujimoto. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 111-112.)—A sample of commercial rice oil, obtained by extracting the crushed rice with light petroleum, was of a greenish-yellow colour, and had the following characteristics: Sp. gr. at 15° C., 0·9273; acid value, 34·75; saponification value, 184·87;

iodine value (Wij's), 107·6; $[n]_{D20^{\circ} C.}$, 1·4742. *Fatty acids:* Sp. gr. at 100° C. 0·8528 (without unsaponifiable matter, 0·8523); melting-point 30·5° C. (without unsaponifiable matter, 32·5° C.); neutralisation value, 183·72 (and 197·66); and iodine value, 109·47 (and 107·82). The unsaponifiable matter (4·78 per cent.) yielded a phytosterol melting at 136° to 137° C. The fatty acids, examined by the usual method, were found to consist of approximately 20 per cent. of palmitic acid, 45 per cent. of oleic acid, and 35 per cent. of an isolinolic acid which yielded a sativic acid melting at 158·5° to 159° C., instead of the usual 173° to 174° C. The mixed fatty acids gave no insoluble bromide. C. A. M.

Niger-Seed Oil. K. Utz. (*Chem. Rev. Fett-u. Harz.-Ind.*, 1911, **18**, 106-107.) —Samples of crude and bleached niger-seed oil gave the following analytical values:

NIGER-SEED OILS.

	Sp. Gr. at 15° C.	Acid Value.	Saponification Value.	Iodine Value.	Reichert-Meissl Value.	Refraction $[n]_{D15^{\circ}}$ C.	Unsaponifiable Matter. Per Cent.
Crude oil ...	0·9252	3·70	123·5	126·8	0·88	1·4768	1·26
Bleached oil ...	0·9250	0·45	217·8	114·0	3·85	1·4764	0·53

FATTY ACIDS.

	Melting-Point, ° C.	Iodine Value.	Refraction $[n]_{D40^{\circ}}$ C.
Crude oil	28·2	113·8	1·4605
Bleached oil	27·8	102·3	1·4605

The sample dried very slowly, even at 100° C., and in this respect did not agree with Allen's statement that niger-seed oil dried rapidly at that temperature.

C. A. M.

Soya Bean Oil. C. Oettinger and F. Buchta. (*Zeitsch. angew. Chem.*, 1911, **24**, 828-829).—Samples of crude and refined soya bean oil gave the following results on analysis. The figures for the saponification and iodine values and melting-points of the fatty acids differ widely from those previously published. The solidification-point (+8° to +16° C.) given by De Negri and Fabris, and copied in many textbooks, is evidently due to a clerical error:

OILS.

Soya Bean Oil.	Solidification-Point.	Sp. Gr. at 15° C.	Acid Value.	Saponification Value.	Iodine Value.	Hehner Value.	Reichert-Meissl Value.	Refractive Index at 20° C.	Unsaponifiable Matter.
	° C.								Per Cent.

Detection of Train Oil in Oils, Fats, and Soaps. J. Marcusson and H. v. Huber. (*Seifensieder-Zeit.*, 1911, **38**, 249-251; through *Chem. Zentralbl.*, 1911, I., 1448.)—The following simplified modification of Lewkowitsch's method is recommended: The separated fatty acids (10 grms.) are shaken in a stoppered cylinder with 200 c.c. of a bromine solution (1 part bromine, 28 parts acetic acid, 4 parts nitrobenzene). If no precipitate appears after standing an hour, the sample is free from train oil and from drying vegetable oils. If a precipitate appears, the mixture is allowed to stand another hour, and then filtered, using a small filter-plate and paper. The precipitate is washed on the filter with ether, weighed, and reduced to powder. It is then heated for half an hour under a reflux condenser with 50 times its weight of benzene, which dissolves the hexabromide of linolenic acid. Complete solution shows absence of train oil in the sample; but if anything remains undissolved, it is filtered off with the use of a hot-water jacketed filter, dried, and its melting-point determined. If it blackens, but remains unmelted at 200° C., it may be taken to be the octobromide characteristic of the train-oil group. If it melts lower than this (hexabromolinolenic acid melts at 175° to 180° C. without decomposition), it is re-extracted with hot benzene, and its melting-point re-determined. If, instead of soaps, oils have to be examined, these may be treated direct with Halphen's bromine solution. If no precipitate forms, train oil is absent; but if one forms, the experiment must be repeated on the separated fatty acids, as no convenient solvent is known for separating the brominated glycerides of train oil from those of vegetable drying oils. G. C. J.

Causes of Loss of Phosphoric Acid on Incineration in Presence of Organic Matter. E. Fleurent and L. Levi. (*Bull. Soc. Chem.*, 1911 [iv.], **9**, 379-393.)—There are at least three causes of loss of phosphoric acid when organic matter containing it is burnt. Of these, the reduction of a portion of any acid phosphates present and combustion of the resulting phosphorus with escape of phosphorus pentoxide has long been recognised and met to some extent by addition of alkali. Addition of sufficient alkali also tends to negative the second cause of loss—namely, the expulsion of phosphoric acid from its compounds by silica; but the addition of solid caustic lime, as is sometimes practised, has but little effect in preventing either of these causes of loss, as it cannot be brought into sufficiently intimate contact with the substance undergoing incineration. A third cause of loss is in some way connected with the fatty constituents of the organic matter, and in some animal matter the loss due to this cause alone may exceed 25 per cent.

So far as the estimation of total phosphorus is concerned, all the above difficulties may be surmounted by destruction of organic matter in the wet way, either by means of sulphuric acid alone, or, preferably, by the successive action of fuming nitric acid and sulphuric acid. But if it be desired to make an exhaustive analysis of the ash of any organic body, incineration becomes necessary, and the authors have worked out the following method: The organic matter is first freed from fat or oil by extraction with ether. It is then carbonised at a low temperature in a closed crucible. The carbonised mass is pulverised, returned to the crucible, and moistened with a known quantity of lime-water, milk of lime, or baryta solution. Working on 10 grms. of substance, it suffices to add 0·05 grm. lime for each 1 per cent. of phosphoric anhydride possibly present. After evaporating to dryness, the contents of the crucible are transferred to one or more boats, which are placed in a combustion-tube in a furnace, and raised to a low red heat whilst a current of carbon dioxide is passed through the tube. The stream of carbon dioxide is then replaced by a slow one of oxygen, when a white ash containing the whole of the phosphoric acid and chlorine of the original organic matter is obtained. When combustion is complete, the temperature is raised for a few minutes to decompose any calcium carbonate. In estimating the total ash or its lime content, account must, of course, be taken of the weighed quantity of lime used in the process. G. C. J.

Colorimetric Method for the Estimation of the Molecular Weight of Polysaccharides. L. Wacker. (*Zeitschr. f. physiol. Chem.*, 1911, **71**, 143-152; through *Chem. Zentralbl.*, 1911, I., 1380-1381.)—The principle of the method has been described in earlier papers (ANALYST, 1908, **33**, 131; 1909, **34**, 410). It is now found that it is unnecessary to have recourse to the inversion method, so long as substances of the general formula $(C_6H_{10}O_5)_nH_2O$ are being investigated. The colour intensity is not exactly proportional to the number of carbohydrate residues present, but the error involved by assuming it to be so is less than 2 per cent., when the comparison is made between polysaccharides of 4 and 10 hexose residues, and this error is negligible in a determination of molecular weight. Lævulose and polysaccharides yielding lævulose on hydrolysis are exceptional, and give rise to colours of greater intensity than are required by theory. The latest directions for carrying out the test, which differ notably from those given earlier (ANALYST, 1908, **33**, 131), are as follows: To each of sixteen cylinders of equal diameter (about 30 mm.) a measured quantity of a 0·01 per cent. solution of a carbohydrate of known complexity (say lactose) is added, the quantities varying from 0·5 c.c. to 8 c.c. Enough water is added to bring the contents of each cylinder up to 10 c.c., and then 2 c.c. of 2 per cent. *p*-phenylhydrazine sulphonic acid and 2 c.c. of caustic soda solution (1:2) are added. In another cylinder 2·5 c.c. of a 0·01 per cent. solution of the carbohydrate to be tested are treated in a similar manner and the colour comparison made at the expiration of four hours, during which the contents of the cylinders are frequently agitated. G. C. J.

Polarimetric Estimation of Sugar by the Method of Jolles. B. Bardach and S. Silberstein. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 540-543.)—If air be admitted to the vessel during the heating of the sugar with the alkali in a thermostat, much less discoloration occurs, and it is therefore possible to employ more concentrated solutions and to polarise the liquid in a 200 mm. tube without dilution or treatment with lead acetate, etc. Experiments with solutions of dextrose (0·5 to 5 per cent.) showed that after twenty hours' heating there was invariably lævorotation, so that in applying the method an empirical value of $-0{\cdot}25°$ is taken as the end of the reaction. A measured quantity of the sugar solution under examination is mixed with sufficient $\frac{N}{1}$ sodium hydroxide solution to render the alkalinity of the liquid decinormal. The solution is polarised, and an aliquot portion placed in a beaker 8 to 10 cm. high by about 5 cm. in diameter, and heated uninterruptedly for twenty hours in a thermostat maintained at about 37·5° C. (36° to 39° C.). The liquid is then cooled, made up to its original volume and again polarised. The proportion of dextrose (D) in mixtures of dextrose and sucrose may be found by means of the formula $D = A - B - 0{\cdot}25$—and that of the sucrose (S) by the formula $S = B + 0{\cdot}25$, where A represents the polariscope reading before, and B that after the action of the alkali. The results tabulated show that the method is accurate (*cf.* ANALYST, 1911, 28). C. A. M.

Estimation of Rubber as Tetrabromide. Decomposition of the Bromide by Nitric Acid. D. Spence, J. C. Galletly, and J. H. Scott. (*Gummi-Zeit.*, 1911, **25**, 801-803; through *Chem. Zentralbl.*, 1911, I., 1451-1452.)—When caoutchouc tetrabromide is decomposed by nitric acid, some bromine is lost, even when silver nitrate is present in excess, and when the initial concentration of nitric acid is kept lower than is specified by Budde in describing his process. The loss of bromine increases with increasing acid concentration, and appears to depend in part on factors which cannot be controlled. Working with much weaker acid than Budde recommends, the authors find that the unavoidable loss of bromine and corresponding error in the caoutchouc determination is about 2 per cent. Following Budde's directions more closely, the results are even lower. G. C. J.

INORGANIC ANALYSIS.

Titration of Alkali Carbonates in Presence of Alkali Hydroxides or Bicarbonates. J. Tillmanns and O. Henblein. (*Zeitsch. angew. Chem.*, 1911, **24**, 874-876.)—It is shown that the separate estimation of alkali hydroxide and carbonate or of carbonate and bicarbonate by titration with acid in two stages, using phenolphthaleïn as indicator in the first stage and methyl orange in the second, may give rise to inaccurate results. Though there may be no visible escape of carbon dioxide during the first stage of the titration, variable amounts of carbon dioxide do, in fact, escape, and the titration should be conducted in stoppered flasks, the stoppers of which should be replaced and the contents shaken after each small addition of acid. In this way more accurate results may be obtained.

An alternative method which gives equally good results is to titrate one portion of the solution, using methyl orange as indicator. To a second and equal portion there is then added the volume of standard acid required in the methyl orange titration; but, instead of using methyl orange, phenolphthaleïn is added to this portion, and the carbon dioxide is titrated against standard caustic alkali, using a stoppered flask, as already described. G. C. J.

Microchemical Test for Aluminium by Means of Caesium Chloride. N. Schoorl. (*Zeitsch. anal. Chem.*, 1911, **50**, 266-267.)—Pure caesium chloride, when added to dilute solutions of aluminium in sulphuric acid, does not give rise to crystals of caesium alum. If, however, the caesium chloride be mixed with a minute proportion of finely powdered caesium alum (1 : 1,000,000), the formation of relatively large crystals of caesium alum is rapid. G. C. J.

Estimation of Arsenic in Pyrites. G. Hattensaur. (*Oesterr. Zeitsch. f. Berg.- u. Hüttenwesen*, 1911, **59**, 175-178; through *Chem. Zentralbl.*, 1911, I., 1378.)—12·5 grms. pyrites contained in a tall beaker are covered with 10 c.c. water and 1 c.c. sulphuric acid, and nitric acid is added gradually till frothing ceases. The mixture is evaporated to a syrupy consistency and then dissolved in boiling water. If the residue is other than white, the solution is decanted into a 250 c.c. flask and the residue is then treated with aqua regia. After evaporating the excess of acid, the solution and white residue are transferred to the 250 c.c. flask, which is filled to the mark, and the contents shaken and filtered. Into 200 c.c. of the filtrate (corresponding to 10 grms. pyrites) hydrogen sulphide is led until the precipitate coagulates, leaving the supernatant liquor clear. The sulphides of arsenic and copper (and antimony if present) are filtered off and the arsenic sulphide dissolved by digestion with ammonium carbonate. The filtered solution is evaporated on the water-bath after addition of some nitric acid. It is then diluted, an excess of silver nitrate added, and the solution exactly neutralised with ammonia, and warmed. The precipitate of silver arsenate is filtered off and washed with cold water till the washings are free from silver. Finally, the precipitate and filter are dried at the mouth of the muffle and cupelled with lead. The arsenic in the pyrites is then calculated from the weight of the silver, after correction for cupellation loss and for any silver in the assay lead.

G. C. J.

Estimation of Arsenic in Schweinfurt Green. A. Heiduschta and A. Reuss. (*Zeitsch. anal. Chem.*, 1911, **50**, 269.)—The sample (0·5 grm.) is mixed in a 150-200 c.c. round-bottomed flask with 5 grm. of ferrous sulphate in small crystals and 60 c.c. of fuming hydrochloric acid. The mixture is distilled, and, after passing up through a spraytrap, the vapours are led down into a 700 c.c. Erlenmeyer flask provided with a double-bored stopper, the second hole of the stopper carrying a Péligot-tube. Flask and Péligot-tube contain caustic potash solution, about 40 grms. of KOH in all, and the flask stands in ice-water. When three-quarters of the acid has been distilled, the apparatus is disconnected and the flame withdrawn. The cooled distillate is neutralised with hydrochloric acid, a considerable quantity of sodium bicarbonate is added, and the arsenic titrated with iodine as usual.

G. C. J.

Method of Measuring the Degree of Vitiation of the Atmosphere. H. Henriet and M. Bouyssy. (*Comptes rend.*, 1911, **152**, 1180-1181.)—Since the animal excretory products to which the vitiation of air is due are all reducing bodies, a measurement of the reducing capacity of the air affords an index of its degree of purity. These excretory products may all be condensed simultaneously with the moisture in the air, so that by condensing a given volume of moisture, calculating the corresponding volume of air, and estimating the reducing substances in the condensed water, comparative values are obtained. For the condensation, the authors use a conical nickel vessel holding about 3 litres, within which is fitted another vessel containing a mixture of ice and salt. From the volume of the liquid condensed upon the cylinder the corresponding volume of air is calculated by means of the formula:

$$v = \frac{m\ (1+\alpha t)}{ad}\ \frac{76}{f},$$

where v represents the volume of the mixture of air and water vapour at t° C. and at the pressure H; m, the weight of the vapour; a, the weight of 1 c.c. of air; d, the sp. gr. of the vapour, and f its tension. Reducing the volume of the mixture to 0° C. and a pressure of 760 mm.:

$$v_0 = \frac{1}{ad}\ \frac{m\mathrm{H}}{f} = 1{\cdot}243\ \frac{m\mathrm{H}}{f}.$$

For estimating the reducing substances, 5 grms. of the condensed water vapour are boiled for five minutes in a 50 c.c. flask with 10 c.c. of a reagent containing 316 mgrms. of potassium permanganate and 425 mgrms. of pure chromic anhydride per litre. The liquid is then cooled, treated with 10 c.c. of a solution containing per litre 10 grms. of ferrous ammonium sulphate and 10 c.c. of pure sulphuric acid (sp. gr. 66° Bé.), and titrated with $\frac{N}{500}$ potassium permanganate solution. A blank estimation is made without the condensed moisture, and the difference between the two results gives the amount of permanganate corresponding to the reducing substances derived from the air. The result is calculated into the number of mgrms. of oxygen per 100 cubic metres of air. In this way the following results were obtained: Atmospheric air (Montsouris Park), 1; air from vicinity of Hôtel de Ville, 10; from room containing animals (rabbits, monkeys, etc.), 13; printing works, 13; badly ventilated office, 14; badly ventilated passage, 17; and dressmakers' workroom, with windows shut, containing twenty workpeople, 21.

C. A. M.

Quantitative Separation of Barium, Strontium, and Calcium. J. L. M. van der Horn van den Bos. (*Chem. Weekblad*, 1911, **8**, 5-10; through *Chem. Zentralbl.*, 1911, I., 1379-1380.)—The diluted solution, acidified with acetic acid, is heated to boiling, and a slight excess of ammonium chromate solution added drop by drop, stirring continuously. When cool, the liquid is decanted through a Gooch crucible, and the precipitate washed three or four times by decantation with hot water containing acetic acid and ammonium chromate. The precipitate of barium chromate is finally transferred to the crucible, and washed with warm water until the filtrate gives but a faint coloration with silver nitrate; the barium chromate is gently ignited and weighed. To estimate the strontium in the filtrate, this is evaporated to dryness, a little water added, and the solution rendered neutral or faintly alkaline by means of ammonia. A little ammonium chromate is next added, and the solution taken almost to dryness. When cool, the residue is treated with 50 per cent. alcohol, which is then decanted through a Gooch crucible, and this treatment repeated several times; finally, the strontium chromate is transferred to the crucible, and washed with strong alcohol. The crucible is dried at 80° to 90° C. and weighed.

The above method may be made volumetric as follows: The solution, containing perhaps 0·3 grm. combined barium and strontium, is diluted to about 300 c.c., heated to boiling, and acidified with 10 to 15 drops of acetic acid, and then there is added, drop by drop, 50 c.c. of $\frac{N}{5}$ potassium bichromate, which has been exactly converted into the normal chromate by the addition of ammonia. When cool, the mixture is made up to 500 c.c. and filtered. To 100 c.c. of the filtrate potassium iodide and hydrochloric acid are added, and the liberated iodine is determined by means of thiosulphate; the difference between the amount of iodine thus found and that corresponding to 10 c.c. of $\frac{N}{5}$ bichromate is the measure of the barium. Another 350 c.c. of the filtrate is evaporated nearly to dryness, a further 10 c.c. of $\frac{N}{5}$ bichromate is added, and the solution neutralised and evaporated nearly to dryness; the residue is triturated with 50 per cent. alcohol, and transferred with more 50 per cent. alcohol to a 250 c.c. flask, which is filled to the mark. The contents of the flask are shaken from time to time during half an hour, and then filtered. To 100 c.c. of the filtrate potassium iodide and hydrochloric acid are added, and the liberated iodine is determined by means of thiosulphate, and calculated back to chromic acid. The difference between the amount of chromic acid thus found and that present in solution before the treatment with alcohol rendered the strontium chromate insoluble is the measure of the strontium. Finally, calcium is precipitated as oxalate in the filtrate from strontium chromate, and estimated volumetrically by means of permanganate.

G. C. J.

Racemic Acid as a Reagent (Precipitant of Calcium and Strontium). A. Kling. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 355-361.)—When a 10 per cent. solution of racemic acid is added to even very dilute (1 : 10,000) solutions of calcium or strontium acetate, a visible crystalline precipitate forms in a few seconds. Though barium racemate is but sparingly soluble, even a 5 per cent. solution gives rise to no visible crystals under several hours when tested in a similar manner. Racemic acid is therefore a delicate test for calcium or strontium in presence of much barium. The reaction cannot be made use of to separate calcium and strontium from barium, as some barium is always carried down with the racemate of calcium and strontium.

The reaction, is however, of service for the estimation of calcium in presence of aluminium, iron, magnesium, phosphoric or citric acid. To the solution, which should preferably contain 0·2 to 0·3 grm. calcium in 100 c.c., 10 c.c. of an acid solution of sodium acetate (10 per cent. sodium acetate, 10 per cent. acetic acid) is added, and this is followed by 10 to 20 c.c. of a 10 per cent. solution of racemic acid. Precipitation is complete within half an hour, at the end of which period the precipitate is filtered off, washed with cold water, and either ignited and weighed as oxide, or dissolved in hot dilute sulphuric acid, and titrated against permanganate. In presence of iron or aluminium the precipitation is incomplete, unless a large excess of alkaline racemate or tartrate is present. The author adds ten to fifteen times as much sodium tartrate as corresponds to the whole of the iron and aluminium before adding the racemic acid. In presence of iron, aluminium, or magnesium, the precipitate is liable to contain notable traces of these elements, and resolution in hydrochloric acid and re-precipitation by sodium acetate and a little racemic acid is necessary to obtain the best results, which are accurate within 1 per cent.

Strontium may be estimated similarly in presence of phosphates and citrates, but not in presence of much iron and aluminium, which render the precipitation far from complete, even when large additions of sodium tartrate are made.

G. C. J.

Estimation of Very Small Quantities of Bromine in Presence of Chlorides and Iodides. H. Baubigny. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 352-354.)—The author refers to his own earlier work (*Compt. rend.*, 1897, **125**, 527, 607; 1899, **128**, 1160, 1236) in refutation of Clausmann's contention (ANALYST, 1911, 241) that small quantities of bromine cannot be estimated accurately by gravimetric methods. For quantities of the order of 0·01 mgrm., a colorimetric method such as Clausmann's must necessarily be employed; but, if sufficient material is available, the author would prefer to take 10 grms., or even more, if such quantity rendered the use of a gravimetric method possible. For quantities of the order of 5 mgrms., the author's method gives results which are never above the truth, and never more than 0·1 mgrm. low.

G. C. J.

Estimation of Chlorides, Chlorates, and Perchlorates in the Presence of Each Other. Marqueyrol. (*Ann. Chim. anal. appl.*, 1911, **16**, 167-168.)—The method is based upon the fact that hot nitric acid liberates chlorine quantitatively from chlorides, and decomposes chlorates with the formation of nitrates, but does not affect perchlorates under the same conditions. Chlorides are detected in the usual way, whilst the presence of chlorates is indicated by the yellow coloration of the liquid and characteristic odour of the chlorine vapours produced on introducing a little of the substance into strong sulphuric acid. In testing for perchlorates the solid substance is gently heated on a sand-bath with an excess of pure nitric acid (sp. gr. 1·33 to 1·38) to decompose chlorides and chlorates, the dry residue fused with sodium carbonate and potassium nitrate, the mass dissolved in dilute nitric acid, and the solution tested with silver nitrate. For a quantitative estimation the chloride is determined in the usual manner. The total chlorine is then estimated in the mass obtained by fusing the original substance with ten times its weight of a mixture of sodium carbonate and potassium nitrate; and finally the chlorine of the perchlorates is estimated in the residue left after destruction of the chlorides and chlorates with nitric acid. C. A. M.

Estimation of Copper in Pyrites and in Burned Pyrites. W. N. Iwanow. (*Chem. Zeit.*, 1911, **35**, 551.)—A portion of the copper in burned pyrites obstinately resists solution by means of nitric acid, but the whole of the copper in either pyrites or burned pyrites may be obtained in solution, suitable for electrolysis, as follows: The finely ground sample (3 grms.) is mixed with an equal weight of reduced iron, and the mixture placed in a thin-walled glass tube, 7 cm. × 1 cm. and closed at one end, and covered with a little reduced iron. The tube and its contents are maintained at a low red heat for a few minutes by means of a Bunsen burner. The still hot tube is placed in a 250 c.c. Erlenmeyer flask and cracked by means of a few drops of water. When cool, 50 c.c. of hydrochloric acid are added and the flask placed on the water-bath for half an hour, or until the iron is wholly dissolved. Some of the copper will separate as sulphide, and the rest is precipitated by means of hydrogen sulphide. The separated copper sulphide is filtered off with the sand, etc., washed, and dissolved in nitric acid. The solution is neutralised with ammonia and electrolysed, with or without separation of the iron. The results agree well with those obtained by Lunge's method, and are sometimes higher. G. C. J.

Valuation of Higher Oxides of Lead. A. Chwala and H. Colle. (*Zeitsch. anal. Chem.*, 1911, **50**, 209-249.)—The authors have experimented with all the many iodometric methods which have been proposed for the valuation of minium and lead peroxide, and conclude that these methods should be abandoned. The sources of error in several of them have been fully traced, and it is shown that satisfactory results cannot be expected even with red lead, which lends itself better to estimation by these methods than does the peroxide, unless the titration takes place in strongly acid solution. It is also shown that the presence of acetates of the heavy metals may lead to notable errors, and generally that methods which depend on the liberation of iodine from iodide by strong oxidising agents in presence of organic substances are untrustworthy.

The method of Lux is much more trustworthy, but it occasionally gives rise to low results, the cause of which has been traced to too long boiling with nitric acid. Better results are obtained by the following method, which avoids this source of error, and dispenses with the use of sulphuric acid. To 1 to 2 grms. of the sample, 100 c.c. of $\frac{N}{1}$-nitric acid, and 25 c.c. of $\frac{N}{1}$-oxalic acid are added, and the mixture is heated to boiling for ten to fifteen minutes, or until decomposition is complete. The solution is then titrated with $\frac{N}{1}$ or $\frac{N}{5}$ permanganate (at 70 to 80° C.), which is added as quickly as possible, a preliminary experiment to determine the approximate quantity facilitating this. G. C. J.

Estimation of Lead in Alloys containing Antimony and Tin. A. G. Blakeley and E. M. Chance. (*J. Soc. Chem. Ind.*, 1911, **30**, 518-519.)—The authors have adopted a method combining the procedure of Rossing (see Treadwell and Hall, Second Edition, II., p. 220) for the separation of the lead and other insoluble sulphides, with A. H. Low's dichromate method ("Technical Methods of Ore Analysis," Third Edition, p. 331), after converting to sulphate and dissolving the lead salt in sodium acetate solution.

Half a gram of the finely divided alloy (or an amount containing 0·3 grm. lead) is dissolved in the minimum quantity of aqua regia, or 5 : 1 hydrochloric acid and potassium chlorate, and the solution evaporated to a pasty consistency on the water-bath. Five c.c. of strong hydrochloric acid are run in, the mixture warmed, and 15-20 c.c. of water and a few crystals of tartaric acid added. The liquid is treated with a slight excess of sodium hydroxide solution (20 per cent.), and any precipitation disregarded. After now adding 50 c.c., or an excess, of sodium sulphydrate (50 per cent. solution saturated with hydrogen sulphide and filtered) the solution is warmed gently on a water-bath, with occasional stirring, during half an hour. The sulphides are flocculent and subside readily. The precipitate is washed by decantation with hot water containing 10 c.c. of the sodium sulphydrate solution per litre, and transferred to the filter, the washing being continued till 15 c.c. of the filtrate give no coloured sulphides on acidification with acetic acid. The filter and precipitate are boiled in a Jena flask with 25 c.c. of nitric acid (2 : 3) until no black particles remain, when 15 to 20 c.c. strong sulphuric acid are added, and the boiling continued till the carbonaceous matter is dissolved and the liquid is of a caramel colour (in about five minutes). After cooling somewhat, 0·1 to 0·2 grm. of potassium permanganate is cautiously added and the heating continued, the addition of permanganate and the heating being repeated till the solution turns slightly pink or green. The solution is again boiled after cooling and addition of 50 c.c. of water, and sulphurous acid or sodium bisulphite solution added till the colour is discharged. The solution is kept hot for fifteen minutes, cooled to room temperature, 25 c.c. alcohol added and filtered. The sulphate is washed with dilute sulphuric acid (10 per cent.), and finally with one quantity of cold water, the precipitate being kept largely in the flask. The precipitate is washed into the flask with a boiling solution of sodium acetate (90 grms. lead-free sodium acetate and 8 c.c. of glacial acetic acid per litre), removing every trace of sulphate from the filter-paper, and the liquid, after addition of more sodium acetate solution, warmed till the sulphate is completely dissolved and a clear solution results. A persistent turbidity indicates an incomplete sulphide separation. Sodium hydroxide (20 per cent. solution) is now added drop by drop till the precipitate just formed does not disappear. If the amount of lead is small, it is best to add phenolphthaleïn and then the alkali till a pink colour is produced. Acetic acid is then added cautiously till the solution just clears or the pink colour is discharged. Ten c.c. of potassium dichromate (10 per cent.) is next added, the liquid boiled gently for one or two minutes till the deep orange precipitate settles on removing the source of heat. The liquid is filtered and the precipitate washed ten times with 5 to 6 c.c. each of a hot dilute sodium acetate solution (50 c.c. cold saturated solution diluted to 1 litre). The precipitate is now again washed back into the flask with dilute hydrochloric acid (1 : 2), and the washing continued till all traces of lead chloride are dissolved and no colour remains on the filter. The filtrate is diluted with water to about 300 c.c., 2 c.c. of potassium iodide (50 per cent. solution) added, the solution gently mixed, and the free iodine titrated immediately with $\frac{N}{10}$ sodium thiosulphate solution, using starch-water as indicator. The thiosulphate is standardised on pure lead foil, treated with nitric and sulphuric acids as before, and the sulphate dissolved, etc., as described. Bismuth in small amounts does not interfere with the accuracy of the method, as it remains in solution as sulphate when the lead sulphate is filtered off. Larger amounts (several units per cent.) of bismuth are liable to cause the contamination of the lead sulphate with an indefinite quantity of basic sulphate of bismuth. The bismuth may be detected during the neutralisation of the acetate solution by the failure of the white precipitate to re-dissolve in excess of acetic acid (see Low's "Ore Analysis," Third Edition, p. 334).

A. R. T.

Rapid and Accurate Method for Estimation of Manganese. F. J. Metzger and L. E. Marrs. (*J. Ind. Eng. Chem.*, 1911, **3**, 333-335.)—Hillebrand pointed out (*U.S. Geol. Survey. Bull.*, No. 422, 162) that manganese was a disturbing factor in the determination of ferrous iron in rock by the sulphuric-hydrofluoric acid method, and that the (positive) error was highest when much hydrofluoric acid was present. This suggested to the authors that, in presence of sufficient hydrofluoric acid, manganese might react quantitatively with permanganate, and this is found to be the fact, all the manganese after the reaction being proved to be in the trivalent form. The value of the permanganate solution in terms of iron multiplied by 0·7868 gives, therefore, the value in terms of manganese. The titration is made in presence of 10 c.c. sulphuric acid (1 : 2), 25 c.c. of hydrofluoric acid and 5 grms. of ammonium fluoride. The total volume of the solution should be 100 to 150 c.c., and convenient beakers for the titration may be made by cutting off the tops of the ordinary ceresin bottles in which hydrofluoric acid is supplied. When a solution of pure manganese sulphate, standardised gravimetrically, is titrated with approximately $\frac{N}{30}$ permanganate, the results are accurate to 1 drop of permanganate, or 1 in 400 when 30 mgrms. of manganese, corresponding to about 20 c.c. permanganate is present. The end-point is slightly masked by the brown colour of manganic salts, if more than 40 mgrms. manganese is present. Ferric salts are without influence on the results, or on the sharpness of the end-point.

The method was applied to twelve analysed samples of steel and two of iron, supplied by the U.S. Bureau of Standards. One gram of each sample was dissolved in 10 c.c. nitric acid (1 : 1), and to the slightly cooled solution 1 grm. of ammonium persulphate was added. When effervescence ceased, the solution was boiled for a few seconds, and then evaporated to dryness, not baked. The residue was taken up in 20 c.c. of sulphuric acid (1 : 2) and 30 c.c. of water, and the mixture boiled until a clear solution was obtained. The cooled solution was transferred to a ceresin beaker, 25 c.c. hydrofluoric acid and 5 grms. ammonium fluoride added, and the titration with permanganate proceeded with. The results were in every case higher—in some notably higher—than those supplied with the samples by the Bureau of Standards, but the authors think their own numbers are to be preferred, as their method involves no precipitation or filtration whereby manganese may be, and, in their opinion, probably is lost when following other methods. If agreement with other workers is more important than absolute accuracy, however, the permanganate can be standardised on an analysed sample.

The use of both nitric acid and persulphate is necessary to oxidise the combined carbon of iron and steel. The graphitic carbon of cast-iron is almost without influence, but the authors filter it off just before adding the hydrofluoric acid and ammonium fluoride, although in only one case has a lower result been obtained on a filtered, as against an unfiltered, solution. As much as 2 c.c. of concentrated nitric acid has no effect on the titration, so that 1 or 2 c.c. of dilute nitric acid may be used to assist solution if the residue has been slightly baked after evaporation. G. C. J.

Estimation of Small Quantities of Manganese, especially in the Ash of Plants or of Animal Organs. G. Bertrand. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 361-370.)—The organic matter is incinerated at a low red heat until no unburned carbon can be seen. The cooled ash is then moistened with hydrochloric acid, warmed on the water-bath for a few minutes, a little sulphuric acid is added, and the mixture evaporated to dryness and again ignited at a low red heat. The treatment with hydrochloric acid and low temperature of the second ignition secure ready solubility of the manganese in the ash. The treatment with sulphuric acid not only eliminates chlorine—an essential preliminary to the persulphate method of estimation preferred by the author—but the last traces of carbon are more easily burned away in a sulphated ash, the fusion-point of which is usually tolerably high.

For estimating the manganese, the author gives preference to the colorimetric method first described by Marshall (*Chem. News*, 1901, **83**, 76), in which potassium persulphate, with the use of a trace of silver nitrate, is employed to oxidise the manganous salt to permanganate. It is shown, however, that Marshall's directions are not only insufficient, but actually misleading. The author dissolves the plant ashes in 10 c.c. of nitric acid (sp. gr. 1·08), adds 5 drops of a 10 per cent. solution of silver nitrate, and at least 0·1 grm. of potassium persulphate. This quantity of persulphate will oxidise 0·4 mgrm. of manganese without risk of manganese dioxide separating. It is recommended that not more of the plant ash should be taken than corresponds to 1 mgrm. of manganese, as otherwise the coloration will be so intense that the accuracy of the estimation will be impaired. Ammonium persulphate must not be used, nor must the addition of silver nitrate be less than that stated. If less silver be used, much more persulphate is required to attain complete oxidation within a reasonable time. The mixture is heated gently until the pink colour shows no further increase in intensity. The temperature is then raised to boiling to destroy the excess of persulphate, and maintained at the boiling temperature until oxygen ceases to be evolved. The cooled liquid is made up to exactly 10 c.c., and its colour matched by that of a standard solution of manganese sulphate which has been oxidised in a similar manner.

The paper includes directions for the successful application of the lead peroxide method to the estimation of the minute traces of manganese found in living tissues. By either method it is possible to estimate quantities of manganese from 0·01 mgrm. to 1 mgrm. with an error not exceeding ±5 per cent. G. C. J.

Exact Method for the Electrolytic Estimation of Metals. W. H. Perdue and G. A. Hulett. (*J. Phys. Chem.*, 1911, **15**, 147-154; through *Chem. Zentralbl.*, 1911, I., 1527.)—To obviate the errors caused by particles of the electrolyte being carried down with a precipitated metal, the use of mercury as a cathode is recommended. The metal is then weighed in the form of an amalgam. The formation of a thin layer of liquid between the platinum dish and the mercury is prevented by a preliminary amalgamation of the platinum. In the case of metals which are only sparingly soluble in mercury, a certain proportion of the precipitated metal may be washed out of the mercury again, and may then take up particles of the electrolyte. Rotation of the mercury cathode will prevent this. C. A. M.

Detection of Nitrites in Water. — Dané. (*Bull. Soc. Chem.*, 1911 [iv.], **9**, 354-355.)—It is proposed to make use of the indole reaction for the detection of nitrites. The reagent employed is a solution of 0·02 grm. synthetic indole in 150 c.c. alcohol (95 per cent.). Of this solution, 2 to 5 c.c. is added to a measured volume of the water to be tested, to which dilute sulphuric acid is next added. If the water contains as much as 0·4 part per million of nitrous acid, the well-known pink or red colour will appear within a minute, and it is said that the reaction may be made the basis of a quantitative colorimetric method for the estimation of nitrites in water. G. C. J.

Modification of the Diphenylamine Test for Nitrous and Nitric Acids. W. A. Withers and B. J. Ray. (*J. Amer. Chem. Soc.*, 1911, **33**, 708-711.)—The authors show that considerable variations exist in the manner of applying this test, in the strength of the reagent used, the amount of sulphuric acid, and the temperature of the reaction. All these factors affect the result. The presence of hydrochloric acid, as is well known, increases the delicacy of the reaction. The following mode of operating is stated to be very delicate: The reagent is prepared by dissolving 0·700 grm. diphenylamine in a mixture of 60 c.c. of strong sulphuric acid and 28·8 c.c. water. After cooling, 11·3 c.c. of strong hydrochloric acid (sp. gr. 1·19) are slowly added, equal to 5 per cent. HCl in the reagent. On standing overnight some of the base separates, proving saturation. One c.c. of the liquid to be tested is well mixed with 1 drop of the above reagent; 2 c.c. of strong sulphuric acid is next run in, in such a way as to form two layers of liquid. The tube is gently shaken to cause slight mixing of the liquids at the point of contact, when it is placed in a water-bath at 40° C. for fifteen to twenty minutes. The test shows the presence of 1 part of nitrite nitrogen in 25,000,000, or 1 part of nitrate nitrogen in 35,000,000. By prolonging the heating to one hour, the test will show 1 part in 32,000,000 or 1 part in 44,000,000 of nitrite and nitrate nitrogen respectively. A. R. T.

Effect of Ignition on Solubility of Soil Phosphates. G. S. Fraps. (*J. Ind. Eng. Chem.*, 1911, **3**, 335.)—Stewart (*Illinois Experiment Station, Bull.* 145) has proposed to estimate the organic phosphoric acid in soils by determining the increase in the quantity of phosphoric acid soluble in 12 per cent. hydrochloric acid, brought about by igniting the sample. It is now shown that certain phosphatic minerals (*e.g.*, wavellite and variscite) only yield 20 to 25 per cent. of their phosphorus to acid under the conditions prescribed by Stewart—namely, twenty-four hours' treatment in the cold—whereas after ignition they are wholly, or almost wholly, soluble.

G. C. J.

Decomposition of Silicates by Fusion with Boric Acid as applied to Qualitative Analysis. E. Rupp and F. Lehmann. (*Chem. Zeit.*, 1911, **35**, 565.)—As a preliminary to a merely qualitative analysis, the method of Jannasch (*Zeitsch. anorg. Chem.*, 1896, **12**, 208) may be much simplified, in particular by omitting the esterification and volatilisation of the boric acid. The authors do not prepare boric anhydride as Jannasch does, but use ordinary boric acid. About 5 to 6 parts of this are mixed with 1 part of the finely divided silicate and the mixture heated in a platinum crucible. As soon as most of the water has escaped, the crucible is covered, and the heating, in a blow-pipe flame, continued for twenty-five to thirty minutes. The product of the fusion is then distributed over the walls of the crucible by giving this a rotatory movement with the tongs. As soon as the fused mass ceases to be fluid, the crucible is partially immersed in water. The sudden contraction causes most of the substance to detach itself from the walls of the crucible, and it is next transferred to a beaker and boiled with 30 c.c. of dilute hydrochloric acid. Only a trace of silica remains undissolved. On cooling, most of the boric acid crystallises out and is filtered off with any other insoluble matter and rejected. It may contain lead chloride, but this is unimportant, as lead, if present, will be detected in the filtrate. The filtrate is evaporated to dryness and dried for an hour. The residue is treated with 40 to 50 c.c. of warm water acidified with hydrochloric acid and the solution filtered from the silica and a second crop of boric acid crystals. The filtrate is submitted to analysis in the usual manner, due regard being paid to the following facts: A single evaporation does not separate silica completely, so that any precipitate apparently of bismuth or aluminium should be further identified. In presence of boric acid, metals of the alkaline earth group may find their way into the precipitate given by ammonium sulphide, but the borates of the alkaline earth metals are readily soluble in a hot solution of ammonium chloride, and by means of this reagent may be separated from the sulphides of the ammonium sulphide group.

G. C. J.

Assay of Silver by Means of the Touchstone. A. Steinmann. (*Ann. de Chim. anal. appl.*, 1911, **16**, 165-167.)—Accurate results may be obtained with the touchstone if the streaks produced by the sample of silver alloy under examination be tested with the nitric acid reagent described below, and the results be compared with those given by the streaks produced by different alloys of known composition. This reagent consists of 40 c.c. of nitric acid (sp. gr. 1·27), 50 c.c. of glacial acetic acid, and 50 c.c. of water. The speed with which this liquid attacks the trace of metal upon the stone enables a close estimation of the proportion of silver to be made. The action of the acid should be arrested by the application of a roll of filter-paper as soon as the streak has become yellowish-brown, without being blackened, and the result is then compared with those given by the standard alloys. In this way it is easily possible to distinguish between silver containing the French legal proportion of 800 mgrms. of silver per grm., and that containing only 795 mgrms. In the case of copper-silver alloys of 900 mgrms. of silver per grm., the surface is thus shown to be of the same composition as the interior, whereas in alloys containing 935 mgrms. the surface is poorer in silver. Alloys of silver with zinc or cadmium are attacked more rapidly by the reagent than copper-silver alloys; but here, also, the proportion of silver may be closely estimated by comparing the results with those given by streaks from standard alloys. C. A. M.

Micro-chemical Test for Sodium. W. Lenz and N. Schoorl. (*Zeitsch. anal. Chem.*, 1911, **50**, 263-265.)—The use of a solution of uranyl acetate in acetic acid as micro-chemical reagent for sodium has been suggested before, but it possesses the disadvantage that the reagent, when stored in glass bottles, dissolves sodium from the glass; and when a small drop of such an old solution is allowed to evaporate alone on a microscope slide, the characteristic tetrahedra of sodium uranyl acetate make their appearance. A better reagent is ammonium uranyl acetate: $NH_4C_2H_3O_2.UO_2(C_2H_3O_2)_23H_2O$. When finely divided, this salt dissolves very quickly, and so can be made use of in the solid state. Potassium gives no similar tetrahedra, but salts of potassium must be separated before applying the test, as they tend to prevent the formation of the crystals of sodium uranyl acetate. If sodium and potassium are present in approximately equal amount, the appearance of the crystals is merely delayed, but if the potassium-sodium ratio is equal to or greater than 5 : 1, the sensibility of the reaction is greatly decreased. G. C. J.

Note on the Titration of Ferrous Oxide in Silicates by the Pebal-Dölter Method. M. Dittrich. (*Ber.*, 1911, **44**, 990-991.)—In the Pebal-Dölter method for the volumetric estimation of iron in silicates, after the decomposition of the latter by treatment with hydrofluoric and sulphuric acids, it frequently happens that portions of the powdered silicate remain undecomposed as strongly adherent hard crusts on the bottom of the platinum crucible. This difficulty occurs more frequently with strongly basic minerals poor in silica and rich in magnesia—*e.g.*, with olivine and rocks containing it. The difficulty may be surmounted by increasing the proportion of silica, by adding to the powdered material, before decomposition, a little quartz, not too finely powdered. Quartz is better than precipitated silica, because the latter is dissolved so quickly that its action in preventing the formation of hard crusts is barely appreciable. The quartz, on the other hand, resists the action of the acid for a certain length of time, and thus maintains the powdered sample in a loose condition. J. F. B.

New Test for Ferrous Oxide, and the Separation of Iron from Aluminium. Charitschkoff. (*Chem. Zeit.*, 1911, **35**, 463.)—By means of a solution of naphthenic acid in light petroleum, ferrous oxide may be quantitatively separated from neutral or faintly acid solutions of its salts, so that the aqueous layer gives no reaction with ferricyanides. The upper petroleum layer is coloured a chocolate-brown if ferrous salts be present. The reaction is as sharp as in the case of copper salts; ferric salts do not respond to the test. This reaction may form the basis of a separation of iron from aluminium. A neutral or slightly acid solution containing both metals is treated so as to convert the iron into the ferrous salt. The liquid is then shaken with a solution of naphthenic acid in light petroleum, and the two layers are separated, the aluminium being estimated in the aqueous portion. J. F. B.

Analysis of Ferrotitanium Alloys containing much Silicon. W. Trautmann. (*Zeitsch. angew. Chem.*, 1911, **24**, 877.)—These alloys cannot be decomposed by simple fusion with bisulphate, even when the operation is several times repeated. They may, however, be easily decomposed as follows: After roasting the sample for some time in a platinum crucible, hydrofluoric acid is added, and subsequently expelled by heating. The mass is fused with potassium bisulphate, and the resulting melt is readily soluble in warm, not too dilute, hydrochloric acid. For the estimation of silicon, a different method must be chosen, and the following is recommended: The roasted alloy is fused with sodium carbonate and a little nitre, and the melt detached from the crucible by the use of nitric acid. After removal of the crucible, complete solution of everything save silica is effected by addition of hydrochloric acid. Sulphuric acid is then added, and the solution evaporated until it fumes. Hydrochloric acid and water are added, the mixture warmed and the silica washed several times by decantation with dilute hydrochloric acid before bringing it on to the filter.

Attempts to estimate carbon in alloys of this type by direct combustion in a current of oxygen, with or without the use of lead peroxide, led to low results. The following figures are recorded: By direct combustion, 1·1 per cent. carbon; by the use of lead peroxide, 1·4 per cent.; by decomposition in a current of chlorine followed by combustion, 2·9 per cent. G. C. J.

Rapid Estimation of Nickel in Steel. G. Raulin. (*Moniteur Scient.*, 1911 [v.], I., 1, 84-86; through *Chem. Zentralbl.*, 1911, I., 1443-1444.)—The steel (1 grm.) is dissolved in 20 c.c. of hydrochloric acid (1 : 1), and the solution boiled with 10 c.c. of nitric acid, and then diluted to 200 c.c. Ammonia is added in quantity sufficient to change the colour of the solution from yellow to red, but insufficient to produce any precipitation, and a measured quantity of potassium cyanide solution (4·45 grms. KCN and 0·5 grm. NaHO per litre) is next added. The iron is then precipitated by means of ammonia, a further 20 c.c. of 2N ammonia is added, the whole made up to 500 c.c. and filtered. To 250 c.c. of the filtrate, 10 c.c. of a solution of ammonium sulphate (600 grm. per litre) is added, together with 5 drops of a 20 per cent. solution of potassium iodide, and the mixture titrated with silver nitrate solution (5·788 grms. per litre) until a permanent turbidity appears. For steels containing less than 10 per cent. of nickel, 0·24 should be deducted from the percentage of nickel found; this represents the error due to adsorption of cyanide by the ferric hydroxide. The correction becomes less with increasing nickel content, and for commercial nickel (98 to 99 per cent.) is practically zero. The estimation is unaffected by the presence of silicon, manganese, chromium, tungsten, molybdenum, sulphur, or phosphorus. G. C. J.

Volumetric Estimation of Sulphur in Iron and Steel. F. G. Elliot. (*Paper read before the Iron and Steel Institute*, May, 1911, p. 11.)—Though preliminary annealing with cream of tartar causes some brands of iron to evolve the whole of their sulphur on subsequent treatment with acid, this is not the case with nickel-chromium steels and other self-hardening material. A better method is the following: The sample (5 grms.) is mixed with 0·25 grm. of anhydrous potassium ferrocyanide and wrapped in a 9 c.m. filter if the sample is a graphitic iron (otherwise in two papers) and placed in a small porcelain crucible and annealed at 750° to 850° C. for twenty minutes in a closed muffle. After annealing and slow cooling outside the muffle, the drillings should still be covered with charred paper, otherwise the temperature or time of annealing has been excessive. The caked contents of the crucible are transferred to a glass mortar, loosened with a pestle, and then transferred to the evolution flask without being allowed to touch its neck. The evolution flask is connected with a condensing-tube 6 inches by 1 inch, containing about 2 inches of water, and standing in a beaker filled with cold water. A tube from this dips into a flask containing 60 c.c. of cadmium chloride solution, which again connects with another flask containing more cadmium solution. Fuming hydrochloric acid (50 c.c.) is now added, and the contents of the flask are rapidly heated until vigorous frothing occurs, when the flame is lowered. When the stream of gas passing through the cadmium solution begins to slacken, the flame is raised so that the liquid just boils, and boiling is continued so long as any gas is given off. The apparatus is disconnected and excess of standard iodine (1 c.c. = 0·00025 grm. S.) is added to the contents of the first absorption flask (usually nothing is found in the second). After addition of 10 c.c. hydrochloric acid (1 : 2), the excess of iodine solution is determined by means of an equivalent solution of thiosulphate, as usual.

The temperature of annealing is of the greatest importance and, unless it can be controlled accurately, it is necessary to work a standard of known sulphur content with each batch of samples. The use of hydrochloric acid of sp. gr. 1·19 and rapid evolution of gas are also essential to accuracy (*cf.* Kinder, *Stahl u. Eisen*, 1908, 249). G. G. J.

Estimation of Sublimed Sulphur in a Mixture of Different Kinds of Sulphur. Taurel and Griffet. (*Comptes rend.*, 1911, **152**, 1182-1183.)—Flowers of sulphur (or sublimed sulphur) consist of a nucleus of crystalline sulphur soluble in carbon bisulphide, surrounded by an amorphous pellicle insoluble in that liquid. The thickness of this pellicle, and consequently the weight of insoluble sulphur, varies very greatly (from 12 to 40 per cent.) with the mode of preparation and with the age of the sample, the insoluble modification undergoing a progressive transformation into the more stable soluble form. If, however, the granules of sublimed sulphur be immersed in carbon bisulphide, the solvent will penetrate through the pellicle, and dissolve the soluble nucleus, without affecting the proportions of the original envelope. On this fact has been based a method of estimating the proportion of sublimed sulphur in a mixture: Two graduated centrifugal tubes are charged, one with 35 c.c. of light petroleum (or other liquid in which sulphur is not readily soluble), and the other with 35 c.c. of carbon bisulphide, and 15 grms. of the sample under examination are slowly introduced into each of the tubes, which are then closed with the finger and slowly shaken until the sulphur is completely distributed. They are next "centrifuged" for ten minutes at a moderate speed, after which they are allowed to stand for a short time, and the volume of sulphur in each tube read.

C. A. M.

Estimation of Total Sulphur in Coal. T. S. Warunis. (*Zeitsch. anal. Chem.*, 1911, **50**, 270-272.)—The coal (1 grm.) is mixed with 2 parts copper oxide and 1 part anhydrous sodium carbonate, and the mixture placed in a porcelain crucible. This is supported in an inclined position in an opening in an asbestos plate, large enough to let the crucible pass half through. The crucible and its contents are heated gradually until the under-side of the crucible attains a red heat, using a Bunsen burner or, for exact work, a spirit lamp. The mixture is stirred from time to time for two hours, and then turned out into a beaker containing bromine water. The crucible is washed with dilute hydrochloric acid containing bromine, and the solution added to the contents of the beaker. More hydrochloric acid is added, and the solution boiled to expel bromine, filtered from coal ash, and the sulphate estimated as barium sulphate as usual. The results are occasionally higher than those obtained by Eschka's method, but always agree well with those obtained by Sauer's method (combustion in a current of oxygen in a combustion tube, containing 3 inches of platinised asbestos, and absorption of the gases by hydrogen peroxide or hydrochloric acid and bromine). G. C. J.

Behaviour of Uranium Phosphates towards Indicators. E. Starkenstein. (*Biochem. Zeitsch.*, 1911, **32**, 235-242.)—In the titration of orthophosphates with uranium acetate, either cochineal or potassium ferrocyanide may be used as the indicator; as soon as all the phosphoric acid has been precipitated as uranium phosphate, the addition of a further quantity of uranium acetate yields a brown coloration with potassium ferrocyanide and a green coloration with cochineal. In the case of cochineal, however, the titration solution must not contain too great a quantity of free acetic acid. Cochineal may be used as the indicator in the titration of glyceryl phosphate, but not potassium ferrocyanide, as this combines with the uranium acetate before the latter reacts with the phosphoric acid of the compound. In the case of pyrophosphates, the titration with uranium acetate yields the theoretical amount of phosphoric acid when cochineal is employed as the indicator, but only one-half the amount of phosphoric acid is found when potassium ferrocyanide is used; the same applies to the titration of inositol phosphate. Only one-half of the phosphoric acid in metaphosphates is titrated when cochineal is used as indicator, and with these salts potassium ferrocyanide cannot be used.

W. P. S.

APPARATUS, ETC.

New Method of Chemical Analysis. J. J. Thomson. (*Discourse delivered at the Royal Institution*, April 7, 1911; through *Nature*, 1911, **86**, 466-469.)—The positive rays with which the author has been working for the last few years afford a means of gaining an insight into the nature of the gases present in a vacuum-tube, and render possible a chemical analysis capable of determining whether, for example, oxygen is present, and, in addition, whether it is in the atomic or molecular condition, and if O_3, or other complex aggregations also occur. The rays after passing through a fine tube in the kathode, are exposed simultaneously to magnetic and electric forces, the former so arranged as to produce a vertical, and the latter a horizontal, deflection of the rays. When neither force is acting, the rays strike a point, *O*, on a screen placed at right angles to their direction, but under the influence of both fields strike a new point, *P*. The length of the vertical line *PN* is equal to the deflection produced by the magnetic field, and the horizontal line *ON* to that of the electric field.

It is known that $PN=A\frac{e}{v}$ and $ON=B\frac{e}{mv^2}$ where *A* and *B* are constants, depending on the strength of the fields and the geometrical data of the tube, *e* is the charge on the particle, *m* its mass, and *v* its velocity, then $\frac{m}{e}=\frac{A^2}{B}\frac{ON}{PN^2}$. When these rays strike a photographic plate it is affected, and on development yields a permanent record of their deflection (*cf. Phil. Trans.*, February, 1911). From the values obtained by measurement of the plates for *ON* and *PN* can be determined the value of $\frac{m}{e}$, which for the same type of carrier is a constant, and this value can be compared for different rays simply by measuring the values of *ON* and *PN*. The locus of *P* is a parabola and not a point, because the rays are not all moving with the same velocity, the slower ones suffering greater deflection. Each type of carrier produces its own line on the plate, and there are as many curves on the plate as there are kinds of carriers; from an inspection of the plate can be found, not only the number of kinds of carriers, but, from the dimensions of the curves, there can at once be calculated their atomic weights. It is in this last respect that the great advantage the new method has over spectrum analysis is obvious.

The author gives as an illustration the photographs of the positive-ray spectrum for nitrogen prepared from the atmosphere, and that from some nitrogenous compounds; in the former there is a line absent in the latter whose $\frac{m}{e}$ value is forty times that of hydrogen. Atmospheric nitrogen, therefore, contains an element of atomic weight 40 (argon). The positive-ray method will detect quantities of a gas too minute to produce any indication in the spectroscope, traces of helium, *e.g.*, having been thus observed. Although but a few months old, the method is already capable of determining with an accuracy of 1 per cent. the atomic weight of a gaseous substance, only $\frac{1}{100}$ mgrm. of the material being required. Impurities in the materials simply produce additional curves, and do not affect the parabola due to the substance under examination, and therefore introduce no error in the determination of its atomic weight.

The method would appear to be peculiarly suitable for the determination of atomic weights, not merely of the emanation from radio-active substances, but also those of the products into which they disintegrate. The rays are registered within a millionth of a second of their formation, and may therefore disclose the existence of intermediate forms of matter having only a transient existence, and so lead to a clearer insight into the processes of chemical action. The following are two out of several photographs described fully in the original paper; the first is that obtained from atmospheric nitrogen, the measurements showing that the atomic weights of the carriers producing the curves were as follows:

Positive.	Negative.
1·00 H +	1·00 H −
1·99 H_2 +	11·2 C −
6·80 N + +	15·2 O −
11·40 C +	
13·95 N +	
28·10 N_2 +	
39·00 Arg +	
100·00 Hg + +	
198·00 Hg +	

H + denotes that the carrier is an atom of hydrogen with one charge, H_2 + a molecule of hydrogen with one charge, N + + an atom of nitrogen with two charges, and so on. Nitrogen prepared from NH_4NO_2 had the following lines:

Positive.	Negative.
6·10 C + +	44·2 CO_2 +
7·02 N + +	65·5 Hg + + + ?
12·08 C +	100 Hg + +
14·01 N +	204 Hg +
27·90 N_2 +	

The spectrum of CH_4 contains a small region with five lines very close together; measurements show that their atomic weights are 12, 13, 14, 15, and 16, corresponding to C, CH, CH_2, CH_3, and CH_4. The author believes that this is the first occasion when the atoms (*sic*) CH, CH_2, and CH_3 have been observed in a free state. A gas through which an electric discharge is passing is a very complex thing, even in the case of an elementary substance like oxygen, in which the lines show that there are present simultaneously—

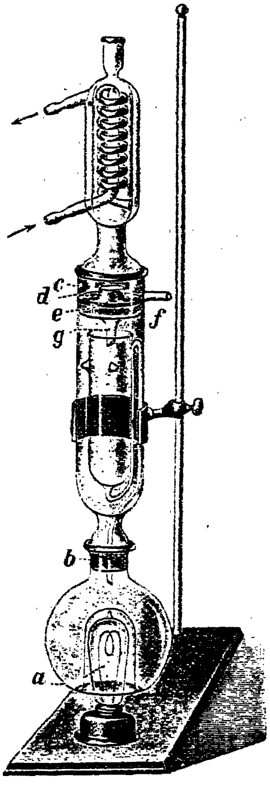
(1) Ordinary molecular oxygen, O_2.
(2) Neutral atoms of oxygen, O.
(3) Atoms of oxygen with 1 positive charge, O +.
(4) ,, ,, 2 positive charges, O + +.
(5) ,, ,, 1 negative charge, O −.
(6) Molecules of oxygen with 1 positive charge, O_2 +.
(7) Ozone with a positive charge, O_3 +.
(8) O_6 with a positive charge, O_6.

And in addition there are free negative corpuscles. An explanation is given of the presence of negatively charged particles, among which have been observed the *atoms* of hydrogen, carbon, oxygen, and chlorine. The two last are not unexpected, but the presence of hydrogen and carbon, usually considered electro-positive elements, is remarkable. No molecules ever occur in the negative side. The paper concludes with a discussion on the corpuscular theory of matter, the view being held broadly that the combination of atoms to form molecules either of compounds or elements fixes corpuscles which were previously mobile, and converts the atoms from conductors of electricity into insulators with a small specific induction capacity.

H. F. E. H.

Control Tests of the Colour Scale used with Schaeffer's Curd Tester. O. von Sobbe. (*Milchwirtsch. Zentralbl.*, 1911, 7, 172-174; through *Chem. Zentralbl.*, 1911, I., 1559.)—The author has made experiments to ascertain whether the quantities of ferric oxide given in Schaeffer's colour-table correspond with the respective shades of colour. Working according to instructions, it was found that after ten minutes the colours did not correspond, but that they gradually developed and were correct after three hours. Since, however, Schaeffer prescribes a time of ten minutes, an error must exist in the use of his table, owing to the incorrect proportions of ferric oxide. According to the author, the table would be correct if five times the prescribed quantities of ferric oxide were taken, or if his numbers, instead of being read as percentages, were taken to represent grms. per 20 grms. of curd.

J. F. B.



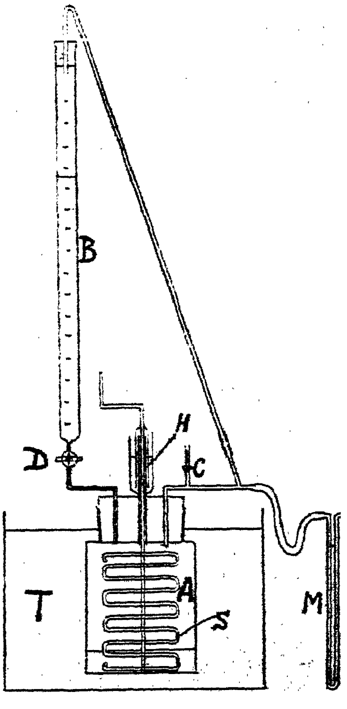
Condenser and Extraction Apparatus. R. Von der Heide. (*Chem. Zeit.*, 1911, 35, 531.)—The condenser and extractor are so constructed that, when the extraction has been carried far enough, the solvent can be distilled off without disconnecting the apparatus. During extraction, the condensed solvent collects in the rimmed plate *d*, and continually overflows through the hole in the raised middle of the plate. When it is wished to distil off the solvent, the condenser is given a quarter turn until the hole *e* (which is in the ground joint of the condenser, not in the plate, as might appear from the sketch) coincides with the outlet *f*, which pierces the wall of the extractor at the joint. The extractor proper with its syphon is removable, and, when it is removed, the remainder of the apparatus may be used as an ordinary reflux condensing apparatus. The new form of flask for electrical heating makes it possible to extract with liquids of relatively high boiling-point, such as water, if the flask be surrounded with an asbestos cylinder.

G. C. J.

Apparatus for Exact Gas Analysis. A. Wilhelmi. (*Zeitsch. angew. Chem.*, 1911, **24**, 870-871.)—Apparatus for exact gas analysis arranged on a single stand, a special feature being arrangements to reduce to a minimum the errors which result from the use of long and comparatively wide capillary connections such as are used with Orsat's apparatus. The apparatus, which is shown in section and fully described in the paper, is made by Eberhardt and Jaeger, Ilmenau. G. C. J.

Measuring Flask for Use in Determining Iodine Values of Oils. M. Dominikiewicz. (*Zeitsch. anal. Chem.*, 1911, **50**, 267-268.)—The neck of the litre flask figured in the paper terminates in a funnel-shaped enlargement. The uppermost part of the cylindrical portion of the neck is ground to accommodate a stopper. After the oil, chloroform, and Hübl solution have been introduced, the stopper is inserted and covered with a 10 per cent. solution of potassium iodide, which renders the flask airtight and absorbs any iodine vapours which may get past the stopper. On lifting the stopper to titrate the contents of the flask, the iodide solution flows in and is washed down by some water from a wash-bottle. The flasks are found useful for other purposes. They are made by Franz Hugershoff, Leipzig.
G. C. J.

Direct Measurement of Changes of Vapour Pressure and Detection of Definite Compounds in Mixed Liquids by its Means. R. Krulla. (*Chem. Zeit.*, 1911, **35**, 471-472.)—The apparatus illustrated serves to follow the changes of vapour pressure when one liquid is added to another in varying proportions. A measured quantity of one liquid (about $\frac{1}{5}$ molar weight) is placed in the closed vessel A, the other in the burette B, the stopcock D of which is closed at first. The temperature of the bath T being maintained at some convenient and constant level, and the cock C being open, the stirrer S is operated by its handle, which works through a mercury seal H. When a state of equilibrium has been reached, the cock C is closed. The manometer M then reads zero. A measured quantity of the liquid in B is run into A through D, and the stirrer again agitated until the level of the mercury in the manometer becomes stationary. Its height is then read. Before proceeding to the next addition of liquid from B, it is convenient to open the cock C and operate the stirrer for a short time, and to commence the next stage of the experiment with the manometer again at zero. G. C. J.



Apparatus for Measuring Radioactivity. B. Szilard. (*Chem. Zeit.*, 1911, 35, 539-540.)—The apparatus described and illustrated in the paper is designed especially with a view to produce an apparatus which, whilst portable, is yet sufficiently sensitive for its purpose. It consists essentially of a magnetic needle pivoted on a vertical point above a scale and in electrical connection with two fixed metallic horseshoe strips about as wide as the needle itself. These horseshoe strips lie in a vertical plane, with their open ends pointing towards the axis of suspension of the needle, and with one arm of each above, the other below, the needle; so that when the box containing the whole apparatus is so placed that this plane is the magnetic meridian, the needle cannot be seen. The needle and strips are insulated from the sides of the box containing them, and this is provided with a glass top and a lens fixed some distance above it, so that the position of the needle at any moment may be observed without error due to parallax. Means are provided for giving a small charge to the needle and strips. In use the apparatus is arranged so that the horseshoe strips just cover the needle; the latter is then charged, which causes it to move out from the meridian; the substance to be examined is introduced into the case on a small sliding shelf provided for the purpose, and the rate of discharge noted. This is compared, as usual, with the rate of discharge when using a known weight of some standard substance, such as uranium oxide. The bottom of the apparatus unscrews, and in its place can be attached a specially constructed condenser suitable for measuring the radioactivity of gases. This also is figured in the paper. The makers are the Laboratoire de Produits Radioactifs, Paris. G. C. J.

REVIEWS.

A Primer on Explosives for Coal-Miners. C. E. Munroe and C. Hall. Bulletin 423 of the United States Geological Survey. Washington, 1909.

An octavo pamphlet of sixty-one pages, including contents, with twenty-one half-tone plates; it is intended to check the improper use of explosives in coal-mines. Combustion and explosion, and the nature of "low" and high explosives in general and as applied to coal-mining, are simply explained. Squibs, fuse, and detonators, the various modes of coal-mining with explosives, including the proper charges and placing of shots, loading and firing, the advantages of electric firing, and the application of explosives to driving shafts and entries, are dealt with. Throughout, the sources of danger, and precautions for avoiding them, are pointed out. A chapter on the transport and storage of explosives (by B. W. Dunn), a description of the tests for permissible explosives, carried out in experimental galleries containing gas or coal-dust mixed with air, and a list of the publications of the department on the subject, are appended. O. E. Mott.

Allen's Commercial Organic Analysis. Fourth edition. Vol. IV. Edited by W. A. Davis, B.Sc., A.C.G.I., and Samuel S. Sadtler, S.B. 8vo. Pp. viii + 466, with 7 illustrations. London: J. and A. Churchill, 1911. Price 21s. net.

In the volume under consideration a large proportion of the space is given to the essential oils and certain constituents of them, such as the terpenes, camphor and other ketones, but this would appear to be fully justified in view of their commercial and technical importance, as well as the wide scientific interest associated with their more exact chemical investigation. It is not to be expected, however, that even within the space assigned to them, such a large group of natural products, so diverse in character and composition, could be described with the same degree of completeness as in a more specialised treatise on the subject, especially as methods of analysis and tests for the detection of adulterants and impurities must likewise be accorded the consideration which their importance demands.

In presenting a survey of the contents of the present volume, or more particularly of the sections devoted to the essential oils and allied subjects, it would seem desirable and of interest to record some general observations, and also to note some details of statement where inaccuracies appear to exist, without, however, attempting to enter upon a more extended discussion, for which the limitations of space would not permit.

The "Hydrocarbons of Essential Oils" are considered in a chapter of twenty-five pages (pp. 163-187), and these are followed by a chapter entitled "Ketones of Essential Oils," which comprises twenty-eight pages (pp. 189-216). A larger section (pp. 217-301), bearing the simple title "Volatile or Essential Oils" is devoted to a broader treatment of the subject, and includes their extraction, composition, general characters, and analysis, the general information under the latter heading being followed by a more detailed description of the methods employed for the detection or estimation of certain compounds. This comprises, for example, the detection of sulphur compounds, estimation of free acids, phenols, alcohols, esters, aldehydes, and ketones, together with the determination of such factors as the iodine value, methoxyl number, optical activity, and refractive index, and tests for some of the more common adulterants. A knowledge of these methods is naturally of very special importance to the analyst, inasmuch as the commercial valuation of a number of essential oils depends, not only on general tests for their identity and purity, but frequently on the quantitative determination of some particular constituent. A chapter entitled "Special Characters of Essential Oils" comprises within the limits of 128 pages (pp. 303-430) a description of the more important individual oils, and this is accompanied by a tabular representation of their principal characters, constituents, and solubilities, which occupies the last thirty pages of the work.

Notwithstanding the general excellence and the many valuable features of the present volume, there are also some apparent defects as well as obvious errors, and it is thought desirable that these should be noted for consideration in a subsequent revision, in order that a work which has achieved so high a reputation may continue to merit the confidence of those who consult it. In the chapter on the "Hydrocarbons of Essential Oils" there appears to be, for example, no reference to the so-called "olefinic terpenes," such as *myrcene*, which occurs in bay oil, sassafras-leaf oil, and the oil of hops, or the isomeric *ocimene*, from *Ocimum basilicum*. On the other hand, under the subject of "Pinene" (p. 180), this terpene is stated to form "a notable proportion of the oil from bay-leaves." It was shown, however, some years ago, that the true bay oil (not laurel oil) contains no pinene, as had previously been asserted, and its presence would therefore be direct evidence of adulteration (*cf.* p. 315). The name Thoms is wrongly printed on p. 189 as *Thorns*, and on p. 210 as *Thomas*.

In the chapter on "Special Characters of Essential Oils" no consideration appears to have been given to such important articles of commerce as the oils of cinnamon and cassia, the oils of wintergreen (*Gaultheria*) and sweet birch, or the oil of bitter almonds, although the comparatively unimportant oils of hyssop and parsley are described. Under "California Bay Oil" (pp. 315, 316) the only information given regarding its constituents is the statement that "the oil contains a hydrocarbon and appears to contain cineol." It has thus here been overlooked (*cf.* p. 446) that this oil was very thoroughly investigated several years ago, and that its principal constituent, a ketone, $C_{10}H_{14}O$, designated "umbellulone," has been specially studied with respect to its constitution (*J. Chem. Soc.*, 1904, **85**, 629; 1906, **89**, 1104; 1907, **91**, 271; 1908, **93**, 252). Under "Nutmeg Oil" (p. 358) there occurs the statement that "the presence of *myristicol* has been noticed by Gladstone and by Wright," although in the investigation referred to in the paragraph immediately following it was shown that the fraction of nutmeg oil to which the designation "myristicol" had previously been applied consisted of several alcohols, all of which have now been definitely identified. A statement concerning the composition of mace oil (p. 359) is not quite correctly expressed, inasmuch as the crystalline compound obtained by Semmler does not pre-exist in the oil, but was formed by the action of alkalies on the liquid constituent now known as *myristicin*, and, being isomeric with the latter, has been designated *iso*myristicin (*J. Chem. Soc.*, 1907, **91**, 2039).

In the "Table of Essential Oils" (p. 434) there occurs, in connection with the oil of *Asarum Europæum*, the word "asarol," a name which was originally given to the chief constituent of the oil of *Asarum Canadense;* but as this compound has since been found to be identical with *d*-linalool, the latter designation should be adopted (*J. Chem. Soc.*, 1902, **81**, 63). On p. 445 the known constituents of oil of hedeoma (American pennyroyal) are given as hedeomol and pulegone, without consideration of the results of a more recent investigation, which are described on p. 377.

In a section immediately following the above, the name *Hedeoma* is incorrectly applied to the leaves of *Mentha pulegium*, which is known as "European pennyroyal," but the two genera are botanically quite distinct. The statement regarding the constituents of oil of hops (p. 445) should be revised in accordance with the more recent investigation of Chapman (*J. Chem. Soc.*, 1903, **83**, 505), and on p. 450 the statement that the known constituents of oil of nutmeg are "chiefly pinene and myristicin" would suggest some amplification (*cf.* p. 358).

The observations above noted, together with a considerable number of typographical errors, would indicate that in these relatively minor details a little more care might have been exercised. Nevertheless, the intrinsic merits of the work are such that it may be hoped it will receive the recognition accorded to its predecessors, and, in view of the large amount of valuable information it contains, that it will continue to maintain its place as a trustworthy guide in the manifold operations of chemical analysis and investigation.

F. B. Power.

RESINS, INDIA-RUBBER, ESSENTIAL OILS.

Dr. M. B. Blackler is the author responsible for the section on resins, with which this volume opens. Those familiar with this subject know that, with a few exceptions, a particular resin cannot be identified by ordinary analytical processes alone, and consequently the analyst who is faced with a problem of this kind has to base his judgment on a great variety of factors, and must as a rule create his criteria from his knowledge of the properties and characters of resins as a whole. Dr. Blackler has kept this fundamental difficulty in mind, and has written and arranged his matter with a view to enabling his readers to obtain a clear idea of the differences which distinguish the chief groups of resins from each other. In the present nebulous condition of resin analysis this is undoubtedly the best method of procedure.

The errors of the article are for the most part inherited from previous editions of this work. On p. 6 it is implied, without any qualification, that abietic acid contains two carboxyl groups; whilst on p. 23 it is correctly pointed out that this view is erroneous, and that the acid is monobasic. The table on p. 6 includes "alban," one of the resins of guttapercha, as a "resene," although some years ago Van Romburgh and Cohen proved that guttapercha alban is an ester. The misleading information about "anime," including the statement that "it appears in general to be closely related to elemi and copal," is reprinted unchanged from the third edition.

Competent Indian authorities appear to be agreed that all shellac contains orpiment, and not only "some of the dirty yellow shellac of commerce," as the author asserts on p. 67. The third edition stated that French turpentine is called "Gallipot, or Barras," and Dr. Blackler not only repeats this erroneous statement on p. 76, but adds at p. 21 the equally inaccurate assertion that French colophony comes on the the market under the name "galipot." Under "African balsam," p. 83, it is re-asserted that this is probably derived from a Copaifera, whereas it is now perfectly well known that it is obtained from *Daniella thurifera*. The old mistake is made of including the oleo-resin elemi under the "gum resins," and its botanical origin is wrongly given. The statement on p. 17 that a variety of acaroid resin is produced in the Bahamas is incorrect, though the author can no doubt quote good authority for his assertion.

The occasional application of the term "gum" to these products is unfortunate, since it is important, in view of the use of this term in commerce, for such widely different materials as true gums, resins, camphor, opium, and rubber that technical writers should restrict it to its proper application.

Practically all the important resins are dealt with, but descriptions of some of the Euphorbia resins and of gamboge ought to have been included, and as Chinese lacquer is now an article of European commerce, some reference should have been made to this interesting product.

T. A. HENRY.

INDIA-RUBBER.

The article on "India-rubber," which comprises india-rubber, rubber substitutes and guttapercha, is by Mr. E. W. Lewis, A.C.G.I. It covers fifty-five pages, of which roughly forty-two pages are devoted to rubber and five pages to guttapercha. The balance of the article, under the heading Rubber Substitutes, deals with fatty (oil) substitutes, with "recovered" or "reclaimed" rubber, and with certain proprietary articles. In the article on india-rubber, Mr. Lewis deals first with latex and its analysis, and then gives a brief sketch of the work on and our knowledge of the composition and of the constitution of the rubber molecule. This is followed by some notes on the physical and chemical properties of crude rubber. The next section—namely, that on the analysis of crude rubber—is of a practical character, and should be decidedly useful to the general analyst who has no special experience of crude rubber. It might perhaps have been desirable to omit the reference to the Schneider process, or to have made the reference to it of a somewhat briefer character. Mr. Lewis would probably be the first to agree that the method has very little, if any, practical value. The remarks dealing with the vulcanisation of rubber, if somewhat brief, are sound, as one would expect from a chemist of Mr. Lewis's practical experience. Considerable space is devoted to the analysis of vulcanised rubber, and for those who desire further information there are ample references to the literature on the subject. On the whole, this section of the article has been dealt with admirably, but it is necessary for the reviewer to point out that recent work has conclusively shown that pyridine is not a suitable solvent for the separation of tar, pitch, and bituminous matter from many—possibly the majority—of rubber mixings (*cf.* Britland and Potts, ANALYST, 1910, **35**, 539). There are some useful notes on the analysis of ebonite and on the methods for determining the physical properties of rubber. Mr. Lewis deals very briefly with the latter, and also with the mechanical properties of rubber, and, in taking this course, he appears to have been well advised, in smuch as the determination of the physical and mechanical properties of rubber require special apparatus and plant which are not likely to be present in the general analyst's laboratory. Without such special apparatus, attempts to determine the mechanical and physical properties of rubber are likely to do more harm than good, but Mr. Lewis has given references to the literature on this subject for those who desire to pursue it further. On the whole, Mr. Lewis is to be congratulated on handling a difficult and intricate subject in a sound and scholarly fashion.

P. SCHIDROWITZ.

THE MICROSCOPICAL EXAMINATION OF FOODS AND DRUGS. By HENRY GEORGE GREENISH, F.I.C., F.L.S., Professor of Pharmaceutics to the Pharmaceutical Society. London: J. and A. Churchill, 1910. Price 12s. 6d. net.

This is a second edition of Professor Greenish's book, which originally appeared in 1903. A section has been added on fibres, and some additions have been made to the previously existing sections of the work, which is one primarily designed as a working textbook for students. The well-known skill and care of the author as a microscopical expert have resulted in a set of drawings which, as far as they go, afford clear indications of the histological structure of many of the materials with which analysts as well as pharmacists are called upon to deal; but, as only typical articles are selected, the list—and consequently the general utility of the book—is limited. The first section is devoted to starches and the second to hairs and textile fibres, the remaining sections dealing with spores and glands (lycopodium, lupulin, etc.), woods, stems, leaves, flowers, barks, seeds, fruits, rhizomes, and roots, about fifty different typical drugs being dealt with, as well as some of the more common food substances, the analysis of which calls for microscopical examination, some of the more common adulterants of powdered foods and drugs being included. The working instructions are good throughout, being the outcome of long personal experience in this important branch of the analyst's art. BERNARD DYER.

IDENTIFICATION OF THE COMMERCIAL DYESTUFFS. Being Volume III. of a Method for the Identification of Pure Organic Compounds. By S. P. MULLIKEN. New York: J. Wiley and Sons. London: Chapman and Hall. 1910. Price 21s. net.

The introductory chapter refers to the difficulty and complexity of the problem involved in the identification of the several hundred definite chemical species of colouring matters liable to be met with in current industrial dyes. In Chapter II. the author gives directions for the general analytical procedure in the examination of an unknown dyestuff, dividing his tests into four groups: (*a*) Preliminary; (*b*) generic, divisional, and sectional; (*c*) co-ordination; and (*d*) special tests.

The reactions indicated under these headings are likely to prove of service to the analyst who is occasionally called upon to examine commercial brands of dyes, many of which are mixtures of several specific colouring matters.

The tests are arranged in a definite order and are referred to by numbers. The preliminary tests include the identification of indigoid dyes and sulphide colours by vat-dyeing experiments with sodium hydrosulphite and sulphide respectively. The generic tests contain descriptions of the colour-discharge effects produced by Rongalite (sodium formaldehydesulphoxylate) and the regeneration of the colour in certain cases by oxidation with potassium persulphate.

Among the co-ordination tests will be found the effect on dyed fabrics of such general reagents as concentrated sulphuric acid, aqueous sodium hydroxide, nitrous acid, and chromic acid (after-chroming).

The application of the foregoing reactions will generally enable the analyst to refer the colouring matter to its proper class, and special tests are now applied for the purpose of identification. Among these special tests may be mentioned—(i.) The precipitating action of sulphuric acid, sodium hydroxide, tannic acid, and the sulphates of calcium, chromium, and copper; (ii.) the dyeing of wool with different mordants; (iii.) the reduction of azo-dyes with sodium hydrosulphite, and the identification of the fission products; (iv.) the absorption spectra of dye-solutions.

Whenever possible, verification tests should be carried out by making comparative dyeings with the identified dye and standard specimens of the same colouring matter.

The greater portion of the volume is devoted to a tabulation of the commercially important dyestuffs arranged in accordance with their reactions towards the reagents employed in the generic or sectional tests, and indicating the tinctorial effects of the dyes on wool or cotton. The last chapter gives useful suggestions for the identification of dyestuffs in mixtures. G. T. MORGAN.

EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

WASHINGTON AND NEW YORK, U.S.A., SEPTEMBER, 1912.

NOTICE.

THE Eighth International Congress of Applied Chemistry will be held in Washington and New York, U.S.A., from September 4 to September 13, 1912, under the patronage of His Excellency the President of the United States. The Hon. President of the Congress is Professor Edward W. Morley, Sc.D., Ph.D., LL.D.; the President, Mr. Wm. H. Nichols, Sc.D., LL.D.; and the Secretary, Dr. Bernhard C. Hesse, 25, Broad Street, New York City.

The Congress is divided into the following sections and subsections:

I. Analytical Chemistry.
II. Inorganic Chemistry.
III*a*. Metallurgy and Mining.
III*b*. Explosives.
III*c*. Silicate Industries.
IV. Organic Chemistry.
IV*a*. Coal Tar Colours and Dyestuffs.
V*a*. Industry and Chemistry of Sugar.
V*b*. India-rubber and other Plastics.
V*c*. Fuels and Asphalt.
V*d*. Fats, Fatty Oils, and Soap.
V*e*. Paints, Drying Oils, and Varnishes.
VI*a*. Starch, Cellulose, and Paper.
VI*b*. Fermentation.
VII. Agricultural Chemistry.
VIII*a*. Hygiene.
VIII*b*. Pharmaceutical Chemistry.
VIII*c*. Bromatology and Pharmacology.
VIII*d*. Physiological Chemistry.
IX. Photo-Chemistry.
X*a*. Electro-Chemistry.
X*b*. Physical Chemistry.
XI*a*. Law and Legislation affecting Chemical Industry.
XI*b*. Political Economy and Conservation of Natural Resources.

Papers will be accepted for reading and discussion in all the above sections, preference being given to those specially adapted for international discussion. They must be sent in not later than July 1, 1912.

A preliminary pamphlet has been issued, and may be obtained from the Hon. Secretary of the British Organising Committee, Charles G. Cresswell, Society of Chemical Industry, Palace Chambers, Westminster, S.W.

June, 1911.

AUGUST, 1911 Vol. XXXVI., No. 425.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

NOTE ON THE COMPOSITION OF BLAUD'S PILL.

By ALBERT E. PARKES, F.I.C., and JOHN D. ROBERTS, B.Sc.

(*Read at the Meeting, May* 3, 1911.)

Blaud's pill, according to the formula recommended by Blaud himself about 1832, was originally prepared from ferrous sulphate and potassium carbonate in equal quantities, compounded with various gums, syrups, etc., to form a workable pill mass, the active constituent being ferrous carbonate, which is formed by the interaction of the two principal ingredients. Since its introduction various alterations in its composition have been made.

At the present time it is incorporated in the British Pharmacopœia as the official *pilula ferri*, and should consist of 150 parts of exsiccated ferrous sulphate and 95 parts of anhydrous sodium carbonate, which are about the theoretical amounts required by the reaction—

$$FeSO_4, H_2O + Na_2CO_3 = FeCO_3 + Na_2SO_4 + H_2O$$

sodium carbonate having been substituted for the original potassium carbonate. The remainder of the pill consists of gum acacia, tragacanth, syrup, and glycerol, the whole being made up into 5-grain pills, each pill containing the equivalent of 1 grain, or about 20 per cent. of ferrous carbonate.

We have recently examined a large number of commercial samples of Blaud's pill, some of which were found to differ considerably in composition from the official formula.

The results of analysis are set out in the table on p. 388, the figures being calculated on the mean weight of five or ten pills.

In numbers 2, 3, 8, 14, 16, 20, 22, 29 and 30, the figures represent the whole pill; in the other cases the pill was examined after removal of its coating. The figures in column 8 represent the amount of SO_3 found in the ash and not in the original pill (except the numbers before mentioned).

Number.	Colour.	Coating.	Ash.	Ash Insoluble in HCl.	Iron as Oxide.	Equivalent to $FeCO_3$ per pill.	SO_3.	Soda, Na_2O.	Potash, K_2O.
			Per Cent.	Per Cent.	Per Cent.	Grain.	Per Cent.	Per Cent.	Per Cent.

28	,,	,,	38·31	3·34	19·61	1·05	4·21	—	—
29	Black, double strength	Gelatine	47·96	7·59	35·97	2·01	0·54	2·04	nil
30	White	Sugar, Blaud and arsenic	—	0·19	12·74	0·90	11·26	8·80	

It is evident from these figures that many of the samples were made from ferrous carbonate, and in Nos. 3, 8, 13 and 16, the amount of sodium carbonate was very low. The ferrous carbonate was probably first prepared by precipitation with sodium carbonate, and the precipitate, without washing, then made up into pills. This would account for the minute quantities of alkali found in some of the samples. Five samples were found to be deficient in iron, and two samples, it will be observed, contained potassium carbonate.

While it may be held that pills made from ferrous carbonate are quite efficient, it must be admitted that they do not satisfy the requirements of the Pharmacopœia.

NOTE ON THE "PEARL COATING" OF PILLS.

By ALBERT E. PARKES, F.I.C., and JOHN D. ROBERTS, B.Sc.

(*Read at the Meeting, May* 3, 1911.)

In the preceding note it will be observed that the majority of the pills were of the variety known as "pearl coated." In as many cases as possible the coating was removed, estimated, and examined. The approximate composition of the coating and of the pill mass is set out in the following table:

Number of Samples Examined.		Coating.				Pill Mass.		
		Average Weight of Pill.	Amount.	Ash.	Ash insoluble in HCl.	Amount.	Ash.	Ash insoluble in HCl.
		Grm.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
21	Maximum	0·52	40·08	34·75	31·59	78·71	35·70	16·19
	Minimum	0·38	21·29	19·20	17·02	59·92	20·09	0·70

On further examination the ash insoluble in hydrochloric acid was found to consist principally of magnesium silicate, and to have the following composition:

	Coating. Per Cent.	Pill. Per Cent.
Silica and insoluble matter	65·4	71·4
Iron and aluminium oxides	4·4	3·8
Magnesia (MgO)	27·9	21·1
Alkalis	1·7	2·0

The use of magnesium silicate (steatite) for the pearl coating of pills appears to have commenced some twenty-five years ago; of late years it has considerably increased, and at the present time almost every official pill of the Pharmacopœia can be obtained pearl coated.

Opinions differ as the the suitability of steatite as a coating for pills. Gilmour (*Pharm. J.*, 1887, 781) and Cowley (*Chem. and Drug.*, 1895, 923) state that the coating is harmless and easily disintegrated; on the other hand, Tichborne ("Year-Book of Pharmacy," 1901) condemns pearl-coated pills, and refers to them as "bullet-like bodies."

When allowed to disintegrate in water or dilute acid, the coating, under the microscope, has the appearance of transparent, sharp, angular particles, resembling finely-ground glass, and, in our opinion, the ingestion of such inert siliceous matter by persons in delicate health must be attended with grave risks. Quite recently the attention of public authorities has been called to the objectionable habit of polishing rice with mineral matter; the use of the same material as a coating for pills must be regarded with equal disfavour, and, if allowed to be used at all, the amount should be restricted to the smallest possible quantity. The variations in the amounts in the samples examined seem to be far greater than there is any necessity for.

The use of a siliceous material as an excipient in the case of "Blaud's Pill" is quite unnecessary. It will be noticed that in the majority of cases the siliceous matter in the pill mass is small, and can be neglected; it is obviously a difficult matter to free the pill entirely from its coating before examination, but in the other cases it has evidently been added to the pill mass before coating, and attention may also be called to the fact that it is these particular pills which are also deficient in alkaline carbonate.

The British Pharmacopœia sanctions the use of kaolin as an excipient in certain pills, which, however, do not include the one in question.

THE COMPOSITION OF MILK.

By H. DROOP RICHMOND, F.I.C.

(Read at the Meeting, May 31, 1911.)

In the present communication the results of the analyses of milk during 1910 made in the laboratory of the Aylesbury Dairy Company are given. The average results of 19,282 samples of milk received from the farms is given in the table below:

Average Composition of Milk during 1910.

Month.	Morning Milk.				Evening Milk.				Mean.			
	Sp. Gr.	Total Solids.	Fat.	Solids-not-Fat.	Sp. Gr.	Total Solids.	Fat.	Solids-not-Fat.	Sp. Gr.	Total Solids.	Fat.	Solids-not-Fat.
		%	%	%		%	%	%		%	%	%
January ...	1·0321	12·50	3·62	8·88	1·0318	12·80	3·92	8·88	1·0319	12·65	3·77	8·88

July	1·0321	12·20	3·37	8·83	1·0315	12·63	3·85	8·78	1·0318	12·42	3·61	8·81
August ...	1·0322	12·37	3·48	8·89	1·0317	12·86	4·00	8·86	1·0319	12·61	3·74	8·87
September ...	1·0324	12·56	3·60	8·96	1·0320	12·98	4·03	8·95	1·0322	12·78	3·82	8·96
October ...	1·0325	12·75	3·75	9·01	1·0322	13·16	4·14	9·02	1·0324	12·96	3·95	9·01
November ...	1·0326	12·89	3·84	9·05	1·0324	13·15	4·11	9·04	1·0325	13·02	3·97	9·05
December ...	1·0323	12·78	3·80	8·98	1·0322	13·04	4·04	9·00	1·0323	12·91	3·92	8·99
Average ...	1·0322	12·43	3·53	8·90	1·0319	12·81	3·92	8·89	1·0320	12·62	3·73	8·89

The usual variations were noticed—that is, the lowest fat occurred in May and June, and the highest in October and November; the drop in solids-not-fat so often found in July and August was scarcely noticed in 1910.

In continuation of the tables published in former years, I give the percentage of the samples falling between each 0·1 per cent. of fat below 3·0; I have extended it this year to include April and July, as quite an appreciable number of samples below the limit were found. In the other months of the year such low samples are practically, if not entirely, non-existent. The table refers to morning milk only, hardly any samples of evening's milk being below 3·0 per cent. of fat.

PERCENTAGE OF SAMPLES OF MORNING MILK FALLING BELOW 3·0 PER CENT. FAT.

	2·9 to 3·0 per Cent. Fat.	2·8 to 2·9 per Cent. Fat.	2·7 to 2·8 per Cent. Fat.	Below 2·7 per Cent. Fat.
April, 1910	1·6	0·3	0·5	0·9
May, 1910	3·0	2·1	0·8	0·5
June, 1910	3·0	1·2	1·0	0·1
July, 1910	0·7	0·7	0·1	—

These results do not greatly differ from those of previous years, but the period when cows frequently yield milk below standard appears to be extending into both April and July.

With reference to the statement that I made last year as to the occurrence of low solids-not-fat during March and April of 1910, which were due to a low percentage of proteins, I give here the composition of the milk from the two farms on which these low solids-not-fat were observed; only the evening milk in each case contained low percentages of solids-not-fat:

	FARM B.						FARM C.		
	March.			April.			March.		
	Average.	Minimum.	Maximum.	Average.	Minimum.	Maximum.	Average.	Minimum.	Maximum.
Total solids ...	12·70	—	—	12·66	—	—	12·54	—	—
Fat	4·24	—	—	4·15	—	—	4·07	—	—
Milk-sugar ...	4·55	—	—	4·52	—	—	4·61	—	—
Proteins ...	3·18	2·96	3·47	3·26	3·11	3·52	3·13	2·99	3·33
Ash	0·73	—	—	0·73	—	—	0·73	—	—
Solids-not-fat ...	8·46	8·20	8·70	8·51	8·30	8·70	8·47	8·15	8·75

In each case about one-half of the samples fell below 8·5 per cent. of solids-not-fat, the bulk of them lying between 8·4 and 8·5; there were only four samples which did not substantially conform to the standard of 8·5 per cent., in which the proteins fell appreciably below the figure corresponding to 0·5 per cent. of nitrogen (3·19 per cent.). These were—

Solids-not-fat ...	8·35	8·30	8·30	8·15
Proteins	2·96	2·96	2·99	3·02

An unusual instance of low solids-not-fat accompanied by a high percentage of proteins was published in the ANALYST (1911, p. 11).

In the last three weeks of December the milk from a farm was found to be constantly below 8·5 per cent. of solids-not-fat. The composition for the month was—

	Average.	Minimum.	Maximum.
Total solids	12·96	—	—
Fat	4·59	—	—
Milk-sugar	3·86	—	—
Proteins	3·72	3·60	3·98
Ash	0·79	—	—
Solids-not-fat...	8·37	8·05	8·95

The acidity of this milk was very low, and averaged 13·4 degrees. Inquiries at the farm showed that the cows were healthy, but were nearly dry, and were only being milked once a day; I learn that this is not an uncommon practice during the winter on farms where cheese is made.

My experience this year has shown that, while the rule that genuine samples containing less than 8·5 per cent. of solids-not-fat should contain 0·5 per cent. of nitrogen and 0·7 per cent. of ash is not an absolute one, the exceptions to this are very few.

DISCUSSION.

Mr. C. REVIS agreed that in the great majority of cases in which deficiency in non-fatty solids occurred it was due to deficiency in milk-sugar. In determining whether a low percentage of non-fatty solids was due to tampering or to abnormality, a determination of the proportion of milk-sugar afforded, in his experience, very useful information, and was well worth the small additional time that it occupied.

FURTHER ANALYSES OF GHEE.

BY E. RICHARDS BOLTON AND CECIL REVIS.

(Read at the Meeting, May 31, 1911.)

SINCE the publishing of our paper entitled "Some Analyses of Ghee" (ANALYST, 1910, **35**, 343), a number of other samples have come into our hands, and, as some of these are known to be samples of ghee as sold in the market in the City of Bombay, we thought it desirable to place the analyses on record. In publishing these results, we feel it necessary to draw attention to the Reichert-Meissl value of 18·24 given for one sample of ghee made from buffalo milk, and published in a paper by Kesava-Menon (*J. Soc. Chem. Ind.*, 1910, **29**, 1428). We feel certain that this is quite an abnormal figure for true ghee, and, if accepted in any way as a representative figure, would lead to the passing of a considerable amount of adulterated ghee as pure. Of all the samples we have examined, none have lead us to suppose that pure ghee has anything but a high Reichert-Meissl value, usually approaching or even exceeding 30.

We again draw attention to the fact that the process of Avè Lallemant, as referred to in our previous paper, is of distinct value in the examination of ghees:

THE DETERMINATION OF THE AMOUNT OF DISSOLVED OXYGEN ABSORBED BY SEWAGE EFFLUENTS CONTAINING NITRITES, AND OF THE AMOUNT OF NITRITE IN SEWAGE EFFLUENTS AND WATER.

By R. W. CLARKE, F.I.C.

(*Read at the Meeting, May* 31, 1911.)

CONSIDERABLE attention has lately been paid to the determination of the amount of dissolved or atmospheric oxygen absorbed by sewage effluents. This has been due in great measure to the fact that, in the fifth report of the Royal Commission on Sewage Disposal, great weight is attached to the amount as a criterion of the purity and non-putrescibility of an effluent.

Two methods of determination are in general use—viz.:

1. Absorption of atmospheric oxygen by means of Adeney's apparatus, the decrease in volume of a known amount of air being measured.

2. Absorption of dissolved oxygen from tap-water, the amount of dissolved oxygen present at the commencement and after definite periods of time being estimated by Winkler's method or one of several modifications thereof. These are referred to in Rideal and Stewart's paper (ANALYST, 1901, **26**, 141).

The Adeney apparatus was found on several occasions to give unsatisfactory results, so it was discarded in favour of purely chemical methods.

In the absence of nitrites, Winkler's method is perfectly satisfactory, and gives concordant results under identical conditions as to dilution and temperature. In the presence of nitrites, however, a definite end-point is not obtainable on titration with thiosulphate, owing to oxidation of N_2O_2 and consequent liberation of a further quantity of iodine, when it is again reduced to N_2O_2, the cycle being repeated, according to the equations:

1. $2HNO_2+2HI=N_2O_2+2H_2O+I_2$.
2. $2N_2O_2+2H_2O+O_2=4HNO_2$.

The method suggested by Rideal and Stewart (*loc. cit.*), while quite satisfactory for the purpose to which it is applied by them, is inapplicable to the effluent before dilution, when the amount of dissolved oxygen absorbed is to be determined, as the whole character of the effluent is, naturally, changed by the oxidising action of the permanganate, and, if applied to the diluted effluent, cannot be relied on completely to oxidise the nitrite, an indefinite end-point being still obtained.

It was found that the difficulty was entirely avoided if free acid was not present. Neutralisation can be effected satisfactorily by adding a small excess of light carbonate of magnesia to the acid liquid. The method may be summarised as follows: The effluent is diluted to a sufficient extent (ten times or more in the case of bad effluents) with good tap-water and thoroughly shaken, and a number of bottles (usually five) of known capacity, approximating to 300 c.c., are completely filled therewith. The amount of dissolved oxygen present at the start, and after one, two, and five days respectively, is determined by adding 1 c.c. of 33 per cent. $MnCl_2$ to the bottom of the bottle by means of a pipette with a long and narrow delivery tube, followed by 3 c.c. of 33 per cent. NaOH containing 10 per cent. KI. The bottle is then shaken, and allowed to stand for some time, atmospheric oxygen being of course excluded. When the mixed hydrated oxides of manganese have settled to the bottom, 3 c.c. of hydrochloric acid are added and the bottle again shaken. A sufficient quantity of $MgCO_3$ to neutralise the free acid is then added, and, after allowing time for the completion of the reaction, the contents of the bottle are poured into a flask and titrated with thiosulphate of known strength (a convenient strength is about $\frac{N}{50}$).

The difference in amount of dissolved oxygen present at the commencement and after a given interval, multiplied by the dilution, gives the amount of oxygen absorbed. The assumption is here made that there is no appreciable change in the amount of nitrites present during the interval. Up to the present all experiments have shown this assumption to be justified.

The possibility of applying the reaction to the estimation of nitrites was at once apparent. Several different methods were tried. The best seems to be as follows: A tall bottle, holding not less than 500 c.c., and having a tightly-fitting stopper, is required. One of the ordinary quart bottles, with spring stopper, such as is used by dairy companies for sterilised milk, is convenient. This is filled with the nitrite-containing water or effluent to within about 20 c.c. of the whole content, the quantity being measured. To this are added 4 c.c. of 33 per cent. $MnCl_2$ and 12 c.c. NaOH and KI solution, as for the estimation of dissolved oxygen. A further quantity of about 1 grm. of KI is added, and the bottle closed and very thoroughly shaken. It is important that a small bubble of air be left in, as the stopper fits sufficiently tightly to cause the bottle to burst on slight increase in temperature if this be not done. The bottle is then allowed to stand at rest overnight. The hydrated oxides of manganese sink to the bottom, leaving a solution of manganese nitrite in water which is free from dissolved oxygen.

A stoppered bottle of known capacity, of about 300 c.c., is then filled with the clear solution by means of a siphon (aeration being avoided), and acidulated with 3 c.c. of HCl; this is then neutralised with $MgCO_3$, and the iodine liberated is titrated with thiosulphate of known strength. A weak solution is best; that used for the determination of oxygen absorbed from permanganate answers excellently. From this result the quantity present in the original water is easily calculated.

Experiments conducted with tap-water containing known amounts of potassium nitrite, varying from 0·04 to 0·6 part per 100,000 of nitrogen, gave results within 5 per cent. of the quantities taken; and the presence of organic matter, such as is commonly present in sewage effluent, appears to cause no error. The long sedimentation of the oxides of manganese is necessary, as the finer particles of manganous hydrate settle down much more slowly than do the more highly oxidised hydrates; and the affinity of manganous hydrate for oxygen is so great that it is impossible to siphon off the liquid without a portion being oxidised, and this causes a liberation of iodine in excess of that due to the nitrite. The other well-known methods of estimating nitrites in the small quantities in which they occur in water and sewage, such as Thresh's, the *m*-diaminobenzene, and the *α*-naphthylamine and sulphanilic acid methods, failed to give such satisfactory results as that above-described. Moreover, the method is extremely simple, and, so far as actual manipulation is concerned, takes very little time, as is also the case with the determination of dissolved oxygen absorbed.

DISCUSSION.

Mr. W. T. BURGESS said that, in connection with the process for the estimation of dissolved oxygen which had been communicated to the Society by Dr. Rideal and himself in 1909, they had observed that, during the time that the effluent was under examination (from one day to five days), the proportion of nitrite present did not sensibly change, and this was confirmed by Mr. Clarke's work. With regard to the dilution of the effluent with ten times its bulk of water, he would point out that the large multiplication of the results which this involved was a decided disadvantage. He thought that as a rule it would be sufficient to dilute with an equal bulk of fully aerated water, provided that the effluent was fully aerated to start with.

Mr. E. HINKS said that he had had an opportunity recently of trying Mr. Clarke's process, and had found that when the solution was neutralised with magnesium carbonate the extension of the end-point by the nitrite was entirely obviated. In the application of the process to the estimation of nitrites he had not been quite so successful. With quantities under 0·1 part per 100,000, his results were always too high, but of course his experience with the process was very limited. One drawback to this part of the process seemed to be that it required so large a quantity of the sample—more than would be likely to be available in ordinary cases after the other determinations had been made.

THE ESTIMATION OF QUININE AS THE ACID CITRATE IN CERTAIN ORGANIC LIQUIDS.*

By T. COCKBURN, F.I.C., and J. W. BLACK.

(*Read at the Meeting, May* 31, 1911.)

The results of the estimation of quinine in organic liquids, such as urine, by direct extraction of the alkaline liquid with ether, are very unreliable. The quinine thus obtained is contaminated with resinous and colouring matter, and therefore results obtained by direct weighing of the ether extract are entirely erroneous.

Nishi's method (Analyst, 1909, **34**, 443) obviates this source of error, by precipitating the quinine, dissolved in ether, as the acid citrate, by the addition of an ethereal solution of citric acid. That the compound formed is of constant composition and corresponds to the acid citrate is proved by Nishi's published results, the accuracy of which we confirmed by a series of estimations, in which we employed pure anhydrous quinine, with the following results:

Quinine taken.	Acid Citrate of Quinine found by Precipitation.	Percentage of Quinine in Citrate Precipitate.	Quinine calculated from $C_{20}H_{24}N_2O_2.C_6H_8O_7$.	Difference.
Grm.	Grm.		Grm.	Grm.
0·0508	0·0812	62·56	0·0509	+0·0001
0·1069	0·1688	63·32	0·1059	−0·0010
0·1366	0·2144	63·75	0·1346	−0·0020
0·1554	0·2476	62·76	0·1555	+0·0001
0·1758	0·2809	62·58	0·1763	+0·0005
0·2100	0·3394	61·87	0·2131	+0·0031
0·2808	0·4398	63·84	0·2761	−0·0047

The theoretical quinine content of the acid citrate $C_{20}H_{24}N_2O_2.C_6H_8O_7$ is 62·79 per cent. Our average figure is 62·95 per cent., and, considering the small quantities of quinine used, the greatest deviations from this average figure are well within the limits of experimental error. The corresponding figure obtained by Nishi was 62·57 per cent. The general characteristics of the acid citrate were given by Nishi, and our results are in perfect agreement with his. The compound is almost completely insoluble in ether, slightly more soluble in cold water and in alcohol, whilst in hot water it readily dissolves. The process as detailed by Nishi proved cumbersome, as part of the precipitate adheres firmly to the sides of the flask in which the quinine is precipitated, necessitating the weighing of this flask, as well as the Gooch crucible containing the major portion of the precipitate.

---

* This work was carried out in accordance with the terms of the "Analytical Investigation Scheme."

We modified the method of collecting the precipitate, whereby the process is simplified, and yields excellent results. The details of the method as simplified by us are as follows: 250 c.c. of the urine are made strongly alkaline with strong sodium hydroxide, warmed and extracted in a separator with ether, the extraction being repeated three times. We found it necessary, in order to lessen the tendency to emulsify, that each extraction should proceed at as high a temperature as is consistent with safety, and that the urine should be strongly alkaline. The ether extracts are collected, washed with small quantities of water, placed in a flask, and the ether evaporated. The residue, consisting of quinine admixed with various impurities, is dried in the water-bath. It is then dissolved in 20 c.c. of anhydrous ether, filtered into a weighed 4-ounce Erlenmeyer flask, the filter-paper and flask being washed with small quantities of ether. With the flask is weighed a filtering-tube, consisting of a small thistle funnel, the bulb of which (diameter 10 mm.) is packed with dry asbestos, the whole being dried in the water-bath. To the filtered ethereal solution is then added 10 c.c. of a saturated ethereal solution of citric acid, and allowed to stand for twenty-four hours. The supernatant liquid is then drawn off through the filter-tube, by means of the usual aspirating apparatus. The precipitated quinine acid citrate, which is usually quite white and free from impurities, is washed three times with 10 c.c. of ether (sp. gr. 0·720) the supernatant ether being drawn off as before. The filter-tube is now placed in the Erlenmeyer flask, the whole dried first at a gentle heat to prevent spirting, and then at 100° C. till constant, and weighed as $C_{20}H_{24}N_2O_2.C_6H_8O_7$.

Known quantities of pure dry quinine were added to urine, and the following results were obtained, using the above method:

Pure Quinine taken.	Quinine Acid Citrate found.	Quinine found.	Difference.
Grm.	Grm.	Grm.	Grm.
0·0306	0·0467	0·0293	−0·0013
0·0499	0·0850	0·0533	+0·0034
0·0682	0·1106	0·0694	+0·0012
0·1000	0·1594	0·1000	±0·0000
0·1093	0·1766	0·1108	+0·0015
0·1406	0·2226	0·1397	−0·0009

The saturated ethereal solution of citric acid is prepared by dissolving citric acid, previously dried *in vacuo*, in anhydrous ether. Care should be taken that the precipitate be not allowed to remain unduly long in contact with the precipitating solution, as thereby high results are obtained; whilst if the ether is not anhydrous, or if the washing of the precipitate with ether is prolonged, the results are too low.

The melting-point of the acid citrate recovered from urine we found to be

194° C., whilst the average of several nitrogen determinations (Kjeldahl) was 5·49 per cent., theory requiring 5·42 per cent.

We applied the method to the estimation of quinine in citrate of iron and quinine, prepared in accordance with British Pharmacopœia requirements, with the following results:

Quinine by Extraction.	Quinine calculated from Acid Citrate.	Difference.
Per Cent.	Per Cent.	Per Cent.
14·47	14·45	- 0·02
14·15	14·07	- 0·08

The process may be employed for the estimation of quinine in the presence of caffeine, but does not afford a means of separation of the common cinchona alkaloids, since all these give a precipitate with an ethereal solution of citric acid.

THE ASSAY OF WOLFRAM CONCENTRATE.

By H. W. HUTCHIN.

WOLFRAM is bought and sold on the unit system, taking tungstic oxide as the basis. The average price per unit during the last five years has been 34s. 6d.; the buyers require a minimum of 60 units, although poorer material may be sold, but at a lower price per unit. The necessity for an accurate method of assay of such a valuable product is obvious. As no reliable volumetric method for the estimation of tungstic acid is known, the determination is in all methods made by weighing pure tungstic oxide. Tungstic oxide results from the ignition of either ammonium tungstate, basic mercurous tungstate, or certain organic salts. All three reactions are used in assays. The use of organic salts is so far restricted to the assay of tungsten in alloys, and does not come within the scope of the paper.

Finely powdered wolfram may be decomposed by boiling with strong hydrochloric acid or by boiling with caustic soda solution. With the acid treatment the tungstic acid is liberated and remains undissolved, but with the alkali it passes into solution as tungstate of soda. A preliminary ignition with lime, or calcium carbonate and salt, or calcium carbonate and ammonium chloride, renders wolfram more easily attacked by acids, but may under certain conditions be attended with undesirable complications. Wolfram fused with caustic alkalis or the alkaline carbonates is converted into tungstate of soda or potash, both readily soluble in water.

The use of acid allows of the final determination being made either by ignition of ammonium tungstate or basic mercurous tungstate, but use of alkali necessitates the adoption of the mercury method.

Such reactions are made use of in one or other of the four methods described hereafter, viz.:

1. " Aqua regia–ammonium tungstate " method.
2. " Aqua regia–mercurous nitrate " method.
3. " Soda digestion–mercurous nitrate " method.
4. " Soda fusion–mercurous nitrate " method.

1. "AQUA REGIA-AMMONIUM TUNGSTATE" METHOD, MORE COMMONLY KNOWN AS THE "AQUA REGIA" METHOD.

To 1 grm. of the finely powdered wolfram in an 8-ounce beaker add about 10 c.c. strong hydrochloric acid, and agitate carefully to prevent caking. Add more acid (about 120 c.c. in all), cover with a clock-glass, and boil briskly till the volume of acid is reduced to about 5 c.c. Allow to cool, add 5 c.c. strong nitric acid, and digest at nearly a boiling temperature for from five to ten minutes. Dilute with water to about 100 c.c., allow to settle, and filter through a 9-cm. filter, wash with water, working so as to obtain as little tungstic acid as possible on the filter. To the beaker add about 10 c.c. distilled water and 10 c.c. dilute ammonia (1 : 1), adding the latter in small quantities down the sides of the beaker. With a rubber-tipped rod remove any deposit from the sides of the beaker into the alkaline liquor, raise to the boil, and stir well (if the suspended matter does not readily subside, boil again until the desired result is attained). Allow to settle, and whilst still hot filter through the original paper into an 8-ounce flask. Wash the beaker two or three times with small quantities of distilled water, decanting each time from any heavy mineral should it be present. Complete the washing of the filter-paper, and reserve the cover-glass, filter-paper, and beaker. Evaporate the solution of ammonium tungstate in the flask to a small volume, transfer carefully to a weighed platinum dish, and continue the evaporation to dryness on a water-bath. Ignite the dish and contents gently at first, and more strongly afterwards. Weigh as tungstic acid.

To the beaker containing the heavy residues add 5 c.c. hydrochloric acid, cover with the original clock-glass, and boil till nearly dry; add a few c.c. of nitric acid, and heat again for ten minutes. Dilute with water, allow to stand till the deposit has subsided, filter though a small paper, and wash beaker and paper several times.

Wash the filter-paper, also the original filter-paper, with a little hot dilute caustic soda solution followed by small washes of distilled water, and collect the alkaline liquors and washings in a beaker. If the clock-glass is stained with tungstic acid, dissolve with a few drops of the soda solution and add to the contents of the beaker. Raise the contents of the beaker to boiling, add about 2 grms. ammonium nitrate, and stir well whilst boiling. Filter through one of the papers previously used, and wash a little. Nearly neutralise the filtrate with dilute nitric acid, add a few c.c. of mercurous nitrate solution, stir well, filter on a small ashless paper, wash, ignite, and weigh as tungstic acid. Add this weight to the weight of the tungstic acid in the platinum dish.

Remarks on the Method.—Fine grinding is essential to success. One grm. is a convenient quantity, but with experience 2·5 grms. may be taken without requiring any modification of the quantities given in the assay.

The complete decomposition with the boiling hydrochloric acid takes about one hour, but it is better to continue boiling if the volume of residual liquors is much more than 5 c.c. The addition of nitric acid, with further digestion, is a concession to custom, but it would seem from experiment that in some instances it is unnecessary; for instance, two samples of wolfram gave 71·57 and 75·6 per cent. respectively, using nitric acid, and 71·6 and 75·54 per cent. respectively, using no nitric acid. Departure from custom is not recommended without a more extended series of experiments. In filtering the acid liquors from the tungstic acid, etc., a special wash-water is unnecessary; with water only the filtrate and washings are free from dissolved tungstic acid. The instructions given for effecting the solution of the tungstic acid in ammonia are based on experience; turbid filtrates seldom occur, and the volume of solution for concentration is reduced to a minimum, thereby saving time without sacrificing accuracy. With a turbid filtrate it is better to continue the assay and determine the amount of impurity in the tungstic acid after weighing, as follows: Add sufficient distilled water to cover the tungstic acid in the platinum dish, and about 1 grm. of pure caustic soda. Digest on the water-bath for a few minutes, till all the tungstic acid has dissolved. Wash the contents of the dish into a suitable beaker, add 3 grms. of ammonium nitrate, boil, filter on a small ashless paper, wash, burn, and weigh. Deduct the weight from the original weight of tungstic acid.

The retreatment of the residues from the ammonium tungstate filtrate is the crucial point of the assay; without it concordant results are rare, the residues being seldom free from tungstic acid. Its presence may be due either to unattacked wolfram or to tungstic acid retained by the residues. The former is due to defective powdering, and may be controlled; with experience it is of infrequent occurrence. The retained tungstic acid does not appear to be within the control of the assayer, but proof of its presence is easy. Wolfram is not soluble in cold dilute caustic soda solution, whereas the retained tungstic acid is. Thus in ten recorded assays the quantity of tungstic acid (not including unattacked wolfram), expressed in percentage, extracted from the residues with cold dilute soda solution, was 0·05, nil, 0·55, 0·25, 0·7, 1·57, 1·1, 2·0, 1·1, 1·9, and 0·55 per cent., respectively.

Impurities frequently present in wolfram concentrates are silica and silicates, arsenic as mispickel, titanium, tantalum, niobium, and fluorine as fluorspar.

The presence of silicates and arsenates soluble in hydrochloric acid would give low results, some of the tungsten being dissolved and remaining soluble even in aqua regia. Fortunately such impurities seldom occur.

Arsenic as mispickel does not interfere with the assay; thus, a sample of nearly pure wolfram with no arsenic added gave 75·6 per cent., and with mispickel added, corresponding to 2·5 per cent. arsenic, assayed 75·65 per cent.

Titanium as ilmenite causes the retention of large amounts of tungstic acid in the residues when dissolving out with ammonia.

In an assay of alluvial wolfram concentrate, containing about 10 per cent. TIO_2

as ilmenite (see No. 5 in table), the amount retained by the residue and soluble in weak caustic soda solution was 3·6 per cent. The addition of 0·5 grm. of ilmenite to an assay of a clean wolfram concentrate caused a retention of 11 per cent. Tantalite and columbite do not affect the assay.

The difficulty experienced by some in the decomposition of wolfram has led to various methods being devised. All are somewhat similar in principle—viz., a preliminary ignition with some suitable material is given, the effect of which is to render the wolfram more easily attacked by acids. A brief account of some original work on these lines may be useful, if only to serve as a warning of the possible pitfalls attending the use of such methods.

One grm. of the wolfram is mixed with 0·6 to 0·7 grm. of ammonium chloride and 3·5 grms. of calcium carbonate; the mixture is heated in a platinum crucible (containing a layer of calcium carbonate at the bottom and top of the charge) for five minutes at a low heat, and then for five minutes at full bunsen heat. The fritted mass may be detached from the crucible when cold. It is sufficient then to boil with dilute or strong hydrochloric acid for a few minutes only, to effect complete decomposition. Unfortunately, the ease of attack is the only good feature of the method. Some of the bad points are—(1) The pronounced solubility of the tungsten in the acid liquors; (2) the presence of only small quantities of arsenic very much increases the solubility effect.

It is admissible as an alternative to determine the tungstic acid in the ammoniacal solution by the mercurous nitrate method. The author is indebted to Mr. J. J. Beringer for first acquaintance with the use of this method for the particular purpose.

The details as given below are based on experience.

II. "AQUA REGIA–MERCUROUS NITRATE" METHOD.

Proceed as described in the "aqua regia-ammonium tungstate" method to the sentence (p. 399) ending "wash with water, working so as to obtain as little tungstic acid on the paper as possible." To the beaker add about 15 c.c. distilled water and 5 c.c. of 10 per cent. caustic soda solution; cleanse the cover-glass with a few drops of very dilute solution, and wash into the beaker; run a few c.c. of dilute soda through the filter-paper, and wash with water, collecting filtrate and washings in beaker; rub down any deposit above the level of the liquid in the beaker with a rubber-tipped rod, raise to the boil, add 3 grms. ammonium nitrate, and continue to boil for a minute or so. Allow to settle; filter, and wash with weak ammonium nitrate solution, collecting filtrate and washings in a large-sized beaker. Dilute to about 200 c.c.; acidify with nitric acid first, then neutralise or make faintly alkaline with dilute ammonia. Add sufficient mercurous nitrate solution, and again neutralise with precipitated mercuric oxide; stir well; filter and wash by decantation; finally transfer all precipitate to the paper and complete the washing. Dry, burn, and weigh as tungstic acid. The residues should be again treated with acid, etc., for unattacked wolfram.

This is a useful alternative method to the ordinary aqua regia method, and gives results comparable with it (samples Nos. 1, 2, and 3, in the table). It is most advantageous for the assay of mixed tin-wolfram concentrates.

III. "SODA DIGESTION–MERCUROUS NITRATE" METHOD.

Digest 0·825 grm. of the finely powdered sample with 20 c.c. of a 25 per cent. solution of caustic soda in a porcelain basin on a water-bath for forty-five minutes; stir well at the commencement to prevent caking; dilute the extract with water, add a little sodium peroxide, transfer to a 250-c.c. flask, and dilute to 250 c.c. To 200 c.c. of a filtered portion (this will represent 0·5 grm. of the material) transferred to a large flask add nitric acid till acid, and then make alkaline with ammonia. Boil, filter, and wash into a suitable-sized beaker. Add to the filtrate containing the tungsten dilute nitric acid till faintly alkaline, then a solution of mercurous nitrate in slight excess; again neutralise with precipitated mercuric oxide; stir well; allow to subside, filter, and wash, first by decantation, and later when transferred to the paper. Dry, burn in platinum crucible, and weigh as tungstic acid. It is advisable to treat the tungstic acid with a little hydrofluoric acid, ignite, and again weigh. The loss, which is usually small and negligible, represents silica.

Fine grinding of the sample and thorough washing of the mercurous tungstate are both essential to good results. The method gives results comparable with the other methods (see Nos. 1, 4, 5, 7, 8, and 9, in the table).

Titanium as ilmenite, tantalite and arsenic as mispickel, and small quantities of arsenate, do not interfere. Large quantities need no consideration, since they do not occur in practice.

IV. "SODA FUSION–MERCUROUS NITRATE" METHOD.

Fuse 0·625 grm. of the finely powdered sample in a nickel dish with about 1 inch of stick soda and 3 grms. sodium peroxide, at first gently, then more strongly, until the fusion is complete. Pour the molten charge on to a clean sheet of nickel, and when cold transfer both dish and caustic mass to a beaker, and dissolve in water. If the solution is green, add a little peroxide of soda, transfer to a 250 c.c. flask, and make up to volume. Filter, and determine the tungsten in 200 c.c. as described in Method III.

Titanium, tantalum, and niobium, do not interfere. Arsenic, unless in excessive amount, is removed, or practically so, by the tin dissolved in the fusion to such an extent as to be too small to influence the assay.

In the table are set out assay results of a considerable number of samples, from which a comparison of the various methods may be made. It is impossible to make such a series of assays without developing a partiality for one or other method; of the four methods dealt with, the old aqua regia method (Method I.) has most to commend it. It gives comparable results on amounts varying from 1 to 2·5 grms., whereas the other methods are limited to quantities of about 0·5 grm. All four methods work well in the presence of scheelite.

Samples 9 to 28 inclusive are of interest, inasmuch as there are given both buyer's and seller's assays on a total quantity of about 250 tons, representing a transaction of considerably over £25,000. The buyer's average assay is 63·58 per cent., the seller's 63·56 per cent.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Solubility of Carbon Dioxide in Beer. A. Findlay and B. Shen. (*Proc. Chem. Soc.*, 1911, **27**, 189.)—Previous experiments on the absorption of carbon dioxide by beer (Lange and Schultze, *Zeitsch. fur das ges. Brauwesen*, 1879, **2**, 369) have been interpreted as showing that beer dissolves more carbon dioxide than the corresponding water-alcohol solution, and the supposed increase has been attributed to adsorption by the colloids in the beer (Emslander and Freundlich, *Zeitsch. physikal. Chem.*, 1904, **49**, 317). These conclusions are not, however, in harmony with experiments carried out by Findlay and Creighton (*J. Chem. Soc.*, 1910, **97**, 536), and the authors now show that carbon dioxide is, as a matter of fact, less soluble in beer than in the corresponding water-alcohol solution, and that the contrary conclusion reached by Langer and Schultze must be attributed to their having used beer supersaturated with carbon dioxide.

Detection of Adulteration of Butter by Ewer's Method. C. Amberger. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 598-606.)—Ewer's method (ANALYST, 1910, **35**, 353) is stated to be capable of detecting the presence of 10 per cent. of cocoanut oil in butter, but it is shown by the results of experiments carried out by the author that this claim only holds good in the case of normal butter. The results obtained, particularly the "difference figure," are influenced by the period of lactation, and butter prepared from the milk of a cow at the end of the lactation period yields a "difference figure" which would point to the presence of more than 10 per cent. of cocoanut oil; these butters yielded Reichert-Meissl values of from 18·15 to 21·7, and were otherwise abnormal from an analytical point of view. Ewer's "difference figure" is also affected when the animals are fed on cocoanut oil cakes or beetroots, and the method may therefore, in special cases, yield results on which erroneous conclusions may be based. W. P. S.

Estimation of Cantharidine in Tincture and Oil of Cantharides. R. Gaze. (*Apoth. Zeit.*, 1911, **26**, 332-333; through *Chem. Zentralbl.*, 1911, I., 1657-1658.)—The author has obtained good results by the following procedure in the case of tinctures: 50 grms. of tincture, 25 grms. of water, and 1 c.c. of sodium carbonate solution (1 : 2), are evaporated together on the water-bath to dryness. The residue is taken up with 10 c.c. of water, acidified with 2 c.c. of 25 per cent. hydrochloric acid, and shaken out with 10 c.c. of chloroform which have previously been used to rinse out the flask. The chloroform is evaporated, and the residue, after standing for twelve hours, is extracted with 10 c.c., and then four times successively with 5 c.c., of light petroleum spirit. The petroleum washings are passed through a filter, and the residue and the filter are subsequently washed with 10 c.c. of water containing a trace of ammonium carbonate, and finally with pure water; the filter and residue are dried at 50° C. The product is dissolved in acetone, the solution is passed through the filter, the solvent is evaporated, and the cantharidine is dried at a temperature below 100° C. The average yield from 100 grms. of tincture prepared from 10 grms. of cantharides is 0·0684 grm., whilst the 10 grms. of cantharides contain 0·1079 grm. For the estimation of cantharidine in *Oleum Cantharidum* 20 grms. of the oil are shaken with 40 grms. of benzene, 1 c.c. of 25 per cent. hydrochloric acid, and 10 c.c. of water. A further 20 c.c. of water are then added, and 5 c.c. of sodium carbonate solution (1 : 2), and the mixture is again shaken for two minutes. The alkaline liquid is separated, and the benzene solution is again shaken with 20 c.c. of water and 5 c.c. of sodium carbonate; lastly, it is washed with 25 c.c. of water. The alkaline solution is evaporated to dryness on the water-bath, the residue is taken up with water, the solution is filtered, acidified, and shaken out with chloroform, the extract being treated as above. Twenty grms. of the oil yielded 0·0194 grm. of cantharidine. J. F. B.

Identification of Cocaine and Substitutes. F. J. Seiter and F. Enger. (*Amer. J. Pharm.*, 1911, **83**, 195-201.)—Cocaine salts react, under certain conditions, with solutions of gold chloride, platinum chloride, chromic acid, and potassium permanganate, to form micro-crystalline precipitates of definite and characteristic forms. Chlorine-water also serves as a useful reagent in distinguishing between cocaine and its substitutes.

The results obtained are shown in the following table:

Reagent.	Cocaine.	α-Eucaine.	β-Eucaine.	Stovaine.	Holocaine.	Acoine.	Euphthalmine.
$AuCl_3$ – 1 per cent. solution.	Fern-like crystals.	Twig-like crystals.	Amorphous precipitate.	Branched crystals.	Amorphous precipitate.	Amorphous precipitate.	No precipitate.
$PtCl_4$ – 1 per cent. solution.	Feathery crystals.	Fine needles.	Leaves, cubes, and rosettes.	No precipitate.	Small stars.	Amorphous precipitate.	No precipitate.
$KMnO_4$ – 1 per cent. solution.	Violet-red squares; slow reduction.	No crystals; slow reduction.	No crystals; slow reduction.	No crystals; slow reduction.	No crystals; immediate reduction.	No crystals; immediate reduction.	No crystals; immediate reduction.
H_2CrO_4 – 5 per cent. solution.	Fine needles; no reduction.	No crystals; no reduction.	No crystals; no reduction.	No crystals; no reduction.	No crystals; no reduction.	No crystals; brown precipitate and solution.	No precipitate.
Chlorine-water.	No precipitate.	Milky turbidity.	Dense turbidity.	Light turbidity.	Yellow turbidity.	Maroon precipitate and claret solution.	No precipitate.

The alkaloid, isolated in the usual ways, is converted into the hydrochloride, and made up to a 2 per cent. solution. Half a c.c. of this is treated with 5 drops of permanganate solution, and the crystals examined under the microscope. Other common alkaloids and the cocaine substitutes immediately or slowly reduce the solution without formation of crystals (*cf.* Hankin, ANALYST, 1911, 2).

A 1 per cent. solution of the alkaloidal substance in quantities of 0·5 c.c. is used for the platinum chloride and chromic acid tests, and 0·5 per cent. solution for the gold chloride test. Two drops, 2 drops, and 3 drops of the respective reagents are used. The precipitate at first formed with chromic acid is redissolved in hydrochloric acid. A. R. T.

A Casein Product. R. Windisch. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 613-615.)—Analyses are given showing the composition of a casein or curd product which is obtained in Hungary as a by-product during the preparation of sour cream. After the cream has been allowed to undergo lactic fermentation, the layer of cream is removed, and the remainder of the liquid is heated until the curd has coagulated into lumps. The latter are then collected and subjected to gentle pressure, the resulting product being used as a food. Analyses of 123 samples of the substance yielded the following average results: Water, 70·05 per cent.; dry solids, 29·95 per cent.; and ash, 0·70 per cent. The quantity of fat present varied from 0·42 to 15·55 per cent. More than one-half of the samples contained less than 20 per cent. of fat, calculated on the dry substance, the lowest fat-content of the dry substance being 1·50 per cent., and the highest 42·80 per cent. W. P. S.

Colour Reactions of Edible Fats and Oils. H. Serger. (*Chem. Zeit.*, 1911, **35**, 581-582, 602-603, 610-612.)—The author has collated the various tests which have been proposed for the purpose of identifying certain oils by means of colour reactions. The tests described include Welman's reaction, Bellier's reaction, Serger's reaction, Kreis's reaction, Wiedmann's reaction, Halphen's reaction, Becchi's reaction, Baudouin's reaction, etc., together with the colorations produced by the oils when the latter are treated with concentrated acids and mixtures of the same. The oils and fats dealt with are cotton-seed oil, sesame oil, olive oil, linseed oil, poppy oil, arachis oil, rape oil, almond oil, peach-kernel oil, cacao butter, cocoanut oil, lard, and beef fat. W. P. S.

Oil from the Seeds of Xanthophyllum lanceolatum. C. Grimme. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 125-126.)—The seeds produced by *Xanthophyllum lanceolatum*, a tree belonging to the Polygalaceæ, yield a fat which is extensively used as food by the natives of Singapore. A sample of the seeds examined by the author yielded 39·17 per cent. of a fat with the following characteristics:

FAT.

Sp. Gr. at 50° C.	Melting-Point.	Solidification-Point.	$[N]_D$ 40° C.	Acid Value.	Saponification Value.	Iodine Value.	Hehner Value.	Glycerol.	Unsaponifiable Matter.
	° C.	° C.						Per Cent.	Per Cent.
0·9021	44·0	41·5	1·4549	52·06	189·5	38·9	95·85	6·41	1·37

FATTY ACIDS.

Melting-Point.	Solidification-Point.	$[N]_D$ 55° C.	Iodine Value.	Mean Molecular Weight.	Neutralisation Value.
° C.	° C.				
55	53·5	1·4424	38·2	268·3	207·2

The fat was not toxic, but the press-cake contained a poisonous saponin, which would render it unsuitable for a feeding-stuff. C. A. M.

Examination of Ether for Anæsthetic and Analytical Purposes. C. Baskerville and W. A. Hamor. (*J. Ind. Eng. Chem.*, 1911, **3**, 378-398.)—The authors have made trial of all the published tests, and as a result they have drawn up a scheme for the examination of ether with particular reference to the detection of avoidable impurities. The scheme includes twelve tests, of which the following, for the detection of peroxides, is new :

The reagent is a 10 per cent. solution of cadmium potassium iodide, which is preferred to potassium iodide because strong solutions of the latter decompose so readily in sunlight. Of this reagent, 2 c.c. is added to 10 c.c. of the ether to be tested, and the mixture is well shaken and allowed to stand for an hour. There should be no visible liberation of iodine within that time. The limit of sensibility of the test is about 0·0025 per cent. of hydrogen peroxide. G. C. J.

Influence of Certain Vegetable Proteins on Wheat Gluten. B. von Fenyvessy. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 658-662.)—Results of experiments are recorded regarding the effect of the addition of different vegetable proteins to wheat flour, the main object being to ascertain the influence of these substances on the physical properties of the gluten of the flour. The addition of wheat gliadin, in quantities varying from 5 to 20 per cent. of the weight of the flour, increased the weight and baking qualities of the gluten ; glutenin also increased the weight of the gluten, but diminished its baking quality. These experiments confirm the statement that the quality of a gluten depends on its composition. Gliadin prepared from rye flour acted in the same way as that obtained from wheat. The fact that rye flour itself does not yield a coherent cake of gluten is due, in the author's opinion, to the presence of substances other than glutenin in this flour. Hordein prepared from barley decreases the baking quality of wheat flour, whilst zëin obtained from maize has no appreciable effect. W. P. S.

Analytical Examination of Linseed Oil. H. R. Jensen. (*Pharm. J.*, 1911, **86**, 839-840.)—The author outlines the following scheme for the examination of linseed oils : Five grms. of oil are saponified for one hour with 6 per cent. alcoholic potash, and the unsaponifiable matter examined for rosin and mineral oils. The fatty acids are thrown out with hydrochloric acid (sp. gr. 1·05) and thoroughly extracted with ether ; the mixed ether extracts are washed with three quantities of 6 c.c. each of water, and the volume made up to 100 c.c. with anhydrous ether. A yield of fatty acids equal to about 93·6 per cent. of the weight of oil taken is generally obtained. To 25 c.c. of this ether extract, contained in a rubber-stoppered flask, are added 15 c.c. ether and 3 c.c. glacial acetic acid; the mixture is cooled in ice-water, and 0·5 to 0·8 c.c. of bromine added, in drops, till in excess. After standing for two to three hours at the same temperature, the precipitate is collected on two interleaved counterpoised filter-papers, the flask and precipitate being washed with six quantities of 8 c.c. each of cooled ether (sp. gr. 0·720), to remove free bromine and lower soluble compounds, then dried at 95° C. and weighed. Too high a melting-point, with yield too high in proportion to iodine value, suggests adulteration with fish oils; too low a yield, an admixture of vegetable and mineral oils. To obtain the actual weight of acids in the ether extract, 25 c.c. are rapidly evaporated in a beaker at 100° C., with the addition of 5·5 c.c. absolute alcohol, the lowest weight obtained being taken as the amount of fatty acids in solution. The melting-point and refractive index of this residue are determined. The ether solution may be used for determining the iodine value, 25 c.c. being diluted to 250 c.c. with any inert solvent, and 25 c.c. solution taken, using 20 c.c. Wijs or Hanŭs solution and 10 c.c. carbon tetrachloride, with two hours' contact. The ether present renders necessary a correction, a 5·6 per cent. reduction of the observed iodine value being made, or, better, avoided by the use of tetrachloride only. The same solution of fatty acids is employed for determining the neutralisation value. The Liebermann reaction cannot be generally applied to the detection of rosin and rosin oils in linseed oil, as the latter contain sitosterol, giving a bluish-violet colour, reddening on standing. The following figures were obtained by the above processes:

	Standard Limits for Linseed Oil.	Laboratory-pressed River Plate Oil, Settled and Filtered.	An Oil apparently Genuine.	An Admittedly Adulterated Oil (Small Quantity Fish Oil present).
Colour	—	pale	pale	medium
Sp. gr. at 15·5° C.	0·9305 to 0·937	0·9319	0·931	0·932

Ether-insoluble hexabromides from fatty acids, melting-point °C.	175 to 180	176 to 178·5	179 to 180	177 to 181·5

A. R. T.

Estimation of Glycyrrhizin and Sugars in Liquorice Powder and Extract. E. Eriksson. (*Arch. Pharm.*, 1911, **249**, 144-160.)—The method proposed is based on the fact that glycyrrhizin is decomposed by hydrolysis into one molecule of glycyrrhetic acid and two molecules of glycuronic acid, and since the latter reduces Fehling's solution, the glycyrrhizin, dextrose, and sucrose may be estimated at the same time. The solution of the liquorice powder is prepared by mixing 10 grms. with an equal quantity of glass powder and a little water in a mortar, and allowing it to stand for some hours, after which the mixture is treated with about 50 c.c. of water, containing three to four drops of alkali solution per 100 c.c. (to convert any free glycyrrhizic acid into its soluble alkali salt), and allowed to stand overnight. The liquid is then made to percolate slowly, its place being continually renewed by fresh alkaline water, until, after about 100 c.c. have been collected, the drops have no taste. The percolate is made up to 200 c.c., 40 c.c. mixed with an equal volume of 90 per cent. alcohol, and heated on the water-bath to precipitate mucilaginous substances, the alcohol evaporated as rapidly as possible, and the liquid filtered. The cold filtrate and washings are treated with 30 c.c. of Fehling's solution and allowed to stand in the cold for twelve to thirteen hours, after which the reduced cuprous oxide is collected, reduced to metallic copper, and the corresponding amount of dextrose calculated. The filtrate is next boiled for three minutes with 30 c.c. of Fehling's solution, then diluted with half its volume of water, and the cuprous oxide collected in an Allihn's tube, and weighed as metallic copper. The result gives the quantity of sugar (sucrose), estimated as hexose, which reduces Fehling's solution on boiling. The filtrate, which now contains only the glycyrrhizin, is treated little by little with 25 per cent. sulphuric acid until no further precipitation occurs. The precipitated glycyrrhizic acid is allowed to stand for two to three hours, then separated, washed carefully with 5 per cent. sulphuric acid, and converted into its potassium salt by treatment with 5 per cent. potassium hydroxide solution. The alkaline solution is filtered and boiled for fifteen hours with Fehling's solution under a reflux condenser. The amount of glycyrrhizic acid may then be calculated from the apparent amount of dextrose by means of the equation $360 : 896 = 50{\cdot}9 : x\ (= 1{\cdot}239)$.

A similar course is followed in the analysis of liquorice extract, and the glycyrrhizin may be estimated prior to the estimation of the dextrose and sucrose in other portions of the liquid. The following results were thus obtained in the analysis of commercial samples of the air-dried powders and extracts:

	Liquorice Powders.						Liquorice Extracts.						
	Italian.	Spanish "Tortosa."	Russian.	Russian.	Russian.	Fresh Root from Atri.	Cassano.	Parone Compagna.	S. Franca.	Corrigliano.	Barraco.	Atri.	Atri, prepared from Fresh Root.
Dextrose, per cent.	1·39—1·43	1·28	—	trace	3·80	—	6·30	3·79	2·70	7·82	15·20	5·90	4·50
Sucrose, per cent.	2·4 —2·57	3·20	6·48	6·50	6·25	2·60	11·80	4·52	8·17	9·06	11·90	12·48	13·60
Glycyrrhizin, per cent. ..	6·65—7·10	6·49	7·70	8·15	7·33	6·72	16·45	14·22	23·90	12·10	11·59	10·20	9·85

If the total amount of glycyrrhizin and sugars in the fresh root (9·12 per cent.) is compared with that in the extract made by the author from that root (27·95 per cent.), the proportion is approximately as 1 : 3. Hence it would seem that there must have been a transformation of some of these substances into one another in the concentration of the extract. C. A. M.

Analysis of Liquorice Juice. E. J. Parry. (*Chem. and Drug.*, 1911, 133; through *J. Soc. Chem. Ind.*, 1911, 30, 647.)—Since the publication of the papers of the author (*Chem. and Drug.*, January, 1910, p. 21), Eriksson (see preceding abstract), and Telle (*Ann. Falsif.*, 1911, 4, 3), a greater amount of reliable information in regard to the composition and analysis of liquorice juice is available than was the case before, and it should now be possible for a definite opinion to be expressed as to the purity of a given sample. The determinations recommended are: Moisture, mineral matter, glycyrrhizin, invert sugars, uninverted sugars, matter insoluble in water, matter insoluble in dilute ammonia, alcohol precipitate (see below); and microscopic examination of the matter insoluble in water and of that insoluble in ammonia. Adulteration of liquorice juice is practised to an enormous extent, and in France steps are being taken to establish standards of purity. The author suggests 9 per cent. of glycyrrhizin as a minimum for normally prepared edible liquorice juices; Spanish juices, which are much richer in glycyrrhizin, have too little "body" to be used alone. With regard to the sugars, the methods of Eriksson for the separate determination of invert sugars and sucrose are open to criticism; moreover, as liquorice root contains an enzyme, the relative proportions of inverted and uninverted sugars in the juice will vary greatly according to the method of preparation. The figures obtained by the author and by Eriksson indicate that a normal edible juice contains not more than 18 per cent. of total sugars. In order to distinguish between natural and added starch in liquorice juice, the sample should be powdered, extracted with water, and the residue extracted with 3 per cent. ammonia solution. The residue should not exceed 6 per cent., and should be compared microscopically with the starch present naturally in liquorice root. When alcohol is added to an aqueous extract of the juice until the alcohol concentration is 70 per cent., a precipitate is produced; according to Telle, this does not exceed 16·5 per cent. in the case of pure juices (except in some doubtful Levant and Spanish juices), whereas it is much higher in the presence of gum, gelatin, and commercial glucose containing dextrin.

Preparation of Madeira and its Composition. F. da Silva. (*Ann. Falsif.*, 1911, 4, 57-65.)—The author describes the usual process followed in the manufacture of Madeira, and gives the results of the analysis of a large number of samples. His general conclusions are as follows: The alcohol amounts on the average to 20 per cent., with a maximum of 23·30 and a minimum of 16·60 per cent. The extract shows an average of 78 grms., with a maximum of 185 and a minimum of 31·6; after deducting the unfermented or added reducing sugars, it averages 30 grms., with a maximum of 82 and a minimum of 12·7 grms. The proportion of tannin estimated by the zinc acetate method is only small—the maximum is 1·05, the minimum 0·07, mean 0·15. The total acidity is generally high, averaging 5 grms. per litre. The sum of the alcohol and acid shows an average of 25, maximum 29, minimum 20; these values are only quoted incidentally, and cannot be compared with those found for ordinary wines. Madeiras are not "dry," but contain a more or less considerable quantity of uninverted sugar. Tannin is present in all Madeiras, the Verdelho wine generally containing more than the Serical wine. J. F. B.

Higher Alcohols occurring in Jamaica Rum. T. von Fellenberg. (*Mitt. Lebensmittelunters. u. Hyg.*, 1911, **1**, 352-357.)—The higher alcohols of Jamaica rum consist chiefly of normal butyl alcohol; small quantities of propyl alcohol are also present, together with traces of isobutyl and amyl alcohols.

Green Colour of Rapeseed Cakes. L. Bussard. (*Ann. Falsif.*, 1911, **4**, 75-77.)—Indian rapeseed cakes are frequently treated with from 0·75 to 1 per cent. of sodium carbonate in order to give them the green colour shown by the European product.

Estimation of Salicylic Acid in Fruit Juices. P. Vierhout. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 664-666.)—The following procedure is recommended for the estimation of salicylic acid in fruit juices, the main feature of the process being the prevention of a persistent emulsion when the juice is shaken with the solvent. For this purpose a considerable quantity of alcohol is added in order to precipitate the pectinous substances present, and the salicylic acid is extracted by means of petroleum spirit, the author having proved that this solvent readily extracts salicylic acid from a dilute alcoholic solution. Fifty c.c. of the juice are acidified with 15 drops of concentrated sulphuric acid, and shaken with 50 c.c. of petroleum spirit (b.p., 50° C.); 25 c.c. of 96 per cent. alcohol are then added, the mixture is again shaken, and, when separation has taken place, the petroleum spirit layer is siphoned off into a graduated cylinder. The alcoholic portion is once more shaken with 50 c.c. of petroleum spirit, after the addition of a further quantity of 25 c.c. of alcohol, and the whole mixture is transferred to the measuring cylinder, the contents of which are diluted with a mixture of 5 parts of petroleum spirit and 2·5 parts of alcohol to a volume of 200 c.c. After shaking, 50 c.c. of the petroleum spirit (equal to 12·5 c.c. of the juice) are transferred to a small corked flask containing a few grms. of anhydrous sodium sulphate. At the end of two hours the solution is filtered through a dry filter into a flask containing 50 c.c. of $\frac{N}{10}$ sodium hydroxide solution, the flask and the sodium sulphate are rinsed with the alcohol-petroleum spirit mixture, and, after the petroleum spirit has been evaporated from the alkaline filtrate, the excess of sodium hydroxide is titrated. A simple calculation then gives the quantity of salicylic acid present. W. P. S.

Tobacco Extracts and their Value. J. Schröder. (*Zeitsch. anal. Chim.*, 1911, **50**, 433-435.)—Large quantities of tobacco-juice are imported into South America to combat sheep-scab and ticks, the chief exporting countries being

Austria, Italy, and the United States. The author considers that payment for this product should be based on the unit of nicotine. At present the price is never less than forty nor more than fifty centésimos per kilo, but the product may contain anything from 1·5 to 11 per cent. of nicotine. The author estimates nicotine in extracts as follows: The extract (10 grms.) is mixed with so much dry sand that a dry powder results. This is slightly moistened with alcoholic potash, placed in a thimble, and extracted with ether for five hours. The extract is cautiously evaporated to two-thirds its bulk on the water-bath, and to the residue 200 c.c. of 1 per cent. aqueous caustic soda are added, and the mixture distilled in a current of steam until the distillate amounts to 500 c.c., the residue in the flask at the end of the operation being 60 to 80 c.c. The nicotine in the distillate is then estimated by titration with $\frac{N}{10}$ sulphuric acid. G. C. J.

Estimation of Tannin in Wines. P. Malvezin. (*Bull. Soc. Chim.*, 1911, 9, 620-621.)—Ten c.c. of the wine are boiled for five minutes with 10 c.c. of a solution of zinc acetate, the mixture then cooled, and treated with 25 c.c. of boiling water, and the precipitate collected and washed with about 100 c.c. of boiling water. The zinc acetate solution is prepared by dissolving 10 grms. of precipitated zinc oxide in the requisite quantity of acetic acid, adding 80 c.c. of ammonia solution, and diluting the liquid to a litre. The precipitate obtained with this reagent is dissolved off the filter by means of dilute sulphuric acid (2·5 c.c. of acid to 100 c.c. of water), the filter-paper washed with 20 c.c. of water, the solution and washings heated to 60° to 70° C., and titrated with $\frac{N}{10}$ potassium permanganate solution, which is added 5 drops at a time until the coloration persists for two minutes and the liquid has a turbid appearance in transmitted light. The number of c.c. used, multiplied by 0·116, gives the amount of gallotannic acid in grms. per litre. The method is stated to give very accurate results. C. A. M.

Detection of Tannin in Solution. G. Grasser. (*Collegium*, 1911, 46-52.)—A method of detecting tannin is based upon the fact that it absorbs iodine, and that the latter will therefore give no coloration with starch until present in excess. Thus, on treating a solution of tannin with a few drops of a dilute solution of iodine and adding starch solution, the presence of the tannin is indicated by the absence of the usual coloration. Only in the case of pine-bark was any coloration that would mask this test observed. Comparative tests with different reagents applied to solutions of gallotannic acid, mangrove infusion, and tannin solution containing much non-tannin substance, showed that in each case $\frac{N}{50}$ iodine solution was the most sensitive, being capable of detecting 0·0001 per cent. of gallotannic acid, 0·01 per cent. of tannin in mangrove infusion, and 0·0034 per cent. of tannin in the liquor rich in non-tannin substances. Zinc acetate in ammoniacal solution detected 0·0005 per cent. of gallotannic acid, but is less reliable than iodine, owing to the fact that it probably precipitates substances other than tannin. The best results were obtained with a solution containing 1 per cent. of gelatin and 10 per cent. of sodium chloride, and in the author's opinion this is the most reliable reagent. Other reagents tried (5 per cent. solutions of tartar emetic with and without the addition of other salts) were less sensitive. Experiments showed that the various tannins do not precipitate one another. C. A. M.

Detection of Turpentine Adulteration. (*U.S. Department of Agriculture, Bureau of Chemistry Bulletin*—Oil, Paint, and Drug Report, April 17, 1911.)—The following are suggested as specifications for three standard grades of turpentine: Standard or No. 1 turpentine should have a sp. gr. at 20° C. of from 0·862 to 0·870; $[\mathrm{N}]_{\mathrm{D}20^\circ\mathrm{C.}}$ 14·68 to 1·476; 95 per cent. should distil below 170° C., and a layer of not less than 200 mm. should be required to equal in colour the Lovibond yellow glass No. 1. On polymerisation with 38 N sulphuric acid the residue should not exceed 1 per cent., should be reddish in colour and viscous, and its $[\mathrm{N}]_{\mathrm{D}20^\circ\mathrm{C.}}$ should be from 1·500 to 1·520. An unadulterated turpentine which does not agree with these requirements may properly be regarded as not of standard or No. 1 quality.

Second quality or No. 2 turpentine should have a sp. gr. at 20° C. of from 0·862 to 0·875; $[\mathrm{N}]_{\mathrm{D}20^\circ\mathrm{C.}}$ 1·468 to 1·480; 90 per cent. should distil below 170° C., and a depth of not less than 100 mm. should be required to equal the Lovibond yellow glass No. 1. The polymerisation residue must not exceed 1 per cent., and must have $[\mathrm{N}]_{\mathrm{D}20^\circ\mathrm{C.}}$ of not less than 1·50.

Third quality or No. 3 turpentine should have a sp. gr. at 20° C. of from 0·865 to 0·880; $[\mathrm{N}]_{\mathrm{D}20^\circ\mathrm{C.}}$ 1·468 to 1·485; 60 per cent. should distil below 170° C., and a depth of not less than 50 mm. should be required to equal the Lovibond yellow glass No. 1. The polymerisation residue must not exceed 1 per cent., and must have $[\mathrm{N}]_{\mathrm{D}20^\circ\mathrm{C.}}$ of not less than 1·500.

The following are the tests for adulteration:

"Straight" wood turpentines are readily distinguished from gum turpentines by their odour, or when they have been very carefully refined, by the odour of the first fraction or of the residue from fractional distillation. One or both of these portions have the peculiar "sawmill smell," and the residue has a camphoric and somewhat nauseating odour characteristic of wood turpentine, which is quite different from the mild, sweet fragrance of gum turpentine.

Destructively distilled wood turpentine and also rosin spirits are more readily distinguished from gum spirits by their odour than is wood turpentine prepared by steam distillation, and they also give distinguishing colour reactions when mixed with sulphurous acid, as suggested by Herzfeld, or with hydrochloric acid (the presence of tin or zinc is not necessary), as suggested by Grimaldi. When steam-distilled wood turpentine has been carefully refined so that 90 to 95 per cent. of it distils at from 155° to 170° C., both of these colour tests are practically useless.

Turpentine adulterated with more than 10 to 20 per cent. of coal-tar oils, or of gasoline or kerosene which have not been deodorised, may usually be readily detected by the characteristic odour of the mixture. The odour of rosin spirits, while quite distinctive, is difficult to detect in mixtures with turpentine. The presence of petroleum oils is also indicated by bubbles, or "beads," persisting for a few moments on the surface of the turpentine shaken in a partly filled bottle.

The presence of more than about 10 per cent. of kerosene or similar mineral oils is readily detected by the spot which a few drops of the sample placed on white paper leaves on drying. Gasoline and other light mineral oils do not leave this spot.

It is possible so to adulterate turpentine that neither the sp. gr., refractive index, or flash-point, is materially altered. Such careful adulteration is rare, but as adulterants cannot invariably be detected by making these determinations, and, further, as mineral oil is the most probable adulterant, it is more rational to at once polymerise the suspected sample, note the volume, colour, and consistency of the unpolymerised residue, and determine its refractive index.

If rosin spirit is present in notable quantities, it may be detected by the amount of residue on polymerisation, in conjunction with lowered initial boiling-point and the deep coloration produced by mixing portions of the original turpentine of the first fraction with sulphurous acid and with hydrochloric acid.

If the initial distilling temperature of the turpentine is less than 154° C., and the original sample gives a reddish colour with sulphurous acid and a greenish-red with hydrochloric acid, and the residue from polymerisation is less than 5 per cent., it is probable that the sample is adulterated with rosin spirits. An odour of rosin spirits in the sample, or in any fraction, would be confirmatory, and all tests should be repeated on the first fraction obtained with a fractionating column. At best the detection of small amounts of rosin spirits is very difficult, and the procedure outlined may often fail to detect its presence.

The presence of marked quantities of coal-tar oils, benzol, toluol, and xylol, is detected by the odour, the lower initial distilling temperature—*i.e.*, between 80° and 155° C.—and by further examination of the first fractions which distil below 155° C. The rise of temperature on shaking during polymerisation is also indicative of the nature of the sample. Coal-tar and petroleum oils do not raise the temperature more than 35° or 40° C. when mixed with sulphuric acid. When the temperature of turpentine mixed with 38 N sulphuric acid does not rise above 50° or 60° C., mineral oil, coal-tar oil, or some other oil than turpentine, is present in large quantities. The older the sample of turpentine, the greater, or at least the more rapid, the rise of the temperature of the mixture.

Non-volatile oils are easily detected by a distillation test.

Estimation of Pyridine in Vinegar. H. Fincke. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 655-658.)—Vinegar manufactured from denatured brandy (which in Germany contains about 0·45 per cent. of pyridine) contains a certain quantity of pyridine, but this quantity is not always proportional to the amount contained in the spirit, as the latter may have been mixed with other alcoholic liquids before the acetic fermentation. In order to estimate pyridine in vinegar, the author recommends a method proposed by Houghton (ANALYST, 1910, **35**, 32), which allows pyridine to be estimated in the presence of ammonia. Five hundred c.c. of the vinegar are acidified with sulphuric acid, and evaporated to a volume of about 40 c.c.; the residual liquid is then transferred to a flask, rendered alkaline, and distilled, the distillate being collected in a receiver containing hydrochloric acid. The acid distillate is transferred to a flask, rendered alkaline, and treated with sodium hypobromite solution in excess in order to decompose the ammonia. The contents of the flask are next distilled and the distillate collected in a measured quantity of $\frac{N}{10}$ hydrochloric acid. When the distillation is completed, the excess of the acid is titrated, using methyl orange as indicator. As a control, the neutralised solution may be titrated with $\frac{N}{10}$ sodium hydroxide solution after the addition of phen[illegible]phthaleïn, the alkali thus used being equivalent to the quantity of pyridine present. The amount of acid used in the first titration should be equal to the amount of alkali employed in the second titration. It is shown that the method yields trustworthy results. W. P. S.

Turpentine Oil from India. (*Bull. Imp. Institute*, 1911, **9**, 8-10.)—The oils are stated to have been prepared from the oleo-resin of the "chir" pine (*Pinus longifolia*), and gave the following results on examination:

			Commercial Russian Oils.	
	A.	B.	(1)	(2)
Sp. gr. at 15° C.	0·871	0·868	0·866	0·884
Optical rotation in 100-mm. tube	-0·75°	-2·17°	+14·5°	+16·3°
Fraction boiling at (per cent. by volume):				
145° to 160° C.	—	—	4	2
160° „ 165° C.	—	—	12	16
165° C. or below	1	1	—	—
165° to 170° C.	54	55	43	36
170° „ 175° C.	25	28	20	18
175° 180° C.	12	9	11	7
180° 185° C.			3	4
185° 190° C.			2	2
190° 195° C.			—	—
Residue	7	6	—	—

The No. I. Russian oil was also found to contain some petroleum.

The figures show the Indian oils to resemble Russian turpentine oils more closely than American oil. The Indian oils are more constant in composition than the Russian oils, which they could replace commercially in the cheaper grades of varnish and for use in black lacquers and disinfectant preparations. A. R. T.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

New Indicator for the Estimation of "Titratable" Alkali in Blood. P. Bernhardt. (*Wien. klin. Wochensch.*, 1911, **24**, 606-607; through *Chem. Zentralbl.*, 1911, I., 1763.)—The indicator consists of 2 volumes of a 1 per cent. aqueous solution of alizarinsulphazide and 1 volume of a 1 per cent. aqueous solution of Grübler's indigocarmine; the mixture, when the reaction is neutral or acid, possesses an intense dark green colour, which changes to a reddish-violet when there is the slightest excess of alkali. The estimation of the alkali in blood is performed by Engel's method, using $\frac{N}{75}$ tartaric acid solution and a special alkalimeter. J. F. B.

Coagulating-Points of Egg Serum and Milk Albumins, and of Serum Globulin, in Ammonium Sulphate Solutions. K. Micko. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 646-654.)—The author has shown previously (ANALYST, 1911, 13) that meat and egg albumins coagulate at different temperatures, and now shows that the method described not only allows the various albumins to be distinguished from each other, but also aids in their identification. The coagulating-point is taken to be that point at which a finely-divided flocculent precipitate is formed, and the determination is made with a solution of the albumin one-half saturated with ammonium sulphate; in the case of globulin, which is precipitated by this concentration of ammonium sulphate, the solution must be one-quarter saturated with the salt. The following coagulating points are recorded: Egg albumin, 71° to 72° C.; milk albumin, 76° to 78° C.; serum albumin, 74° to 76° C. When the albumins have been once precipitated with ammonium sulphate in the cold, their coagulating points are affected; egg albumin thus treated coagulates, under the above conditions, at 68° to 71° C.; milk albumin, 46·5° to 56·5° C.; serum albumin, 71° to 73° C.; and globulin, 66·5° to 74° C. A second precipitation with ammonium sulphate does not materially affect the coagulating points. W. P. S.

Influence of Viscosity on the Action of Invertase according to the Concentration of Saccharose. P. Achalme and M. Bresson. (*Comptes rend.*, 1911, **152**, 1420-1422.)—Opinions have been divided as to the influence of the concentration of sugar on the velocity of the action of invertase. O'Sullivan and Thompson concluded that the action of invertase, other things being equal, is proportional to the quantity of sugar present in the liquid, and that it increases or decreases with it. Duclaux, on the other hand, held that a given quantity of invertase produces an effect which is always the same without regard to the quantity of sugar present, and that it acts as a constant force which in a given time can only effect a definite amount of work. Other authors have found that in dilute solutions the inverting action is practically proportional to the quantity of sugar, but that with stronger solutions, starting from $\frac{N}{20}$ or 1·71 per cent., the velocity of inversion appears to be independent of the concentration of the sugar; lastly, for concentrations of 35 per cent. and over, the speed of inversion decreases as the concentration of sugar is increased. The present authors have verified this and find an explanation in the variations of the viscosity of the sugar solution according to its concentration. If, instead of calculating the absolute quantity of sugar inverted in a given time, the time be calculated which is necessary for the inversion of a given proportion—say 25 per cent.—of the original quantity of sugar present, a curve is obtained which is nearly horizontal for low concentrations and nearly vertical for high concentrations of sugar. At the same time a curve illustrating the increase of viscosity with concentration of sugar is found to run practically parallel with this time curve, the viscosity increasing only slowly at low concentrations and very rapidly at high concentrations. If the absolute quantity of sugar inverted in a given time be considered, it will be seen that the retardation due to the increase in viscosity acts in opposition to the acceleration due to the increase in concentration. For low concentrations the retardation is small, and allows the influence of mass action to be perceived; at moderate concentrations the two opposing influences are balanced; whilst at high concentrations the retardation due to viscosity increases faster than the acceleration due to concentration and becomes predominant.

J. F. B.

Estimation of Fat in Pathological Urine. S. Kakiuchi. (*Biochem. Zeitsch.*, 1911, **32**, 137-144; through *Chem. Zentralbl.*, 1911, I., 1722.)—Fifty c.c. of urine are heated in a beaker of about 200 c.c. capacity, with 14 c.c. of sodium hydroxide solution (sp. gr. 1·5) on the boiling water-bath for two hours, the beaker being covered with a watch-glass. After cooling, the contents are placed in a separating funnel of 500 c.c. capacity, treated with 30 c.c. of concentrated hydrochloric acid, and cooled. The liquid is then shaken with 70 c.c. of ether; the ethereal extract is separated, and the treatment is repeated with a fresh quantity of ether. The residue, after evaporation of the ether, is dried for two hours at 50° C., and then dissolved in light petroleum spirit. After standing for an hour, the petroleum extract is filtered through a layer of asbestos and the petroleum is evaporated. The dish containing the extract-residue is heated in a vacuum apparatus for three hours under a pressure of 30 to 40 mm. at the temperature of the boiling water-bath, and is weighed, after drying in a vacuum desiccator. Under these conditions, normal urine yielded only 0·0003 grm. of residue, whilst in a sample of chyluric urine, 0·423 grm. of residue per 100 grms. of urine was obtained, having the properties of a fatty acid of high molecular weight. J. F. B.

Hippuric Acid as a Cause of the Failure of the Spectroscopic Test for Hæmoglobin in Urine. F. A. McDermott. (*J. Amer. Chem. Soc.*, 1911, **33**, 992-995.)—Solutions of hippuric acid of a concentration such as may occur in urine are distinctly acid to litmus, and have the power of destroying hæmoglobin, or at least of rendering it inactive spectroscopically. If 2 drops of blood be added to 25 c.c. of a saturated solution of hippuric acid—a very dilute solution owing to the low solubility—hæmoglobin cannot be detected spectroscopically after five minutes, at the end of which time the colour of the solution will have changed from the pinkish tint of a dilute blood-solution to that of a strong solution of ferric alum. Since sodium hydroxide destroys the spectrum of hæmoglobin almost as fast as strong acids do, whereas ammonia has no such action, it is suggested that any sample o urine which must be preserved for spectroscopic examination should be neutralised, or rendered slightly alkaline with ammonia, at the earliest possible moment.

G. C. J.

ORGANIC ANALYSIS.

Detection and Estimation of Small Quantities of Acetic Anhydride in Acetic Acid. M. G. Edwards and K. J. P. Orton. (*J. Chem. Soc.*, 1911, **99**, 1181-1185.)—The authors base a method upon the fact that 2-4-dichloroaniline reacts rapidly with acetic anhydride, but not with acetic acid, at the ordinary temperature with formation of an anilide, readily separable and convertible into a chloroamine, and the amount of which can be determined.

Two grms. or more of 2-4-dichloroaniline are added to 100 c.c. of the acetic acid to be examined, and the mixture kept at 16° C. in a water-bath overnight. The reaction is rapid, but considerable time is required for the last traces of anhydride to disappear. The whole is diluted with water to 20 per cent. acetic acid, and the solution extracted with chloroform, 10 c.c., 7 c.c., and 5 c.c., of solvent being successively used for each 100 c.c. of the liquid. The aqueous solution is finally washed twice with 1 c.c. of chloroform. The whole of the anilide, together with part of the aniline, is thus removed, and the unchanged aniline is extracted from the chloroform by shaking with 10 per cent. hydrochloric acid, 160 to 200 c.c. being used for each grm. of aniline added. The acid liquid is finally washed twice with 1 c.c. of chloroform. The mixed chloroform extracts are added to an equal volume of glacial acetic acid, and dilute bleaching-powder solution slowly added, the amount of bleaching-powder solution being three to five times that required to convert all the anilide into chloroamine, and in volume equal to the glacial acetic acid, which is then diluted to 50 per cent. strength. The reversible reaction—

$$\mathrm{Ar.NHAc + Cl_2 \rightleftharpoons ArNClAc + HCl}$$

is then nearly complete.

Sufficient $\frac{N}{20}$ bleaching-powder solution is now added to dilute the acetic acid to 20 per cent. Thus, if 30 c.c. of glacial acid were first added to the chloroform solution, then (1) 30 c.c. bleaching-powder, and (2) 90 c.c. $\frac{N}{20}$ bleaching-powder solution should be added. Any red colour here shows the incomplete removal of aniline. The chloroform is now shaken with 30 to 40 c.c. of $\frac{N}{20}$ bleaching-powder solution to free it from acetic acid, and the solvent evaporated in a current of dust-free air at a temperature not exceeding 25° C. The orange-yellow coloured residue is dissolved in 5 to 10 c.c. of chloroform and treated with 5 per cent. potassium iodide and a little acetic acid, and the freed iodine titrated with $\frac{N}{20}$ thiosulphate. The results are satisfactory. A. R. T.

Proportion of Asphalt insoluble in Alcohol-Ether in Mineral Lubricating Oils. H. Loebell. (*Petroleum*, 1911, 6, 774-775; through *Chem. Zentralbl.*, 1911, I., 1722-1723.)—For the lubricating value of mineral oils the percentage of asphalt is not by itself a sufficient measure, a determination of the consistence is also an important factor. The author recommends the following modification of Holde's alcohol-ether method, in order to obtain a more rapid drying of the oil and asphalt: About 5 grms. of the oil are dissolved in 140 c.c. of ether, and precipitated by 70 c.c. of alcohol; after standing for five hours at 15° C., the deposit is drained with gentle suction in a Gooch crucible, washed until free from oil, and the residue is dissolved in hot benzene. A piece of dry cotton-wool is steeped in the hot solution, the benzene is evaporated off, the remainder of the asphalt adhering to the walls of the vessel is wiped off with cotton-wool, and the whole of the cotton-wool is packed in a filtering thimble 6 to 8 cm. long and 3 to 4 cm. wide. The thimble is suspended from the cork of a flask of 300 c.c. capacity, containing 60 to 80 c.c. of absolute alcohol, and connected with a reflux condenser. The flask is immersed in a bath of boiling water to a short distance above the top of the thimble. After extraction with the alcohol for about two hours, the flask is exchanged for a similar one, containing 60 c.c. of benzene, and after boiling the latter for fifteen to thirty minutes the hot benzene solution is poured through a filter, which is then washed with benzene. The residue left on evaporation is free from oil and paraffin, and it is weighed after drying for a short time at 105° C. The percentage of asphalt found in this way is much lower than by Holde's method. Oils containing a high proportion of asphalt—say 2 to 4 or more per cent.—should be examined in this way; further, the consistence of the precipitated asphalt should be ascertained.

J. F. B.

Testing of Coal-Tar Creosote. C. E. Sage. (*J. Soc. Chem. Ind.*, 1911, **30**, 588-591.)—Coal-tar creosote should be "the product of the destructive distillation of bituminous coal, and free from admixture with other oils." The methods of sampling adopted are important. The bulk must be liquefied, and the sample (6 half-gallon quantities) removed from different parts of a tank, mixed, and filled into cans and sealed. Creosote in barrels can only be sampled with an iron, and uniformity is difficult to obtain.

Specific Gravity.—This is best observed at 60° C., 100 c.c. of the sample being weighed, and compared with water at the same temperature. *Expansion Coefficient.*—One hundred c.c. of the sample at 40° C. is warmed to 80° C. in a flask graduated from 100 c.c. to about 106 c.c. on the neck. The increase in volume should be recorded. This increase is on the average 1 per cent. for each 13·3° C. *Flash Point.*—This determination is made in the Pensky-Marten apparatus on a portion of the sample not previously heated. Oils usually flash at 186° to 190° C. *Fluidity.*—This consists in noting whether the creosote is fluid at 40° C., and by keeping 100 c.c. of the sample at 15° C. for six hours, and stirring occasionally after adding a crystal of naphthalene. The result is specified as "fluid," "quite solid," or "some salts deposited," etc., as the case may be. *Solubility in Benzene.*—Insoluble carbonaceous matter should not exceed 0·25 per cent. This is determined by filtering 100 grms. of the hot creosote through a tared paper, and washing the residue with benzene, when the residue is weighed after drying. *Viscosity.*—This test is of little or no value. *Distillation.*—Fractional distillation of creosote should be carried out in a specified apparatus. The author uses a hard glass retort of 8 ounces capacity (up to the bend), the thermometer bulb being immersed in the liquid, and less than ½ inch from the bottom of the retort. The retort should be asbestos-covered, and the thermometer should have a range of 190° to 360° C. The presence of water in creosote interferes with the fractionation, so that in the case of creosotes containing more than 1 per cent. of water it should be specified that it be first distilled to remove water, any oil simultaneously distilling being separated and returned to the bulk, and the distillation of the dry oil then proceeded with. All the fractions are measured at 60° C., to insure fluidity. The measurements usually recorded are: Distillate up to 210° C., between 210° to 235°, 235° to 270°, 270° to 315°, and undistilled residue over 315° C. The water is separately measured, solvent naphtha being added, if necessary, to the mixture of water and the first fraction distilled, in order to obtain a clear reading.

Naphthalene.—The distillate below 270° C. is cooled and filtered through filter-cloths and the residue pressed between blotting-paper. *Tar Acids.*—The fractions distilling up to 315° C. are shaken out with caustic soda solution (15 per cent.), and the alkali subsequently acidified, and the freed acids measured at 60° C. The results when the test is carried out on the original creosote are inaccurate. A more precise method of stating the amount of "tar-acids" is required. *Pyridine Bases* are determined in the fractions distilling below 315° C. They are important from the point of view of the value of these materials as the basis of sheep-dips and disinfectants. *Undistilled Residue.*—This should be examined for separated "pitchy" matter, as such separation is undesirable when the creosote is to be used for impregnating timber. *Sulphonation.*—English creosote does not naturally contain any considerable proportion of paraffins, or not more than about 0·5 per cent. Blast-furnace creosote (high-boiling fractions) contains about 5 or 6 per cent. The paraffins may be detected by determination of the refractive index of the sulphonation residue.

Paraffins have $[N]_{D 20^\circ C.}$ of about 1·45 to 1·50, blast-furnace creosote distillates range from 1·48 to 1·54, and coal-tar distillates from 1·57 to 1·63, or higher.

When distilled from an 8-ounce retort (covered), with the thermometer-bulb immersed in the liquid, pure coal-tar distillates will yield fractions above 300° C., having $[N]_{D 20^\circ C.}$ above 1·60. A. R. T.

Estimation of Camphor in Smokeless Powder. Marqueyrol. (*Ann. Chim. anal. appl.*, 1911, **16**, 209-210.)—The method is based upon the fact that if a solution of camphor in ether be evaporated over sulphuric acid in a desiccator, the loss in weight determined at regular intervals (*e.g.*, ten minutes), and a curve plotted in which the periods of time form the abscissæ and the corresponding weights the ordinates, a point is reached where the curve bends abruptly. This ordinate, OM, indicates the weight of camphor in the solution. In applying the method to smokeless powder 10 grms. of the finely divided sample are extracted for about ten hours with ether in a Soxhlet apparatus, and the solution allowed to evaporate in a basin (about 65 to 70 mm. in diameter and 35 to 40 mm. in depth) which is placed in a desiccator containing sulphuric acid. The ordinate $OM = p$, corresponding to the ethereal solution, is ascertained as described, and the basin then heated at 30° to 40° C. so as to expel the camphor completely. If the weight of the residue be represented by p^1, the weight of the camphor is represented by $p - p^1$. C. A. M.

Method for the Accurate Estimation of Traces of Water in Ether. D. Tyrer. (*Proc. Chem. Soc.*, 1911, **27**, 142-143.)—It is occasionally of importance to determine with accuracy the amount of water contained in a sample of "wet" ether. A method susceptible of a great degree of accuracy can be based on the fact that the addition of a little water to ether greatly increases its solvent power for some solutes. The most suitable substance which can be used as a solute is cadmium iodide. According to Eder (*Dingl. Polytech. J.*, 1876, **221**, 189), cadmium iodide is soluble in "absolute" ether to the extent of 28 per cent. Using a very dry sample of ether, it was found by the author, however, that cadmium iodide is practically insoluble in ether. It is to be presumed that the high value obtained by Eder was due to the ether he used containing water and alcohol. In the following table is given the solubility of cadmium iodide at 12° C. in pure ether and in ether containing various quantities of water. The ether used was Kahlbaum's pure material, prepared from ethyl alcohol, and thoroughly dried by twice distilling over phosphoric oxide:

Grms. of Water in 100 of Ether.	Grms. of CdI_2 per 100 of Solvent.	Grms. of Water in 100 of Ether.	Grms. of CdI_2 per 100 of Solvent.
0·0	0·143	0·90	6·46
0·10	0·78	1·00	7·30
0·30	2·07	1·10	8·27
0·50	3·36	1·14 {satu- rated}	8·68
0·70	4·77		

The above results were read from a smoothed curve of experimental values. On inspecting the table it will be seen that an addition of 0·1 per cent. of water to dry ether increases the solubility of the cadmium iodide by about 0·64 unit. Now, as the solublitity can be determined with ease to within an error less than 0·01 unit, the percentage amount of water in the ether can be found to less than 0·001 unit. This method of analysis might be extended to the determination of traces of water in the alcohols, it being only necessary to find a suitable solute and to obtain a perfectly anhydrous alcohol.

Estimation of Formaldehyde by the Ammonia Method. A. Beythien, H. Hempel, P. Simmich, W. Schwert, and C. Wiesemann. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 671-673.)—In the method of estimating formaldehyde by treating the latter with ammonia or with sodium hydroxide and ammonium chloride, and titrating the remaining alkali, the accuracy of the results obtained depends to a considerable extent on the indicator employed in the titration. Rosolic acid yields the most trustworthy results, cochineal and methyl-orange are less suitable, whilst litmus, phenolphthaleïn, and Congo-red are quite useless. W. P. S.

Estimation of Nitrogen in Liquids. D. Furnrohr. (*Wochensch. Brau.*, 1911, **28**, 257-258.)—For the estimation of nitrogen in beer worts it is often directed that a trace of yeast be added, the sugars fermented, and the liquid concentrated on the sand bath or open flame to a syrupy consistence. The addition of yeast is quite unnecessary, and of course inimical to the accuracy of the results. Evaporation over a flame is most objectionable, since it leads to caramelisation of the liquid and to erratic results, nitrogen being lost during evaporation. The author quotes analyses of the same wort, which show that evaporation of the wort at temperatures over 150° C. results in serious errors from the above cause. He has devised a constant-temperature bath which can be adjusted at 150° C., and which is capable of holding six Kjeldahl flasks, the contents of which may be left to evaporate without any danger of frothing over or loss of nitrogen by caramelisation. The mouth of each flask protrudes through the top of the bath, the rest being protected by a cylindrical screen in the body of the bath. J. F. B.

Characteristics of Different Varieties of Dammar Resin. C. Coffignier. (*Bull. Soc. Chim.*, 1911, 9, 549-561.)—The chief results obtained in the examination of different kinds of commercial dammar resin are summarised in the following table:

	Sp. Gr. at 18° C.	Melting-Point.	Acid Value.	Saponification Value.	Insoluble in—					
					Alcohol.	Ether.	Benzene.	Acetone.	Carbon Tetrachloride.	Amyl Acetate.
		°C.			Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Padang dammar (Sumatra)	1·036	95° (soft at 55°)	31·4	33·7	20·30	4·50	soluble	14·70	soluble	6·20
Borneo dammar ...	1·048	120° (soft at 70°)	35·1	64·5	23·60	9·60	7·50	20·40	8·40	10·10
Singapore dammar	1·057	95° (soft at 55°)	30·1	39·3	19·10	1·00	soluble	14·00	2·50	4·10
Pontianac dammar	1·025	110° (soft at 65°)	19·9	30·9	22·40	4·10	soluble	16·40	soluble	4·60

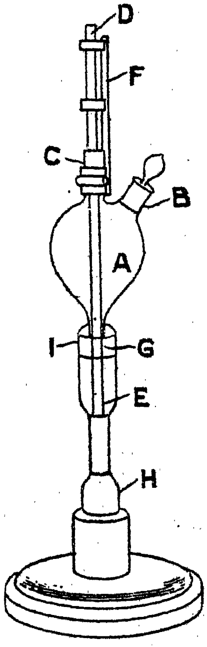
C. A. M.

Action of Permanganate on Organic Substances. J. Hetper. (*Zeitsch. anal. Chem.*, 1911, 50, 343-370.)—The author has studied the action of permanganate on nearly one hundred commonly occurring organic substances under the following conditions: Into a 200 c.c. flask 25 c.c. of a $\frac{N}{5}$ or $\frac{N}{2}$ permanganate solution (containing 20 to 40 grms. of phosphoric acid per litre) is introduced, and to this is added a measured quantity of a solution of the substance to be tested, preferably such a quantity as will reduce not much more than 10 c.c. of the permanganate. The volume of the mixture is made up to about 100 c.c. with water, and the flask placed on a vigorously boiling water-bath in a ring which is nearly as large as the maximum diameter of the flask. With volatile substances a reflux condenser is necessary. The heating is continued for one and a half to two hours, the contents of the flask being shaken every half-hour or so. At the end of this time the colour of the permanganate is discharged by addition of 25 c.c. of $\frac{N}{5}$ or $\frac{N}{2}$ oxalic acid solution (containing 50 grms. sulphuric acid per litre), and the excess of oxalic acid is then titrated with permanganate. Treated in this way a considerable number of important organic compounds decompose almost exactly the amount of permanganate which corresponds to oxidation to CO_2, H_2O (and NH_3). Ethyl alcohol is oxidised quantitatively to acetic acid, which is not further oxidised, and in general the methyl group when directly attached to another carbon atom resists oxidation, with the result that there is another large class of compounds which absorb almost exactly 4 atoms less oxygen per molecule than corresponds to complete oxidation to carbon dioxide and water. Among such compounds are lactic acid, toluidine, rosolic acid, and antipyrin. The resistance of the methyl group to oxidation is also shown by the behaviour of methyl alcohol, the oxidation of which is far from complete at the end of two hours, although formaldehyde and formic acid are rapidly oxidised to carbon dioxide and water. The author expressly disclaims any attempt to overestimate the importance of his work, but he points out that the analyst sometimes finds himself in possession of an aqueous solution which contains but one organic substance which reduces permanganate, and his tables show with what degree of exactness many such substances can be estimated. They also afford a means of establishing the purity or identity of some substances by the use of a very small quantity of material. G. C. J.

Proposed Uniform Method of carrying out comparative Tests for the Valuation of Raw Rubber. F. Frank. (*Gummi-Zeit.*, 1911, **25**, 990-992; through *J. Soc. Chem. Ind.*, 1911, **30**, 560.)—The proposals described were made to the German section of the International Rubber Testing Committee, and comprise viscosity determinations of solutions of the raw rubber, and vulcanisation tests. The apparatus described for the determination of viscosity consists of a pear-shaped glass vessel, A, with side tubulure, B (fitted with a ground-in stopper), and provided with an aluminium valve-rod, D, sliding through guides, and ground to fit the lower opening of the glass vessel, which ends in a metal tube, E, forming the outlet. The pear-shaped solution-holder, A, fits, by means of a ground-glass joint, G, into the top of the graduated receiver, H. The escape of air from this vessel while the solution is flowing into it is provided for by means of holes in the ground-glass joint at I. In carrying out the test, 200 to 500 grms. of the raw rubber are cut up, softened in hot water for thirty minutes, washed as rapidly and with as little working as possible on the rollers, run into a sheet "as thin as paper," and dried in a dark room without artificial heat. The washing process should not occupy more than twenty minutes. Any variations in details from the standard method must be carefully noted. The solution recommended is a 3 per cent. solution in commercial xylol of sp. gr. 0·867 to 0·869 at 15° C., 90 per cent. distilling between 135° and 140° C. The sample—9 to 15 grms. of dry rubber—is cut up fine, allowed to soak in about 100 c.c. of xylol for a short time, then stirred, and the final weight made up by the addition of more xylol, after which the solution



is agitated at intervals until homogeneous. This should not take more than thirty hours in all. For the preparation of the solution a dark glass jar of about 1 litre capacity, fitted with a metal screw-cap through which a stirrer passes, or simply a brown glass litre bottle, with glass stopper, may be used. The solution vessel should in either case be tared before use. Measurements are carried out at 20° C. The pear-shaped vessel is filled to the 200 c.c. mark, the valve-rod lifted, and the time taken for the solution to fill the receiver up to the 100 c.c. mark (in a footnote 200 c.c. is recommended) is accurately noted. A second determination should be carried out after the solution has stood in a dark place for eight to ten days. It is suggested that glycerol of sp. gr. 1·25 should be used to standardise the apparatus. For the vulcanisation tests the remainder of the rubber sample is mixed with eight or ten per cent. of sulphur and vulcanised in the form of a sheet 5 mm. thick, either always in the press or always in a vulcanising pan, for either one hour at 4 atmospheres, or one hour at 3 atmospheres. The vulcanised sheet is tested chemically for combined sulphur—difference between total and acetone-soluble sulphur—and mechanically, in the form of rings of 5 by 4 mm. section, punched or cut out from the sheet. The Schopper-Dalén apparatus is recommended for the mechanical tests by the members of the German section, but it is not desired to enforce the use of this apparatus.

Ceará Rubber. (*Bull. Imp. Institute*, 1911, **9**, 1-8.)—Specimens of Ceará rubber from various sources gave the following results on analysis:

A. R. T.

Effect of the Glycerol Method of Saponification upon the Fatty Acids. H. Mielck. (*Chem. Zeit.*, 1911, **35**, 668.)—A comparison of the values of the fatty acids obtained by Zoul's method of saponifying fats with the aid of glycerol (*Chem. Zeit.*, 1911, **35**, *Rep.*, 23) and by the ordinary method of saponification with alcoholic alkali, has shown that the former causes slight oxidation. Thus the iodine values (Wijs) of the fatty acids from bone fat ranged from 49·6 to 51·4 in the case of the glycerol method as against 54·7 to 54·9 in the case of the ordinary method. There were also marked differences in the solidification points. If a carbon tetrachloride solution of the fatty acids obtained by the glycerol method is allowed to stand for twelve hours, it yields a dark brown deposit. Hence in the author's opinion the method of saponification with alcoholic alkali ought to be used when a "titre" estimation of the fatty acids is required. C. A. M.

INORGANIC ANALYSIS.

Analysis of Aluminium and Aluminium Alloys. G. Kleist. (*Chem. Zeit.*, 1911, **35**, 668-669.)—Silicon is estimated as in Thorn-Smith's method (*Chem. Zeit.*, 1911, **35**, *Rep.* 188), but without the addition of sulphuric acid. For the estimation of iron from 2 to 5 grms. of the turnings are boiled with about 100 c.c. of dilute sodium hydroxide solution, the resulting solution rendered strongly acid with sulphuric acid (1 : 1) and filtered, and the filtrate diluted to about 600 c.c. and titrated with standard permanganate solution. Copper and tin are estimated together by precipitation with hydrogen sulphide in the filtrate from the silicon, and ignition of the precipitate in a porcelain crucible. If tin is present it is estimated as described below. The filtrate from the copper and tin is concentrated to about 100 c.c., and the iron precipitated by means of sodium hydroxide solution. In the presence of much iron (over 1 per cent.) the precipitate must be dissolved and the precipitation repeated. Traces of zinc are precipitated from the alkaline filtrate by means of hydrogen sulphide.

Aluminium alloys usually contain up to about 10 per cent. of copper, 6 per cent. of tin, and up to 10 per cent. (rarely up to 30 per cent.) of zinc, together with silicon and iron as impurities. The copper, zinc, silicon, and iron are estimated as in the case of pure aluminium. For the estimation of the tin from 1 to 2 grms. of turnings are treated with about 150 c.c. of hydrochloric acid (sp. gr. 1·19), and the flask immediately closed with a perforated rubber stopper, and heated until solution of the metal is complete. The boiling solution is then titrated with iron chloride solution, which has been standardised upon pure tin. The amount of tin thus found is calculated into tin oxide, and deducted from the weight of the combined copper and tin oxides previously estimated. Or the combined copper and tin precipitate may be treated with 2 c.c. of nitric acid (1 : 4), the liquid filtered from the tin oxide, and the filtrate treated with about 5 c.c. of sulphuric acid (1 : 1), diluted to about 120 c.c., and electrolysed at 60° to 70° C. The filtrate from the copper and tin is concentrated to about 100 c.c., rendered alkaline with ammonia, and treated with dilute sulphuric acid (1 : 1) until all aluminium hydroxide has dissolved, care being taken to avoid an excess of acid. The solution is diluted to about 400 to 500 c.c., and the zinc precipitated by means of a current of hydrogen sulphide. The precipitate is washed with water acidified with sulphuric acid and containing some hydrogen sulphide and ammonium sulphate, and then dissolved in hot dilute hydrochloric acid. The solution is rendered faintly alkaline with ammonia, boiled and filtered, and the filtrate slightly acidified with sulphuric acid and again treated as described.

C. A. M.

Separation of Aluminium from Beryllium. Wunder and N. Chéladzé. (*Ann. Chim. anal. appl.*, 1911, **16**, 205-209.)—Two methods, based upon the solubility of beryllium hydroxide in a concentrated solution of ammonium carbonate, are shown to give incorrect results. The following method is satisfactory, and may be used in the presence of iron, which is separated simultaneously with the beryllium. The mixed hydroxides are dissolved in hydrochloric acid, the solution evaporated to dryness in a platinum basin on the water-bath, and the residue taken up in the smallest possible quantity of water. A saturated solution of sodium or potassium hydroxide is now added drop by drop, with continual stirring, until the gelatinous mass first obtained is just redissolved. A large excess (400 c.c.) of water is then added, and the liquid boiled for an hour, the evaporated water being replaced from time to time. The precipitated beryllium hydroxide is collected, washed with boiling water, ignited, and weighed as beryllium oxide (BeO). The filtrate is acidified, and the aluminium precipitated with ammonia. The results in the test estimations quoted agree closely with the theoretical amounts. It is essential, however, to have sufficient sodium or potassium hydroxide to keep the whole of the aluminium in solution.

C. A. M.

Separation and Estimation of Barium in Presence of Calcium and Magnesium by the Action of Acetyl Chloride and Acetone on the Mixed Chlorides. F. A. Gooch and C. N. Boynton. (*Zeitsch. anorg. Chem.*, 1911, **70**, 400-407.)—The aqueous solution, containing about 0·1 grm. of barium chloride, is first concentrated to 3 c.c. or less; to this 30 c.c. of a mixture of acetyl chloride and acetone (1 : 4) is added at the rate of 2 drops a second, the mixture being kept cool in running water and well stirred. The separated barium chloride is filtered off on asbestos in a Gooch crucible, washed with acetone, and dried at 135° C., or ignited at a low red heat. Barium may be separated in this way from ten times its weight of calcium or magnesium, and estimated with an error not exceeding ±0·1 per cent. It is important that the mixture be kept cool during the addition of the acetyl chloride to the aqueous solution, and, consequently, the rate of this addition should not exceed that stated.

Strontium cannot be quantitatively separated from barium nor from calcium and magnesium by similar means.

G. C. J.

Phenomenon of Occlusion in Precipitates of Barium Sulphate, and its Relation to the Exact Determination of Sulphate. J. Johnston and L. H. Adams. (*J. Amer. Chem. Soc.*, 1911, **33**, 829-845.)—The investigation of Allen and Johnston (ANALYST, 1910, **35**, 331) has been continued, and on the knowledge gained attempts have been made to find a direct method for the determination of sulphate, which should be generally applicable, exact, and require only small and easily determined corrections. The belief is expressed that there is little chance of discovering any exact method which shall be generally applicable and require no corrections, and yet not owe its accuracy to a compensation of errors. Where, however, the composition of the solution is approximately known—a condition which frequently obtains in practice—the following calibration method will yield results accurate to 0·05 per cent.: To the solution (300 c.c. for a precipitate to weigh 2 grms.) 50 c.c. of concentrated hydrochloric acid is added, and the mixture heated to boiling. A 10 per cent. solution of barium chloride is then added at such a rate that about four minutes is required to run in the necessary 22 c.c. The mixture is evaporated to dryness on the water-bath, the residue taken up with hot water, and the barium sulphate filtered off, washed free from chloride, ignited carefully to avoid reduction, and heated to constant weight over a bunsen-burner. The necessary correction is determined by a concurrent calibration of the method—that is, by dissolving an equivalent weighed amount of pure sodium or potassium sulphate (dried for an hour at 200° C.) in a medium, such that the resulting solution is as nearly as may be of the same composition as the solution to be analysed, and determining the sulphate in this solution as already described. The difference between the calculated amount of barium sulphate and that actually found is the correction to be applied to the weight of the precipitate obtained in the actual analysis. The correction is usually small, and represents the balance of errors which are individually small under the conditions described. The use of a large quantity of acid reduces the occlusion of soluble sulphates by the precipitate, and gives to this a coarsely granular form, which facilitates all the subsequent operations, whilst very little barium sulphate passes into the filtrate, as the acid is almost wholly eliminated during the evaporation. G. C. J.

New Reaction of Bromine. G. Denigès. (*Bull. Soc. Chem.*, 1911, 9, 542-544.)—A delicate test for bromine is based upon the fact that it gives a purple coloration with the derivatives obtained by reducing strychnine with hydrogen. A suitable reagent may be prepared by mixing together 5 c.c. of a 1 per cent. aqueous solution of strychnine, 5 c.c. of hydrochloric acid (sp. gr. 1·18 to 1·19), and from 4 to 5 grms. of pure granulated zinc, heating the mixture to the boiling-point, then leaving it for five to ten minutes, at the ordinary temperature, cooling it in water and decanting the supernatant liquid. When 5 c.c. of an aqueous solution of bromine, containing not more than 1 grm. per litre, are shaken with 1 c.c. of this reagent, a purple coloration is soon developed, and the spectrum of the liquid shows a characteristic absorption band in the yellow. The test is capable of detecting 0·01 mgrm. per c.c. of solution, but in the case of such dilute solutions it is advantageous before adding the reagent to add to the liquid one drop of a 2 to 4 per cent. solution of potassium hydroxide, and to compare the tint with that given by a blank solution containing the same quantity of alkali and reagent in 5 c.c. of water. The reaction is quite distinct from that given by chlorine and other oxidising substances. Bromine may be detected in the atmosphere by passing a slow current of air through 5 c.c. of $\frac{N}{10}$

sodium or potassium hydroxide solution, and then adding 1 c.c. of the reagent. The analogous derivatives of brucine give an olive coloration, changing to yellow both with bromine and with chlorine. C. A. M.

Microscopical Examination and Identification of Carbon. G. A. Roush. (*J. Ind. Eng. Chem.*, 1911, **3**, 368-372.)—The author has applied the principles of metallography in the examination of carbon such as is used in the electrical industry. Since the orientation of the particles of carbon varies with the shape of the particles and with the shape of the die through which they are forced during manufacture into electrical carbons, at least three sections should be prepared from the block under test, and preferably these three sections should be perpendicular to the three principal axes of the block. The samples, after being removed from the block by means of a hack-saw, are first flattened by touching against an emery wheel or dressed with a file. The flat surface is then polished with No. 1 or No. 0 emery paper and this is followed by successive grades of Crocus paper from No. 0 to No. 0000. The polished surface is then either "heat-etched" or "relief-polished." Heat-etching is accomplished by raising to a red heat in the flame of a blast lamp, allowing the softer particles to oxidise in the open air until the gloss of the polished surface just disappears, and then cooling rapidly with the bellows. Relief-polishing is effected with chamois leather or cloth. It serves the same purpose as heat-etching in wearing away the softer constituents of the block and leaving the harder ones in relief. The samples are next mounted on microscope slides by means of sealing-wax, and examined by reflected light, under a magnification of 70 and of 200 diameters. Occasionally a higher magnification is useful, when a sample is found in which the raw materials have been ground very finely. The paper is accompanied by thirty microphotographs which show that petroleum coke, retort carbon, and natural graphite, can as a rule be readily distinguished, and that the proportions in which they occur in a mixture can be approximately determined. G. C. J.

Detection of Chromium in Steel. V. Stanck. (*Chem. Zeit.*, 1911, **35**, 308.)—The metal is dissolved in dilute sulphuric acid (1 : 5), the solution is boiled after the addition of ammonium persulphate, and the presence of chromium is then detected by shaking the solution with hydrogen peroxide and ether.

Estimation of Chromium in Chrome Ironstone. O. Nydegger. (*Zeitsch. angew. Chem.*, 1911, **24**, 1163-1164.)—The ore is opened up by means of a borax flux, which is prepared in advance in quantity to avoid risk of mechanical loss by evolution of carbon dioxide during the fusion. The flux is prepared by fusing together 2 parts of anhydrous sodium carbonate and 1 part of borax glass, and continuing to heat with the blowpipe flame until a tranquil fusion results. The cooled mass is coarsely powdered, and, since it is extremely hygroscopic, stored in air-tight vessels. Of this flux, 5 grms. is mixed with 0·5 grm. of the ore in a platinum crucible, which is lightly covered and heated in a powerful Bunsen flame until, on tilting the crucible, no particles can be seen at the bottom. A rotatory motion imparted to the crucible at frequent intervals hastens the process, which is usually complete in one to two hours. The cooled crucible is with its contents digested with 300 to 400 c.c. water containing 4 c.c. of sulphuric acid, and the crucible, when clean, removed from the beaker. A trace of chromic oxide, always present in the product of the fusion, is completely oxidised by boiling with 0·2 grm. of potassium persulphate, which also precipitates any manganese as peroxide. The boiling is continued for thirty to forty minutes to destroy the excess of persulphate, and the solution filtered from manganese peroxide. The chromic acid in the filtrate is then estimated by titration with a solution of ferrous ammonium sulphate standardised on pure potassium bichromate. The sulphuric acid solution of 5 grms. of the flux usually has a measurable oxidising action on a ferrous solution, and this should be determined once for all on each batch of flux prepared. G. C. J.

Analysis of Calcium Cyanamide. A. Monnier. (*Chem. Zeit.*, 1911, **35**, 601-602.)—Methods are given for the estimation of the cyanamide nitrogen and the total nitrogen in calcium cyanamide. In the case of the cyanamide nitrogen, the author finds that Caro's method (precipitation with silver nitrate in ammoniacal solution) yields low results, probably owing to the slight solubility of silver cyanamide in ammonia. He therefore proposes that 25 c.c. of a 1 per cent. solution of the calcium cyanamide be mixed with 10 c.c. of formic acid and evaporated almost to dryness; the residue is then dissolved in water, diluted to a volume of 25 c.c., and 10 c.c. of the solution are treated in a nitrometer with sodium hypobromite solution. The treatment with the formic acid results in the formation of urea according to the equation: $CN.NCa + H_2O + 2HCOOH = CO(NH_2)_2 + Ca(COOH)_2$, and the nitrogen liberated from the urea is a measure of the cyanamide nitrogen. As regards the estimation of the total nitrogen, it is stated that the ordinary Kjeldahl method yields 1 per cent. less nitrogen than is found when the digestion is carried out after the addition of salicylic acid and zinc dust, and the author concludes that this 1 per cent. of nitrogen is present in the form of a compound which has not yet been identified; this compound is converted by oxidising agents, such as hydrogen peroxide, into nitrites and nitrates.

A. Stutzer (*Chem. Zeit.*, 1911, **35**, 694), in commenting on the above paper, states that Caro's method yields correct results if the nitrogen be estimated in the silver precipitate; owing to the formation of double and basic compounds, the titration of the silver, as carried out by Monnier, does not accurately measure the amount of cyanamide nitrogen. He also states that he has always found the results obtained by the ordinary Kjeldahl method to agree with those yielded by the salicylic acid-zinc dust method. W. P. S.

Separation of Cerium by Potassium Permanganate. E. J. Roberts. (*Chem. News*, 1911, **103**, 303-304.)—One of the most useful methods for the separation of cerium from other rare-earth metals depends upon its oxidation by permanganate—

$$3Ce_2O_3 + 2KMnO_4 + H_2O = 6CeO_2 + 2KOH + 2MnO_2$$

—the reaction taking place in a cerous nitrate solution when sufficient alkali is present to combine with the nitric acid set free. The author has found the following to be the best mode of operating to insure efficient separation: The solution used for precipitation should contain the reagents in the proportion of 1 molecule of permanganate to 4 molecules of dry sodium carbonate in any convenient quantity of water. The solution of rare-earth nitrates, free from other acid radicles, is boiled and neutralised with sodium carbonate solution. Potassium permanganate solution is then added in small quantities till the red colour is just permanent, when the mixed permanganate and alkali solution is run in very slowly with constant stirring, the solution being kept near the boiling-point throughout the process. A faint permanganate colour is maintained, a little permanganate solution being run in, if necessary, from time to time. When the precipitation of the cerium is nearly complete, the colour of the solution is bleached more slowly after each addition of the precipitant, and the acidity of the liquid should be tested occasionally with litmus-paper, small quantities of alkali or mixed solution being added till the liquid is nearly neutral and still faintly coloured. The liquid is heated and stirred for ten minutes and filtered hot, and the precipitate washed with boiling water till the washings give no precipitate with ammonia. To insure complete removal of the cerium, the liquid must finally be made quite neutral, the filtrate then giving no test for this metal with hydrogen peroxide.

The test is made after boiling the filtrate with alcohol to remove permanganate. The precipitate of cerium and manganese hydroxides is dissolved in hydrochloric acid, the solution diluted, precipitated with oxalic acid, and the cerium oxalate reconverted to nitrate. On repeating the above process with this material, a pure cerium salt is obtained. The neodymium and praseodymium present in the cerium precipitate obtained after the first separation cannot be wholly removed by a nitric acid treatment of the precipitate. A. R. T.

Estimation of Manganese by the Bismuthate Method. W. F. Hillebrand and W. Blum. (*J. Ind. Eng. Chem.*, 1911, **3**, 374-376.)—It is pointed out that the theoretical factor for the ratio $Na_2C_2O_4 : 2Mn$ is 0·16397, not 0·16024, as stated by Brinton (ANALYST, 1911, 305). Brinton described experiments which led him to recommend the use of the empirical factor 0·1656 in calculating the manganese titer of permanganate. Brinton's reasoning is not vitiated by the above arithmetical error, and his results, so far as they go, do support the use of the factor recommended by him. But the authors describe experiments which support equally well the use of the theoretical factor, and they point out that Brinton's chain of reasoning assumes the accurate standardisation of his manganese sulphate solution, and an error of less than 1 per cent. in the figures supplied with samples by the Bureau of Standards, with which they are associated. Brinton's method of standardising his manganese sulphate solution would include as manganese any iron, calcium, or magnesium, and the authors disclaim a higher accuracy than 1 per cent. for the figures supplied by the Bureau of Standards, so far as these figures relate to iron with less than 1 per cent. of manganese. It is doubtful whether the manganese content of such material can yet be ascertained with a greater accuracy than 1 per cent., which is exactly the amount by which Brinton's factor differs from the true theoretical factor.

G. C. J.

Use of Ether in the Analysis of Metals. F. Mylius and C. Hüttner. (*Ber.*, 1911, **44**, 1315-1327.)—Rothe (*Mitt. d. Kgl. Techn. Versuchsaust.*, 1892, 132) has shown the use that can be made of ether in the analysis of steel; and more recently Mylius (Analyst, 1911, 303) has worked out a very exact method for the assay of gold bullion, in which ether is used to separate the greater part of the gold from the other metals. The present paper describes the behaviour of the chlorides of thirteen other metals when these are shaken with equal volumes of ether and of water or hydrochloric acid of varying strength. The figures in the table show the percentage of the metal which passes into the ethereal layer:

Metallic Chloride.	Water.	Hydrochloric Acid, Percentage of HCl—								
		0·18	1·0	2·5	5·0	7·5	10·0	12·5	15·0	20·0

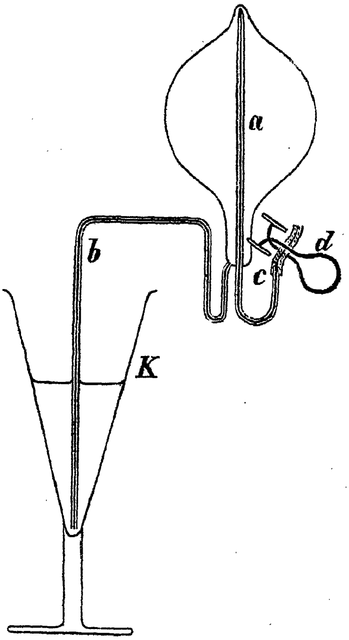
The solubility of arsenious chloride and antimonic chloride in ether is not sufficiently high to give the ether process any advantage over other methods for separating these metals. The table is, however, of value to the analyst using Rothe's method for iron, or that of Mylius for gold, as it shows what other metals may be expected to pass into the ether with the iron or gold. Since over 90 per cent. of any gold present passes into the ethereal layer, whether the hydrochloric concentration be 2 per cent. or 20 per cent., this concentration may in practice be so chosen as to keep back any particular impurity. In general it should be kept low, as the solubility in ether of most metallic chlorides is increased by the presence of much acid; but that of mercuric chloride is decreased, and that of antimonious chloride reaches a maximum with acid of 7·5 to 10 per cent. strength, and then falls again. Stannic chloride behaves like antimonious chloride, but the abnormality is less marked in this case.

G. C. J.

Volumetric Methods for the Estimation of Mercury depending on Reduction to Metal. F. Reinthaler. (*Chem. Zeit.*, 1911, **35**, 593-595.)—All the published methods covered by the title have been tried, and the following modifications of Feit's method (*Zeitsch. anal. Chem.*, 1889, **28**, 318) is recommended as surpassing any of them in accuracy. Like Feit's original method, it has the disadvantage that the mercury in the solution to be tested must all be in the mercuric state. To the mercuric solution, which should be nearly neutralised with caustic soda, $\frac{N}{10}$ sodium arsenite is added in quantity more than sufficient to reduce the whole of the mercury to the metallic state. A current of carbon dioxide is led into the flask by means of a tube which has a bulb blown on it, which serves to loosely stopper the flask and to keep the end of the tube just above the surface of the liquid. The flask and its contents are then heated on the water-bath for half an hour to one and a half hours, a gentle stream of carbon dioxide being continued all the time. When the reaction is complete, the precipitate should contain no large particles nor possess any green tinge, but should be a uniform dark grey "flowing" powder. The mixture is cooled, and the excess of arsenious acid titrated directly with $\frac{N}{10}$ iodine. Filtration is unnecessary, as the mercury is in globules of such a size that solution of mercury by iodine is so slow that no inaccuracy is involved by adding a distinct excess of iodine and titrating back with arsenite. This is one advantage of the method as compared with Feit's original method. The other is the increased accuracy, which is within 0·05 c.c. of the solutions used, and is attained at the expense of the small amount of trouble required to conduct the reaction in a non-oxidising atmosphere. The method is not as quick as that of Rupp (*Arch. Pharm.*, 1905, **243**, 300), and Rupp's method has the advantage that it is applicable to mixtures of mercuric and mercurous salts, which are first reduced to metal by some reducing agent without action on iodine in acid solution, the mercury being then dissolved in excess of $\frac{N}{10}$ iodine solution and the excess of iodine determined by means of thiosulphate. But, as originally described, Rupp's method does not yield results of the highest accuracy, and the modifications of it (for instance, that of Muller, *Bull. Soc. Chim.*, 1907, **1**, 1169) complicate it without notable improvement in the accuracy of the results. G. C. J.

Detection of Nitrates and Nitrites in Water. G. Denigès. (*Bull. Soc. Chim.*, 1911, **9**, 544-546.)—The hydro-strychnine reagent for bromine (see p. 427) may also be used for the detection of traces of nitrites and nitrates in water. On adding 0·5 c.c. to 10 c.c. of water containing nitrites, a rose-coloured tint is immediately developed; and if the amount of nitrous acid does not exceed 0·1 mgrm., a rapid colorimetric estimation may be made by comparison with standard samples. In the absence of nitrites, no coloration is produced by nitrates even when present in large quantity; but if the liquid be treated with half its volume of sulphuric acid (sp. gr. 1·84) free from nitrous products, a rose coloration develops on shaking. The reaction is capable of detecting 0·5 mgrm. of nitric acid per litre. In the presence of both nitrites and nitrates, the coloration will be intensified after the addition of the sulphuric acid. The nitrites may be eliminated by evaporating 10 c.c. of the water to dryness after the addition of 2 drops of ammonia solution and 3 to 4 drops of acetic acid. The residue when taken up with 10 c.c. of distilled water ought not to give any coloration with 0·5 c.c. of the reagent, but in the presence of nitrates should give a more or less intense red coloration. Chlorides do not interfere with the reaction. C. A. M.

Estimation of Nitric Oxide, and its Behaviour towards Water. L. Moser. (*Zeitsch. anal. Chem.*, 1911, **50**, 401-433.)—Nitric oxide cannot be preserved without change in contact with water; but if mercury be used as the retaining medium, the dry or moist gas can be preserved indefinitely. Nitric oxide is absorbed completely and quickly when shaken in a Hempel pipette with a saturated solution of ferrous sulphate made faintly acid with sulphuric acid; but the method fails in presence of nitrous oxide, on account of the high solubility of this gas in water, even when this is saturated with a salt such as ferrous sulphate. Previous saturation of the ferrous sulphate solution with nitrous oxide changes the large positive error to a small, but not insignificant, negative one; for the absorption of nitric oxide by the liquid reduces its capacity to hold nitrous oxide in solution, and this gas is set free, with the result that the nitric oxide may be underestimated by as much as 4 per cent. Divers' sodium sulphite method (*J. Chem. Soc.*, 1899, **75**, 82) possesses no advantage over the ferrous sulphate method, and the absorption is much slower. The gravimetric methods for the estimation of nitric oxide require such elaborate precautions to render them quantitative that they are rarely applicable. Among volumetric methods, that which makes use of permanganate has the advantage that this reagent is without action on nitrous oxide; but the apparatus recommended by Lunge (*Zeitsch. angew. Chem.*, 1890, **8**, 567), a train of bulbs, requires to have its air contents displaced by carbon dioxide, and this leads indirectly to errors which cannot be kept as low as 2 per cent. The author has devised the apparatus here illustrated, with which results are obtainable which are never more than 0·5 per cent. low. The apparatus consists of a glass bulb of 120 c.c. capacity, shaped like a glow-lamp, into which two capillary tubes are sealed, one of which, *a*, reaches nearly to the point of the bulb. The bulb is filled with the permanganate solution by charging the wineglass with 100 c.c. of $\frac{N}{10}$ permanganate and 40 c.c. 2N sulphuric acid, and applying suction at *c* by means of a water-pump. When the capillary *a* is filled with liquid up to the pinchcock, the latter is closed, and the gas burette containing the gas mixture is connected to *c* by the rubber connection. The pinchcock is opened and the gas driven over into the bulb, the pinchcock closed, and the bulb shaken whilst keeping the end of *b* sealed in the wineglass. Shaking is repeated after an interval of a few minutes, and when no further contraction takes place the permanganate is expelled from the apparatus and titrated. G. C. J.



Detection and Estimation of Nitric Acid and Nitrous Acid in Water. J. Tillmans and W. Sutthoff. (*Zeitsch. anal. Chem.*, 1911, **65**, 473-495.)—The authors give the conditions under which both nitric and nitrous acids may be detected and estimated by means of the diphenylamine reaction. Although this reaction is well known, it has been found to yield very uncertain results, principally owing to the fact that the water tested did not contain a sufficient quantity of chlorides, the presence of which is essential to the sensitiveness of the test. The concentration of the sulphuric acid employed is also of importance. Under the conditions given below, the method is stated to be capable of detecting the presence of as little as 0·1 mgrm. of nitric acid (N_2O_5) per litre; the blue coloration is fully developed in about one hour, and its intensity is exactly proportional to the amount of nitric acid present. The reagent is prepared as described previously by one of the authors (ANALYST, 1911, 67) for the detection of nitrates in milk. One c.c. of the water, to which 2 c.c. of saturated sodium chloride have been added per 100 c.c., is mixed with 4 c.c. of the reagent, the liquid being kept cool during the mixing, and after the lapse of one hour the blue coloration which develops is compared with that yielded by known quantities of nitric acid under similar conditions. If the water contains more than 2·5 mgrms. of nitric acid per litre, the blue coloration produced will be too deep for comparison, and the water must be diluted before being tested. For the detection of nitrous acid (nitrites) in water the reagent must be diluted, 200 c.c. of water being added to 500 c.c. of reagent. Five c.c. of the water are mixed with 5 c.c. of the diluted reagent, and if nitrous acid be present a blue coloration develops immediately. The presence of chlorides is not necessary, and consequently nitrous acid may thus be distinguished from nitric acid. The test is as sensitive for nitrous acid as for nitric acid, and the coloration in both cases is fairly stable. If the water under examination contains both nitrates and nitrites, the latter are estimated in a portion of the sample; the nitrites are then decomposed in another portion of the water, and the remaining nitrate is estimated. For the removal of the nitrites, 100 c.c. of the water may be mixed with 5 drops of dilute sulphuric acid and 0·2 grm. of urea, and allowed to stand for about sixteen hours; the nitrous acid is thus decomposed according to the equation:—

$$2HNO_2 + CO(NH_2)_2 = CO_2 + 2N_2 + 3H_2O$$

whilst the nitric acid is unaffected. For the same purpose 100 c.c. of the water may be evaporated to a volume of 25 c.c. after the addition of ammonium chloride; in this case the nitrous acid is decomposed according to the equation:—

$$NaNO_2 + NH_4Cl = NaCl + N_2 + 2H_2O.$$

W. P. S.

Estimation of Phosphoric Acid as Magnesium-Ammonium Phosphate. G. Jörgensen. (*Zeitsch. anal. Chem.*, 1911, **50**, 337-343).—The author defends his method (ANALYST, 1909, **34**, 392) against the criticisms of Bube (*Zeitsch. anal. Chem.*, 1910, **49**, 525).

G. C. J.

Application of the "Glow Reaction" to the Detection of the Platinum Metals. L. J. Curtman and P. Rothberg. (*J. Amer. Chem. Soc.*, 1911, **33**, 718-724.)—Platinum metals, especially when in a finely divided state as obtained by reduction of their salts, possess the property of condensing relatively large volumes of gases upon their surfaces at ordinary temperatures, and the reaction is frequently so energetic that the metallic "sponge" glows intensely. The authors have applied this "glow reaction" to the detection of these metals when a mixture of air and illuminating gas is passed over the finely divided metal.

The substance to be tested is brought into solution by the usual methods, and about 0·2 c.c. absorbed in a piece of thin asbestos-paper by alternately dipping the "paper" in the solution and heating till the required volume has been absorbed. The moist paper, held in tongs, is heated to redness in the Bunsen flame, removed from the source of heat, and while hot, but after the redness has ceased, it is brought into the stream of a mixture of illuminating gas and air from a Bunsen burner. If platinum is present, the asbestos will begin to glow. This glow must last for some time, and may be renewed, after dying out, by reheating the asbestos and again holding it in the gas. The asbestos-paper must be very thin (0·5 cm. × 3·0 cm. and 0·3 mm. thickness) and the burner arranged to supply a good mixture of gas and air, without too great pressure. If desired, the intensity of the glow may be increased by passing the gases through a warmed burner.

The test is sensitive to extremely small quantities of the metals, the limits found being: Platinum, 0·002 mgrm.; palladium, 0·0005 mgrm.; rhodium, 0·0009 mgrm.; and iridium, 0·005 mgrm. The presence of other substances does not, for practical purposes, interfere with the test, which may therefore be applied directly to a solution without preliminary treatment for the separation of other substances. Compounds which, however, leave a heavy residue on ignition (alkalis, etc.), impair the test to the extent that quantities of platinum near the limit will not glow in their presence.

The solution to be tested must, of course, be concentrated so that 0·2 c.c. will contain sufficient metal to give the test, and failure to obtain a glow-reaction shows that the metal is not present in the volume absorbed in an amount equal to that indicated as the limit for that metal. Osmium and ruthenium salts do not respond to the test. As a test for platinum the method is rapid and sensitive. A. R. T.

Sodium Thiosulphate as Standard in Alkalimetry. W. Feld. (*Zeitsch. angew. Chem.*, 1911, **29**, 1161-1163.)—When excess of mercuric chloride is added to a solution of thiosulphate, the latter is oxidised in accordance with the following equation: $Na_2S_2O_3 + 2HgCl_2 + H_2O = Hg_2Cl_2 + Na_2SO_4 + 2HCl + S$. It is suggested, therefore, that sodium thiosulphate, which is obtainable commercially in a state of great purity, affords one of the best available standards for controlling solutions intended for use in alkalimetry. In standardising $\frac{N}{10}$ alkali, about 0·5 grm. of crystallised thiosulphate ($Na_2S_2O_3.5H_2O$) is accurately weighed, dissolved in water, and the solution added to about 40 c.c. of a cold saturated solution of mercuric chloride. Excess of mercuric chloride is essential, as otherwise black mercuric sulphide separates. Five minutes is allowed for the reaction to complete itself, and then about 30 c.c. of 4N ammonium chloride is added to prevent the precipitation of yellow mercuric oxide by the caustic alkali which would mask the colour of the indicator. Methyl orange is added, and the titration with the caustic alkali proceeded with. The error of the method is ± 0·05 c.c. of $\frac{N}{10}$ alkali. G. C. J.

Estimation of Sulphides in Alkali-Metal Cyanides. E. C. Rossiter. (*J. Soc. Chem. Ind.*, 1911, **30**, 583-588.)—The author has experimentally examined three methods for the determination of sulphides in sodium and potassium cyanides —namely, the Ewan method (ANALYST, 1909, **34**, 117), the method of Williams (*J. Soc. Chem. Ind.*, 1906, **26**, 137), and the "mercury method," in which the sulphide is separated and weighed as mercuric sulphide, obtained by adding mercuric chloride to a solution of the sample, and warming till coagulation of the precipitate takes place. The last-named method is not accurate to more than about 0·005 per cent. As a result the author has devised a modified lead nitrate method, whereby the sulphide in cyanides can be determined to about 0·001 per cent., or one part in 100,000. The cyanide is first tested by the above-mentioned Ewan process, and from the result obtained the quantity of lead nitrate required to precipitate the sulphide in 100 grms. of the sample is calculated. This quantity of finely powdered lead nitrate (dried over sulphuric acid), plus 10 per cent. excess, is added to 100 grms. of the sample and 200 c.c. of air-free water. The mixture is stirred and slightly warmed till all cyanide is dissolved; a drop of standard sodium sulphide is then added to a little of the solution, withdrawn and first filtered, to determine the presence of an excess of lead. This excess of lead is then estimated by adding standard sodium sulphide solution till a small quantity of the solution after filtration shows no trace of lead on adding a drop of sulphide solution. If only 0·015 per cent. of sulphide is present in the sample, 150 or 200 grms. are taken for the determination. A. R. T.

Detection and Estimation of Thorium by Means of Iodic Acid. (Separation of Thorium from Scandium.) R. J. Meyer. (*Zeitsch. anorg. Chem.*, 1911, **71**, 65-69.)—The use of iodic acid in the quantitative separation of thorium from cerium has been described by Meyer and Speter (ANALYST, 1910, **35**, 281). In making use of the same reagent for the detection of traces of thorium in presence of much cerium the conditions of success are sufficient concentration of nitric acid (to retain the cerium in solution) and of iodate to decrease the solubility of the thorium iodate in the acid solution. To 2 c.c. of the solution to be tested, which must contain no free hydrochloric acid, there is added 5 c.c. of a solution (I.) made by dissolving 10 grms. potassium iodate in 100 c.c. dilute nitric acid (1 : 2). Under these conditions the precipitation of thorium is almost complete, but the precipitate may contain iodates of cerium and other earth metals, according to their concentration in the original solution. To the mixture in the test-tube, therefore, there is next added 10 c.c. of a weaker iodate solution (II.) made by dissolving 4 grms. potassium iodate in 500 c.c. dilute nitric acid (1 : 9). The mixture is heated to boiling, when the iodates of cerium, etc., dissolve, whilst that of thorium remains undissolved if the original 2 c.c. of solution taken for the test contained as much as 0·25 mgrm. of thorium. Zirconium is precipitated by iodic acid, but the iodate of zirconium can be distinguished from that of thorium by its solubility in oxalic acid. The precautions requisite in quantitative work, to overcome the tendency of cerous salts in nitric acid solution to become oxidised to the ceric state, are unnecessary, as such oxidation proceeds so slowly that its extent is negligible during the time occupied by a qualitative test. But since ceric iodate is difficultly soluble in nitric acid, the solution to be tested should first be boiled with sulphurous acid to reduce any ceric salts.

Separation of Thorium from Scandium.—Scandium iodate being soluble in nitric acid, the iodate method affords a means of separating scandium from thorium. The total earths from 3 to 4 grms. of mineral are separated by the oxalic acid method and weighed as oxides. The oxides are dissolved in hydrochloric acid, the solution evaporated to dryness, the residue taken up with water, and thorium and scandium precipitated in boiling solution by means of ammonium thiosulphate. The precipitate is redissolved in hydrochloric acid and reprecipitated with thiosulphate to eliminate completely the other cerium and yttrium earths. The thiosulphate precipitate is then decomposed by means of nitric acid, and the solution is filtered from the separated sulphur and evaporated to dryness. The residue is taken up with 5 c.c. of water and a few drops of nitric acid, and the thorium precipitated by addition of 5 to 10 c.c. of solution I. From 10 to 20 c.c. of solution II. are added, and the mixture digested for fifteen minutes at 60° to 80° C. The thorium iodate is filtered off, washed with solution II. and then transferred to a beaker by means of a wash-bottle jet. It is decomposed by boiling with ammonia and the thorium hydroxide is filtered off, washed free from iodate, dried, and weighed as ThO_2. In the filtrate from the thorium iodate the scandium is precipitated by means of ammonia, and finally weighed as Sc_2O_3. G. C. J.

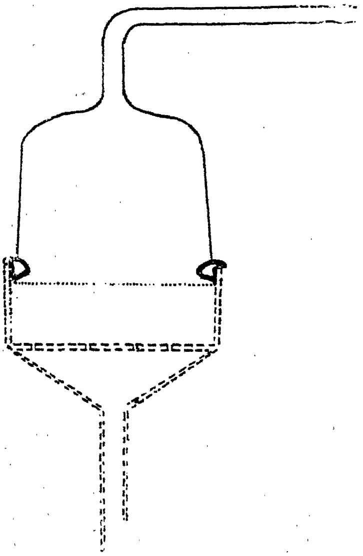
Analysis of Ferro-Vanadium and Estimation of Vanadium in Presence of Arsenic. W. Trautmann. (*Zeitsch. anal. Chem.*, 1911, **50**, 371-372.)—In presence of vanadic acid, arsenic acid is not reduced by sulphurous acid, and in hot strong sulphuric acid solution arsenious acid is instantly and quantitatively oxidised to arsenic acid by means of permanganate. The troublesome separation of arsenic preparatory to a vanadium titration is, therefore, unnecessary. The author fuses powdered ferro-vanadium with a mixture in equal proportions of sodium peroxide and carbonate, and extracts the melt with hot water and filters. The filter, with its contents, is dried, incinerated, and fused once more, and the product of the fusion extracted with water and the filtered solution added to the principal solution contained in a 2-litre flask. The solution is made strongly acid with sulphuric acid and heated to boiling, and a few drops of permanganate are added to oxidise any arsenic reduced by the hydrogen peroxide on acidifying. Reduction of the vanadium is effected by means of an aqueous solution of sulphurous acid, the excess of which is expelled by boiling whilst passing a current of carbon dioxide, and the vanadium is then titrated with permanganate as usual. G. C. J.

APPARATUS, ETC.

Some Forms of Glass Manometer. C. G. Jackson. (*J. Chem. Soc.*, 1911, **99**, 1066-1071.)—Three varieties of glass manometer, suitable for the measurement of pressures of vapours which attack mercury, or for measurements in which the experiment requires the manometer to be at a high temperature, are described and illustrated in the paper. The author has made use of one of these manometers in

studying the dissociation of cupric bromide, and the application of the manometer to such a purpose is explained, and the whole arrangement of apparatus is figured in the text.
G. C. J.

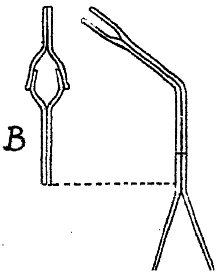
Addition to the Buchner Funnel. A. C. G. Egerton. (*Proc. Chem. Soc.*, 1911, **27**, 189-190.)—The apparatus consists simply of a small glass hood, which can be connected to a drying-tube. The glass hood is made of such a diameter that it fits inside a Buchner funnel, the joint being made air-tight with a rubber ring situated in a groove round the rim of the hood. It is well to employ a gentle pressure with the ring of a retort-stand to hold the hood in position, unless working with air under diminished pressure. A precipitate collected in the usual manner on the funnel can be dried by means of this simple additional apparatus in a very short time. Besides dispensing with the trouble of transferring the precipitate to a desiccator, the apparatus saves much time in the drying. The drying is most rapid when a steady, not too rapid, stream of air is drawn through the apparatus by means of the filter-pump after passing through a large drying-tower filled with calcium chloride; further, the hood, which is made of blown glass or, for very rapid drying, of metal, can be warmed with a flame. The precipitate can, if desired, be dried under diminished pressure by affixing a screw clip to the air inlet of the drying-tower. Another application of the apparatus is the drying of a precipitate in a non-reactive atmosphere; the gas can be circulated round and round, if necessary, by means of a blowing arrangement fitted to the filter-pump.

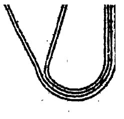


This small, inexpensive apparatus changes a Buchner funnel into an exceptionally efficient desiccator, which dries, not only precipitates collected on the funnel by the usual methods employed therewith, but also can be used conveniently for drying crucibles, etc., in a current of dry air.

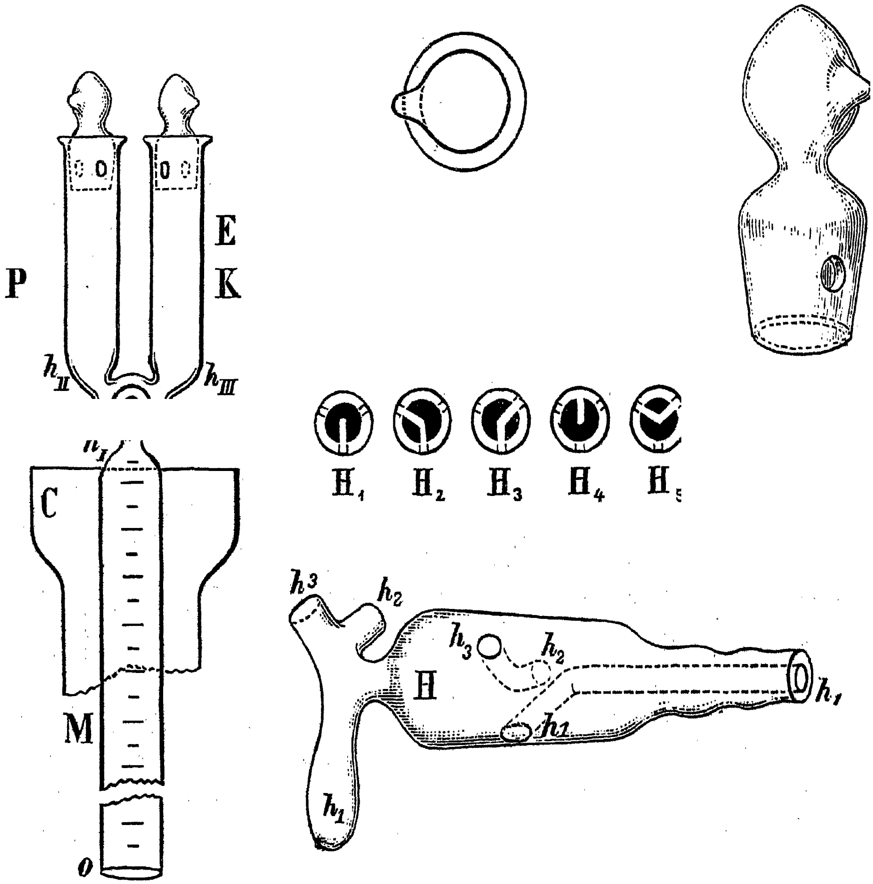
Melting-Point Determinations. G. A. Menge. (*U.S. Treasury Dept. Hygienic Lab. Bulletin*, 1911, 70, 1-101.)—A report of experiments carried out with the object of prescribing, in the ninth U.S. Pharmacopœia, the use of a simple method, so far rigidly defined, that it may be expected to yield approximately identical results in the hands of all operators. The apparatus finally recommended is a 10 by 3 cm. test-tube with walls about 1 mm. thick, and constructed of glass which will stand heating over an open flame. The test-tube is half filled with sulphuric acid, or for high temperature work, with a mixture of 70 parts by weight of sulphuric acid with 30 parts of potassium sulphate. The liquid is stirred continuously by a suitable (hand) stirrer. The substance to be examined is contained in a capillary tube not less than 0·8 mm. nor more than 1·25 mm. in internal diameter, this tube to contain a solid column of the substance 3 mm. high. The substance is heated rapidly to within 25° C. of its melting-point, then at the rate of 3° a minute until it begins to melt, as judged by the observation that some one point in the column of sample has collapsed against the side of the capillary. The rate of heating is then reduced to 0·5° a minute. A melting *interval* is to be returned, the beginning being that temperature at which some point in the column collapses, the end the temperature when the last trace of sample becomes liquid. All results should be corrected for the emergent stem of the thermometer in accordance with a prescribed formula. It is suggested that, if possible, some department of the U.S. Government should issue official thermometers of uniform construction. In that case a table or curve should be incorporated in the Pharmacopœia, showing the corrections to be made for the emergent stem. The need for uniformity of method in the determination of melting-points is illustrated by reference not only to foreign pharmacopœias, but to recently published and widely conflicting values which have been given for substances which are readily obtainable in a state of extreme purity, as judged by the shortness of the melting interval and other criteria. G. C. J.

Determination of the Density of Liquids. H. Hartley and W. H. Barrett. (*J. Chem. Soc.*, 1911, **99**, 1072-1074.)—Two forms of pyknometer were used, each made from test-tube glass, weighing about 5 grms. and holding 20 to 25 c.c. The form B, used for determining densities at temperatures below that of the laboratory, has a bulb to allow the liquid to expand, and a cap which should be ground on outside. The diameter of the capillary is 0·3 mm. The authors make use of a counterpoise made from the same kind of glass as the pyknometer, and having nearly the same surface area. By making the external volume of the counterpoise nearly equal (within 0·5 c.c.) to the sum of the volumes of the pyknometer and of the liquid it holds when full, the calculation of a series of densities may be greatly simplified without introducing an error greater than 2 units in the sixth decimal place of the density, even if the temperature should rise 10° C. and the barometer falls 30 mm. between the weighings of the pyknometer full of water and of the liquid to be tested. By the use of this apparatus and a thermostat constant to ±0·01° C., the authors were able to determine the densities of dilute (under 2 per cent.) aqueous solutions of several salts with an error not exceeding four parts in a million. In order to obtain this degree of accuracy in the case of liquids with a larger co-efficient of expansion, more accurate temperature regulation would be required. G. C. J.





Apparatus for Flue Gas Analysis. **A. Gawalowski.** (*Zeitsch. anal. Chem.* 911, **50**, 435-439.)—The apparatus consists of a 100 c.c. measuring-tube, surmounted y a three-way cock of special construction, and provided with two nitrometer cups ach of which is stoppered, the hollow stoppers having each a hole which may be nade to coincide with a hole in the ground seating. In the illustration one form of he three-way cock is shown on an enlarged scale; but it has been found better to make the plug of these cocks hollow and to fuse in small tubes rather than to bore channels in a solid plug. In use, the measuring-tube, which is open at the bottom, is sunk in a cylinder C of brine, the cock being in the position H_1 in which the measuring-tube is connected to the channel h_1, which allows air to escape. The end of the plug h_1 is now connected to the flue and the measuring-tube raised. The cock is turned to the position H_2 or H_3, and the first charge of gas blown off through either of the cups by sinking the tube in the brine cylinder. The tube is refilled with gas, its volume adjusted to exactly 100 c.c., and strong potash is admitted from the cup NP. After measuring the reduction in volume due to absorption of carbon dioxide, alkaline pyrogallol is added from the same cup NP and the oxygen estimated.



Finally, an ammoniacal solution of cuprous chloride is admitted from the other cup K to absorb carbon monoxide. As made now, the open end of the measuring-tube is somewhat constricted to facilitate closing by the finger, if it be desired to shake the contents of the tube. The maker is C. Glatzl, Mährisch-Ostrau. G. C. J.

Apparatus for the Maintenance of Constant Pressures Above and Below the Atmospheric Pressure. Application to Fractional Distillation. J. Wade and R. W. Merriman. (*J. Chem. Soc.*, 1911, **99**, 984-997.)—For pressures below that of the atmosphere, air is exhausted continuously from the system by an ordinary water-pump. For pressures above that of the atmosphere, air (or other gas) is forced in continuously by an automatic compressor, actuated by falling mercury. The pressure is kept constant by a regulator consisting of an open syphon manometer, which allows air to escape from or enter the system as soon as the desired excess or diminution of pressure is exceeded.

Devices are described in connection with fractional distillation, more especially for changing the receiver without disturbing the pressure. G. C. J.

REPORT.

Analysis of Potable Spirits, and its Bearing on the Definition of Whisky. E. A. Mann. (*Government Paper, Western Australia,* 1911.)—An analytical examination of 108 samples of whiskies of all kinds, together with a critical consideration of the figures placed before the English Royal Commission (1908), have convinced the author that it is quite possible to classify spirits by means of chemical analysis alone; thus it can be safely stated which are pure malt, pot still spirits, and which are blends containing at least 75, 50, or less than 50 per cent., of pot still spirit. A large number of very complete analyses are given, the Allen-Marquardt method being employed for determining the higher alcohols (*cf.* Mann and Stacey, ANALYST, 1907, **32**, 219, 258). The Report concludes with a concise description of the other methods employed, and photographs of special apparatus are included. A. R. T.

NOTE.—This is directly opposed to the commonly accepted opinion of this country.—EDITOR.

REVIEWS.

LABORATORY TEXT-BOOK FOR BREWERS. By LAWRENCE BRIANT. Third edition. Edited by HAROLD HARMAN. Pp. 444. London, 1911. Published by Fell and Briant. Price 10s. 6d. net.

Those familiar with the first edition of this well-known textbook, published some twenty-five years ago, will remember it as practically the first attempt to describe analytical processes of use in a brewer's laboratory. In the edition now under review, the author and his editor have, wisely we think, adhered to the original plan of describing processes of a well tried and eminently practical kind. The textbook contains fifteen chapters, entitled as follows :

I. Apparatus and Manipulation. II. Part I.: Nitrogenous Bodies or Proteins; Part II.: Enzymes; Part III.: Carbohydrates. III. Malt Analysis and Interpretations; Part I.: White Malt; Part II.: Coloured Malt; Part III.: Barley. IV. Unmalted Grain. V. Sugars. VI. Caramel. VII. Hops. VIII. Water Analysis. IX. Sulphites. X. Original Gravity of Beer. XI. Complete Analysis of Malt Wort and Beer. XII. Estimation of Arsenic in Brewing Materials. XIII. Microscopical Work. XIV. The Polarimeter. XV. Standard Solutions and Reagents.

In all cases where the method of analysis of a brewing material is described an actual example is given, together with interpretations, the latter being of an essentially conservative kind. While, however, courses other than safe and sound ones, have been avoided, we must confess to some sense of disappointment that an advisory chemist of Mr. Briant's experience still views a question like that of the influence of wort nitrogen from grounds which seem largely speculative. In spite of all that has been said in a general way about the influence of the "soluble uncoagulable albuminoids" on the stability of the finished beer, we think we can still deny the existence of the experimental evidence by which these factors have been connoted. We can quite agree that a high specific gravity for the cold-water extract of malt indicates an unsuitable material, but beyond this we still require direct proof that it is the nitrogenous constituents of the extract which influence the stability of beer, and, until such proof is forthcoming, all this talk about good and bad nitrogen will remain unconvincing. Our sceptical outlook is not intended to cast doubt on the value of this book, which, however, contains some matter open to criticism—*e.g.*, we do not like the author's procedure by which he standardises Fehling's solution for the volumetric estimation of sugar. Surely in these days, when pure chemicals (the author specifies them) are readily procured, Fehling's solution can be made up as a standard solution? And, in any event, we do not believe that it can be accurately standardised by an invert sugar solution prepared according to the author's description.

We also question whether the free sulphur in hops can be determined by passing "a current of hydrogen through a decoction of hops, when, if present, the sulphur will unite with that gas to form sulphuretted hydrogen"; in fact, this method is generally known to be worthless for quantitative purposes.

There are minor blemishes in the book which call for some notice. Thus proteins soluble in alcohol are not "protamines," the name of a totally different class, but, if the American term be used, "prolamins." Other errors which may prove very irritating, especially to the novice, concern some of the physical constants quoted. The optical constant of maltose is given (p. 93) as $[\alpha]_{D3\cdot86}+138$, which is not correct; and in the footnote on the same page we find the sign $[\alpha]_{D17\cdot5}$ without any explanation that 17·5 refers to the temperature of observation. Similar mistakes occur in describing other sugars—*e.g.*, on p. 211. The erroneous curve for invert sugar in the diagram on p. 102 seems in danger of perpetuation, and we take the opportunity of pointing out that, instead of as shown, the curve should lie at all points as the mean of the curves for glucose and lævulose.

For those brewers who wish their laboratory run on safe and sound, rather than highly scientific lines, we think Mr. Briant's book fully justifies the title he has given to it.

RUBBER. By CLAYTON BEADLE and H. P. STEVENS, M.A., Ph.D., F.I.C. (Pitman's Common Commodities of Commerce.) 1911. London: Sir Isaac Pitman and Sons, Ltd. Price 1s. 6d. net.

This booklet is one of a series on "Common Commodities of Commerce," and its object, according to the authors' prefatory note, is to supply an account of the production of the raw material, and the subsequent manufacturing processes, which will be found suitable to the requirements of the average reader who is desirous of obtaining general information on the subject, to the planter who wishes to know something of the manufacturing side of the industry, and to the manufacturer who is interested in the preparation of his chief raw material. The little work is brightly written and eminently readable, and contains a number of illustrations of rubber-trees and manufacturing machinery. The coloured frontispiece, which is from a water-colour painting by Dr. Stevens, affords an excellent idea of the appearance of plantation *hevea*-trees. The book is obviously not intended for the analyst or scientific worker, and it would, therefore, be unfair to criticise it from this point of view. P. SCHIDROWITZ.

NATIONAL PHYSICAL LABORATORY. Collected Researches. Vol. VII. 1911. Pp. 228 + iv.

This volume includes the records of eight different researches, more than half the total space being occupied with an account of Rosenhain and Lantsberry's researches on the properties of some alloys of copper, aluminium, and manganese, to which is appended an interesting note on the corrosion of alloys of copper and aluminium when exposed to the sea. The results of this work have appeared already in the Proceedings of the Institution of Mechanical Engineers, and it should be said that there is nothing in this volume which has not already appeared elsewhere; but the files of six different journals would have to be searched to find the eight papers here collected together. Dr. Kaye's work on the expansion and thermal hysteresis of fused silica will be of interest to many chemists; and Paterson and Rayner's experiments on comparative life-tests of glow lamps will be of interest to a smaller number. The object of these latter experiments was to determine the agreement which it is possible to obtain when life-tests are carried out on glow lamps by different laboratories. So far as the tests go, they indicate that measurements of the useful life of carbon filament lamps can be carried out on the basis of the Engineering Standards Committee's specification to give results within an accuracy of ± 5 per cent. From an experimental point of view, tests on metallic filament lamps should yield a higher accuracy. G. C. JONES.

NATIONAL PHYSICAL LABORATORY. Report for the year 1910. Pp. 102, with four plates.

The first nine pages are occupied with the Report of the Executive Committee, which reviews briefly the whole of the work accomplished during the past year, and a statement of work proposed for the year 1911 fills another seven pages. These are followed by the Report of the Director on the Physics Department, and the Reports to the Director by the Superintendents of the Engineering Department, the Department of Metallurgy and Metallurgical Chemistry, and of the Richmond Observatory. The Report of the Advisory Committee for the National Experimental Tank is also included.

Of special interest to chemists is the report (pp. 45-52) of a research which had for its object to determine the cause of the higher readings given by the Abel-Pensky flash-point apparatus (particularly the German form of this apparatus), as compared with those yielded by the ordinary Abel tester. The true cause of the differences has almost certainly been ascertained, and a detailed report to the Petroleum Commission is promised. The results of work carried out at the National Physical Laboratory are communicated to the particular learned society they are most likely to interest, but as the domains of the societies overlap, it is not always easy to find a particular paper which one may know to have issued from Teddington. The present report meets this difficulty by including a list of all papers (official or unofficial) read during the years 1909 and 1910 by members of the staff of the National Physical Laboratory. G. C. Jones.

INSTITUTE OF CHEMISTRY.

Pass List: June—July Examinations, 1911.

(Examinations were held in London and Glasgow.)

Of thirty-one candidates who presented themselves for the Intermediate Examination, the following seventeen passed: J. L. S. Allen, K. C. G. Arbuthnot, B.A., R. Clark, T. W. Derrington, E. C. Evans, B.Sc., H. Gilmour, R. E. Griffiths, B.Sc., C. L. Hinton, R. P. Keith, J. G. King, R. Linch, B. B. Murdoch, M.A., B.Sc., M. J. Robb, B.Sc., J. W. Tait, M.A., F. G. Tarn, T. A. Wilson, F. G. C. Walker. Of thirty-four candidates who presented themselves for the Final Examination for the Associateship, twenty-three passed. In the Branch of Mineral Chemistry: G. Hamilton, S. R. Illingworth, A.R.C.S., E. A. Masters, B.Sc., C. B. Ross, B.Sc., J. Sorley, A. F. Suggett; in the Branch of Physical Chemistry: Arthur Bramley, B.Sc., A.R.C.S.; in the Branch of Organic Chemistry: E. Anderson, O. L. Brady, B.A., D. S. Dawson, B.Sc., W. Jewell, J. A. McRae, M.A., W. G. Prescott, S. P. Schotz, D. B. Steinberg, B.Sc., J. C. White, L. Wilson, B.Sc.; and in the Branch of the Chemistry of Food and Drugs, Fertilisers and Feeding Stuffs, Soils and Water: H. J. Evans, Miss M. Gazdar, B.Sc., H. Lowe, B.Sc., W. R. Pratt, H. B. Stevens, J. A. L. Sutcliffe. Of four candidates examined for the Fellowship, two passed in the Chemistry of Food and Drugs, etc.: J. Hawthorne, B.A., Ph.D., and A. Miller, M.R.C.S., Major I.M.S.; and one a Special Examination in General Chemistry: G. H. Stanley, A.R.S.M. One Candidate for the Intermediate Examination presented himself at Singapore in June, and passed: A. M. Bailey. The Board of Examiners reported on seventy candidates in all, and of these forty-four passed.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE EFFECT OF FEEDING WITH COCOANUT CAKE AND LINSEED CAKE ON THE COMPOSITION OF BUTTER-FAT.

By H. T. CRANFIELD.

WHILST there is a considerable difference of opinion as to whether feeding influences the composition of milk or not—and many experiments have been carried out with this object in view—little investigation seems to have been made in this country concerning the influence of feeding on the composition of butter-fat. In Germany, however, some work has been carried out by H. Lührig (*Zeitsch. Untersuch. Nahr. Genussm.*, 1906, **11**, 11), which deserves notice in connection with the present communication. Lührig watched the effect of feeding with cocoanut cake on the composition of the butter, and found that there was a considerable rise in the Polenske number, and but little effect on the Reichert-Meissl number. In consequence of this variation he recommended an increase of 0·8 in the limits adopted by Polenske for genuine butters in his original paper in 1904.

At the present time cocoanut cake is being placed on the English market in much larger quantities than in previous years; and since it is not unlikely that this food will be used more extensively by dairy farmers in the near future, I decided to take advantage of an experiment on the feeding of dairy cows which was being carried out during the spring of this year at the Midland Agricultural and Dairy College.

DETAILS OF THE EXPERIMENT.

Two sets (A and B) of four cows* each were employed, each cow receiving the following ration daily: 56 pounds mangels, 7 pounds oat-straw chaff, 2 pounds mixed meal (bran, dried grains, rice meal), and 14 pounds hay. In addition to this ration, all the cows received during the first week 5 pounds of undecorticated cotton cake daily. In the second and third weeks Set A received 5 pounds of cocoanut cake, and Set B 4½ pounds of linseed cake. These foods were reversed in the fourth and fifth weeks, and for the last week all the cows reverted to cotton cake.

---

* All the cows were cross-bred shorthorns.

Three times a week about half a pint of cream was reserved—a consecutive night and morning—from the milk of each set of cows. The cream was ripened with a starter, and churned after twenty-four hours in a small glass experimental churn. Once a week the whole of the milk from a consecutive night's and morning's milking was separated, and the cream (corresponding to one of the small samples) churned in an ordinary barrel churn. A sample from this bulk of butter was taken for analysis, to serve as a control in the method of churning and also in the analytical determinations.

The samples of butter were melted at a low temperature, and filtered in the ordinary way. The refractometer figure, Reichert-Meissl number, Polenske number, and Shrewsbury and Knapp figure, were determined. The results are recorded in the accompanying table:

Number of Sample.		$[N]_D$ 35° C.		Reichert-Meissl Number.		Polenske Number.		Shrewsbury and Knapp Figure.

Averages.—In compiling these averages, the transitory samples have been omitted—viz., Nos. 3, 9, 10, and 15:

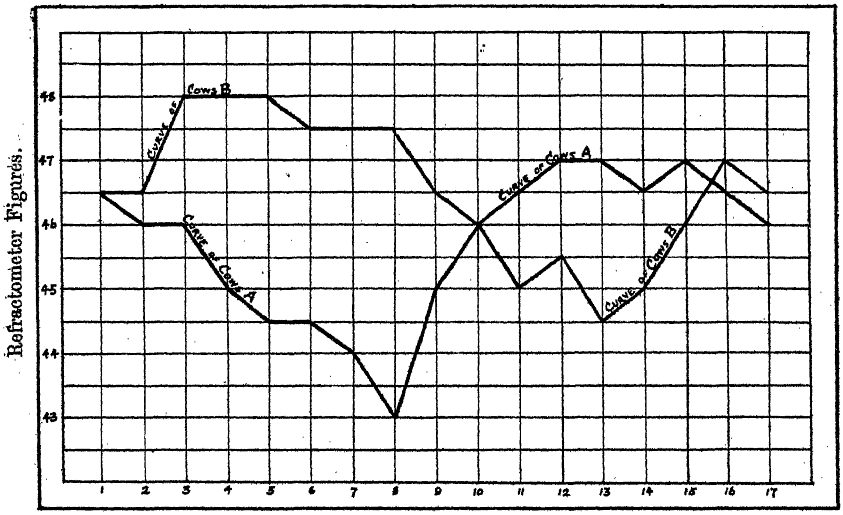
		$[N]_{D\,35^\circ}$ C.	Reichert-Meissl Number.	Polenske Number.
Cocoanut cake	A ...	44·2	29·5	3·3
	B ...	45·4	30·2	2·9
Linseed cake	A ...	46·2	29·1	2·3
	B ...	47·7	29·1	1·7
Cotton cake	...	46·4	30·8	2·3

It will be seen from this table that the figures given by the bulk samples of butter agree very closely, and in many cases are identical, with the corresponding small samples of butter.

Refractometer Figure.—On perusing the foregoing table, it will be noticed that the two cakes have had a marked influence on this figure. The linseed cake caused a distinct rise in the refractive index, while the cocoanut cake gave a reverse variation. The rise and fall of this figure can be easily seen in the accompanying curves:

REFRACTOMETER CURVES (35° C.).

A & B Cotton. 1st Week. A Cocoanut. B Linseed. 2nd & 3rd Weeks. A Linseed. B Cocoanut. 4th and 5th Weeks. A & B Cotton. 6th Week.



Number of Sample.

Reichert-Meissl Number.—The influence of the feeding on this number is not so great as in the case of the refractometer figure. Certainly some slight variation seems apparent—viz., a falling in the case of the linseed cake, and a rise due to the cocoanut cake. Both cakes, however, give a lower average figure than the cotton cake.

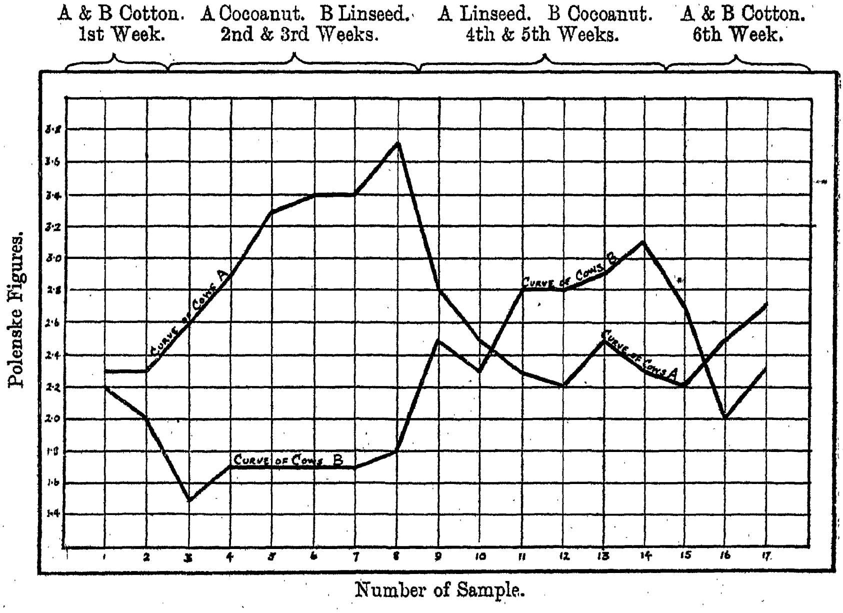
Polenske Number.—On this number the feeding has had a most remarkable influence, the linseed cake causing the figure to fall to a very low point, while the cocoanut cake raised the number considerably.

Taking the figures obtained from Samples 8 A and 8 B, we get the following comparison:

	8 A.	8 B.
Reichert-Meissl number	29·5	29·6
Polenske number	3·7	1·8

The curve given below shows very closely the variations in this figure during the experiment:

POLENSKE CURVES.



Polenske in original paper (1904) compares the Reichert-Meissl and Polenske numbers obtained for normal butters, and gives the highest figures allowable for genuine butter. In this experiment several samples gave figures outside Polenske's limits. For example—

Number of Sample.	Reichert-Meissl Figure.	Polenske Figure.	Polenske Highest Allowable Figure.
6 A	28·9	3·4	3·0
8 A	29·5	3·7	3·5
Bulk 8 A	28·7	3·4	3·0

Lührig (*loc. cit.*) quotes even higher figures than these, but the amount of cocoanut cake fed in his experiment was up to 6 kgrms. daily—a quantity much in excess of that fed during this experiment. In view of the likelihood of the increased use of cocoanut cake in this country for feeding dairy cattle, this influence is of importance to the butter-producer.

Shrewsbury and Knapp Figure (ANALYST, 1910, **35**, 36).—The method for this estimation has only recently been brought to the notice of analytical chemists, and with a view to testing the method, I made a few determinations, obtaining the results given in the previous table. All the results given are the mean of at least two determinations, and where the variation exceeded 0·5 a third estimation was made. Shrewsbury and Knapp mention a limit of 32 for their figure for genuine butter, but it will be seen from my figures that this limit has been exceeded in six cases, one giving as high a figure as 40·1, which, according to Shrewsbury and Knapp, would represent over 10 per cent. added cocoanut oil. It seems, therefore, that this method does not show any superiority over the Polenske method, though it is certainly a more expeditious estimation to carry out.

Rancidity.—The cakes appeared to have a different effect on the keeping properties of the butter-fat. The samples were all kept in small corked bottles or flasks, and it was noticed after several weeks that the butters from the linseed and cotton cakes had turned quite white and rancid, while those from the cocoanut cake showed only a slight change. This preservative effect is undoubtedly an advantage in favour of cocoanut-cake-fed butter.

Quality of the Butter.—The following report was given on the quality of the weekly samples of butter in bulk, and for this report I am indebted to Mr. Alec Todd, Instructor in Dairying at the Midland Agricultural and Dairy College:

"No very great differences were shown in the texture and flavour of the two sets of butters. The butter from the cocoanut cake, however, had as a rule a firmer and less oily texture and better flavour than the linseed-cake butter."

CONCLUSIONS.

1. It is apparent from these results that feeding has a great influence on the composition of butter-fat.

2. The feeding of cocoanut cake to dairy cows produced a butter which gave a refractometer figure below the normal, while the Polenske number was very high. The Reichert-Meissl number was, however, quite normal.

3. Feeding with linseed cake influenced the butter in respect of the Polenske number, butters from this source giving a figure much below the normal. The refractometer figure was also influenced, a distinct rise being noticeable.

4. Cocoanut cake produced a butter of good quality, possessing better keeping properties than butter from linseed or cotton cakes.

5. The Shrewsbury and Knapp method for detection of cocoanut oil in butter possesses practically no advantages over the Polenske method.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Assay of Aconite. A. B. Stevens. (*Bulletin of Pharmacy*, June, 1911 through *Pharm. J.*, 1911, **87**, 34.)—The United States Pharmacopœia method, which is practically that of the author, is more rapid if carried out as originally devised; that is to say, the evaporation at 60° C. is performed in a flat-bottom evaporating-dish, and 5 grms. pumice powder are added to the percolate before evaporation. In this way the subsequent solution and filtration are much hastened.

The deterioration of aconite by age or moisture can be detected by both chemical and physiological methods of assay. Thus, a sample of aconite, showing 0·837 per cent. of alkaloids on assay, and giving the characteristic tingling sensation in a dilution of 1 : 1,200, gave the following results after the treatments specified:

	Alkaloids found per Cent.	Physiological Test.
1. Moistened with water and kept for several days in stoppered bottle with cotton moistened with chloroform	0·67 ; 0·66 ...	1 : 700
2. Moistened and kept in warm place till dense mould formed	0·30 ; 0·32 ...	1 : 450

Experiments by F. O. Taylor (*J. Ind. and Eng. Chem.*, 1909, **1**, 549) have shown that by the action of heat aconite preparations may be reduced almost to a physiologically inactive condition, and yet the chemical method of assay would not alone serve to detect this deterioration. Moreover, so far from the decomposition products causing the titration method to yield high results, in most cases the results were lower than by the gravimetric assay. Ordinarily, therefore, the deterioration of the drug may be chemically determined; and if due to heat, it may be detected by volumetric assay, since the weight of the ether-soluble residue is increased and its basic properties decreased. Aconite contains considerable quantities of chloroform-soluble bases (insoluble in ether) which are quite inactive physiologically. Thus, chloroform should not be used for the assay of aconite. The Squibb method of determining the largest dilution at which the characteristic sensation on the tongue may be produced is useful when applied by a sensitive person, but the results are very variable with different persons.

A. R. T.

Composition of Sweet Apricot Kernels. L. Rosenthaler and W. Schaeffer. (*Pharm. Zentralb.*, 1911, **52**, 507-508; through *Chem. Zentralbl.*, 1911, II., 35.)—The uthors have examined specimens of edible apricot kernels obtained from the South f France; the kernels had a pleasant, almond-like taste quite different from that of he bitter kernels imported from Japan. Their composition was as follows: Water, ·33; oil, 53·40; crude fibre, 4·76; ash, 2·60; total soluble matter, 27·87; reducing ugars, 8·08; reducing sugars after hydrolysis, 11·64; and proteins, 31·4 per cent. he oil expressed from the kernels had the following physical and chemical properties: Sp. gr. at 15° C., 0·9182; $[N]_{D\,25^\circ\,C.}$, 64·7; solidifying-point, 14·5° C.; iodine value, 95·03; saponification value, 187·76; Reichert-Meissl value, 0·96; insoluble fatty acids, 73·48 per cent. The oil was optically inactive. The fatty acids gave the following values: Solidifying-point, 5·1° C.; $[N]_{D\,25^\circ\,C.}$, 53·7; iodine value, 98·41; mean molecular weight, 290·55. The oil yielded negative results with Halphen's, Baudouin's, Soltsien's, and Becchi's tests, but gave a blue-violet coloration with Bellier's test, the coloration developing gradually and fading in a few minutes. The elaidin test yielded a viscous mass. W. P. S.

Detection of Cocoanut Oil in Butter by Means of Ewer's Method. E. Nockmann. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 754-757.)—Results of analyses are recorded which show that when cows are fed on beetroot leaves the composition of the butter obtained from the cows is so altered that the figures obtained by Ewer's method (ANALYST, 1910, **35**, 353) are such as would indicate the presence of cocoanut oil in the butter. Of seven samples of butter obtained from cows fed on beetroot leaves, five gave "difference figures" varying from 7·8 to 8·9, the average figure for these butters before the period during which the cows were fed on the beetroot leaves being 11·5. It is also pointed out that the presence of 10 per cent. or more of cocoanut oil in butter can be detected by the usual analytical methods (*cf.* ANALYST, 1911, 404). W. P. S.

Detection of Cocoanut Oil in Butter by Means of Fendler's Method. A. Hepner. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 758-760.)—When examined by the ester method described by Fendler (ANALYST, 1910, **35**, 355), the mixed butter of a herd of cows gave a distillation figure of 4·7; but after the cows had been fed for some time on beetroot leaves this value rose to 7·5 (average), and on certain dates was over 9·0. The author considers, therefore, that the method possesses no advantage over the usual analytical processes for the detection of cocoanut oil in butter (*cf.* preceding abstract). W. P. S.

Examination of Honey by Fiehe's Reaction. H. Lührig and A. Scholz. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **21**, 721-741.)—Fiehe's reaction (ANALYST, 1908, **33**, 397) depends on the detection of hydroxymethylfurfural, traces of which are produced by the action of mineral acids on sucrose during the inversion of the latter in the preparation of artificial honey (invert sugar). As honey contains both sucrose and organic acids, it might be assumed that, when pure honey is heated, the sucrose is inverted, and that such honey would yield a positive reaction with Fiehe's reagent. A large number of experiments are recorded by the author; in these experiments sucrose and honey solutions were heated to 80° C. for thirty minutes or longer after the addition of varying proportions of different organic acids, and then tested with the reagent in the usual way. It was found, however, that there is a minimum concentration for each organic acid below which the reaction is not obtained. For instance, the sucrose or honey solution must contain not less than 0·1 per cent. of oxalic, or 2 per cent. of lactic, acetic, formic, butyric, or salicylic acids, before a positive reaction is obtained with the reagent. The small quantities of organic acids present in natural honey do not cause the latter to give a reaction with Fiehe's reagent, even when the honey has been heated for one hour at a temperature of 100° C. W. P. S.

Estimation of Nicotine in the Presence of Pyridine Bases. L. Surre. (*Ann. Falsif.*, 1911, 4, 331-334.)—The method proposed depends on the fact that nicotine has an optical rotation of −161·55° (200 mm. tube at a temperature of 20° C.), whilst pyridine and similar bases are optically inactive. The author finds that, for solutions containing from 1 to 6 per cent. of nicotine, the rotation is exactly proportional to the concentration, and that the presence of pyridine does not modify the rotation. Fifty c.c. of the sample are placed in a flask, together with 1 grm. of calcined magnesia and 2 grms. of powdered pumice, and distilled. When about 25 c.c. of distillate have come over, water is admitted to the flask drop by drop from a tapped funnel (the addition of the water can be regulated so as not to interfere seriously with the boiling of the contents of the flask), and the distillation is continued until 150 c.c. of distillate have been collected. This quantity will contain the whole of the pyridine present and also the greater part of the nicotine, and the amount of the latter is then estimated polarimetrically. Let A be the reading observed (angular degrees); then (for 50 c.c. of the sample taken and 150 c.c. of distillate) the amount of nicotine in grms. per litre of the sample will be $A \times 18{\cdot}57$. In order to obtain the whole of the nicotine, the contents of the flask are further distilled, with the gradual addition of water, until a second quantity of 150 c.c. of distillate have been received; and this distillate, containing only nicotine, is titrated with $\frac{N}{10}$ sulphuric acid, using luteolin as indicator; each c.c. of $\frac{N}{10}$ acid is equivalent to 0·0162 grm. of nicotine. As the quantity of nicotine in the second distillate is very small, the titration is more trustworthy than the polarimetric estimation. The method yields satisfactory results, the error not exceeding 0·7 grm. of nicotine per litre. W. P. S.

New Method for the Detection of Salvarsan. J. Abelin. (*Münch. med. Wochenschr.*, 1910, 58, 1002-1003; through *Chem. Zentralbl.*, 1911, II., 55.)—The est depends upon the formation of a bright red colour when diazotised dihydroxyiamino-arsenobenzene (salvarsan) is treated with alkaline resorcinol solution. A mall quantity of salvarsan is dissolved in about 3 c.c. of water, 4 drops of dilute ydrochloric acid are added, and the mixture is treated with a 0·5 per cent. sodium itrite solution, the mixture being cooled during the addition. The diazotised substance exhibits a greenish-yellow fluorescence, and when the solution is added drop y drop to a 10 per cent. resorcinol solution rendered alkaline with sodium hydroxide, red coloration is produced. Phloroglucinol, α-naphthol, etc., may be used in place resorcinol, but the latter gives the best results. The test may be applied directly o the urine of persons who have been taking salvarsan, as the constituents of the rine are without influence on the reaction. The test will detect the presence of lvarsan in the urine of a patient two hours after the substance has been injected bcutaneously. Atoxyl yields an orange coloration when it is diazotised and eated with resorcinol. W. P. S.

Estimation of Sugars in Feeding-Stuffs. A. H. Bryan, A. Given, and M. N. Straughn. (*J. Ind. and Eng. Chem.*, 1911, **3**, 486-492.)—The authors have compared two methods in general use—namely, extraction with (1) hot diluted alcohol (50 per cent.); and (2) cold sodium carbonate solution. The action of alcohol at the temperature employed, and of the sodium carbonate, in killing the enzymes or preventing their action, is an important factor in these methods, since by the activity of these ferments sugar is produced from the starch present in the products under examination, thus seriously affecting the results. The methods are best carried out as follows:

Alcohol Digestion Method.—One hundred and fifty c.c. of alcohol (50 per cent. by volume) and 12 grms. of the finely-ground material in a 300 c.c. graduated flask, are kept on the water-bath for one hour, the vapour from the flask being condensed by placing a small funnel in the neck. If the material be acid, 1 to 3 grms. of calcium carbonate should first be added. The contents of the flask are cooled and, if desired, allowed to stand overnight, and made up to 300 c.c. volume by the addition of neutral alcohol (95 per cent.). After thorough mixing, 200 c.c. of the supernatant liquid are evaporated at 100° C. to about 20 to 30 c.c. Sufficient saturated neutral lead acetate solution is added to produce a flocculent precipitate, and, after standing, the volume is made up to 100 c.c. with water and filtered. An excess of dry sodium carbonate is added to remove the lead. After filtration, 25 c.c. of the filtrate are mixed with 25 c.c. of water for estimating the reducing sugars by the method of Munson and Walker (*U.S. Dept. Agriculture, Bur. Chemistry, Bull.* 107 [revised], 241). Fifty c.c. of the filtrate are rendered neutral to litmus-paper by means of acetic acid, 5 c.c. strong hydrochloric acid added and allowed to stand overnight for inversion. The solution is neutralised with dry sodium carbonate and made up to 100 c.c. If necessary the solution is filtered and 50 c.c. used for the estimation of total sugars (*loc. cit.*). The amount of cuprous oxide or copper obtained in the above determinations represents the sugar (as dextrose) in 2 grms. of material. To correct for the space occupied by the insoluble material of the grain or cattle-food, the percentages of sugar found must be multiplied by 0·97, since 12 grms. of the material occupy 9 c.c. of the 300 c.c.

Sodium Carbonate Digestion Method.—The addition of sodium carbonate to the cold-water extraction method inhibits the action of enzymes on the starch, and the results obtained agree with those of the alcohol method. A mixture of 8 grm. of the finely-ground material with 190 c.c. of sodium carbonate solution (0·2 per cent.) at room temperature is taken at intervals for two and a half hours. The acidity of the material, if any, must be determined and corrected by the use of a stronger alkaline carbonate solution. Ten c.c. of neutral lead acetate solution are added, and the liquid filtered. The use of alum as a clarifier gives inaccurate results. The reducing sugars on 25 c.c. of the filtrate (= 1 grm. substance) are determined by Allihn's method (*Bull.* 107, p. 49). Fifty c.c. of the same filtrate are inverted by the acid method already described, neutralised and made up to 100 c.c., and in 25 c.c. of the solution (= 0·5 grm. substance) the total sugars by Allihn's method are determined. The amount of sucrose is obtained by multiplying the percentages of dextrose before and after inversion by the factor 1·044, then subtracting, and multiplying the difference by 0·95 as usual. No correction is usually necessary for the volume of the material, but if this be very wet, a correction may be applied for the dilution due to moisture in the sample. If only total sugar after inversion is to be estimated in substances where the amount is small, 8·8 grms. of material are extracted as above, and 50 c.c. of the solution inverted, neutralised, and 25 c.c. (=1 grm. material) used for the reduction. Reducing sugars are calculated as dextrose or as invert-sugar, and total sugars expressed as "by acid hydrolysis calculated as dextrose."

The alcohol method is very reliable, but with the sodium carbonate method care must be taken, and after clarifying the solution with lead acetate, the work must be rapidly completed as the enzymes become active again. Some materials cannot usefully be examined with this alkali method, as they do not give clear filtrates.

A. R. T.

Simple Volumetric Method for Testing Spiritus Ætheris Nitrosi. O. Herting. (*Pharm. Zeit.*, 1911, **56**, 423; through *Chem. Zentralbl.*, 1911, II., 103-104.)—The method recommended by the author for testing the strength of *spiritus ætheris nitrosi* is as follows: A mixture of 10 c.c. of water and 5 c.c. of a cold-saturated solution of potassium chlorate, free from chlorides, is placed in a glass-stoppered flask of 100 c.c. capacity; to the mixture are added 5 c.c. of the spirit to be tested, and 5 c.c. of 10 per cent. nitric acid. The whole is allowed to remain for thirty minutes with frequent shaking, and 10 c.c. of $\frac{N}{10}$ silver nitrate solution are then added. The contents of the flask are again shaken, and the excess of silver nitrate is titrated back with thiocyanate in presence of ferric ammonium sulphate. One c.c. of $\frac{N}{10}$ silver solution represents 0·0255 grm. of ethyl nitrite. J. F. B.

Valuation of Tea. A. A. Besson. (*Chem. Zeit.*, 1911, **35**, 813-815; 830-332.)—The author has analysed and examined some ninety samples of teas, of which forty-three were Chinese teas and the remainder Ceylon, Java, and Indian products. Particular attention was paid to the proportion of stalk in the samples, but it was found that there was very little relation between the amount of stalk and the price and quality of a tea as shown by a tasting test. It was ascertained, however, that Java tea grown at an altitude of 4,500 feet was of distinctly better quality than that grown at 1,800 feet. The analytical results obtained were as follows:

	Moisture.	Stalk.	Ash.	Caffeine.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Chinese green tea ...	6·00 to 7·69	0·4 to 5·3	4·88 to 7·46	2·13 to 3·22
Do. Foochow ...	6·29 to 9·06	4·1 to 17·5	4·80 to 5·73	2·23 to 3·64
Do. Hankow ...	6·48 to 8·33	8·6 to 17·1	4·95 to 5·65	2·65 to 3·64
Ceylon tea	4·57 to 8·12	5·8 to 43·4	4·54 to 5·65	2·80 to 4·10
ndian tea	4·00 to 8·08	11·5 to 37·4	4·72 to 5·64	3·31 to 4·15
ava tea	8·22 to 10·50	4·4 to 29·9	5·53 to 7·32	2·22 to 4·54

W. P. S.

Chemical Differentiation between Fermentation Vinegars and "Vinegar Essence," particularly with Respect to the Amount of Formic Acid. H. Fincke. (*Deut. Essigind.*, 1911, **15**, 145-148; through *Chem. Zentralbl.*, 1911, I., 1887.)—Most of the samples of fermentation vinegars examined by the author were found to be free from formic acid. Three samples containing pyridine also contained formic acid to the extent of 0·10 to 0·38 part per 1,000 of total acid, increasing with the proportions of pyridine. Eight samples of wine vinegar contained quantities ranging from 0·06 to 0·51 part of volatile acids capable of reducing mercuric chloride, the higher values being obtained with samples containing high proportions of wine, but whether these bodies consisted entirely of formic acid was not determined. Genuine fermentation vinegars are generally free from formic acid, but vinegars prepared from "essence" contain appreciable quantities, so that not only can fermentation vinegar be differentiated from diluted "vinegar essence" in this way, but mixtures can also be detected with some degree of certainty. Samples of "vinegar essence" showed quantities of formic acid ranging from 0·39 part to 12·04 parts—average, 4·38 parts per 1,000 of total acid. J. F. B.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Estimation of the Age of Blood-Stains. A. de Dominicis. (*Boll. Chim. Farm.*, 1911, **50**, 273-276; through *Chem. Zentralbl.*, 1911, II., 232.)—A portion of the stained material of about 5 sq. mm. is immersed in 1 c.c. of pure glycerol (sp. gr. 1·23) in a test-tube 12 mm. in diameter, which is gently given a single shake at intervals of a minute, and a note taken of the time required for solution. The yellow solution is kept protected from the air, and compared with the solutions obtained in the same way from blood-stains of known age, the relationship between the colour of which and the time required for solution is also known. The presence of blood is detected by means of the spectroscope. Blood-stains which dissolve within a minute are undoubtedly of recent origin, whilst the longer the solution period the older the stain. C. A. M.

Opsonin Reaction. H. Kronberger. (*Zeitsch. exper. Pathol. Therap.*, 1911, 9, 87-96; through *Chem. Zentralbl.*, 1911, II., 53-54.)—A method of estimating opsonins is described; the estimation is best carried out on the defibrinated blood taken from the patient and the control-subject during digestive leucocytosis. Fresh cultures of bacteria should be employed in the preparations of the emulsions, and the opsonin preparations may be stained with the ordinary stains used for bacteria and leucocytes. The reaction velocity of the opsonin is observed at intervals of ten, twenty, thirty, and sixty minutes, in a series of mixtures prepared from the bacteria and blood of the patient and the control-subject. Under these conditions the bacteria are chemotactic towards the leucocytes, and show a distinct alkaline chromatin reaction, but are negatively chemotactic towards the lymphocytes, with an acid reaction on the nucleus. W. P. S.

Biological Method for Identifying Various Fleshes. A. Saint-Sernin. (*Ann. Falsif.*, 1911, **4**, 334-338.)—The method depends upon the fact that blood-serum obtained from a rabbit which has been inoculated previously with the blood-serum of another animal possesses the property of forming a precipitate when mixed with a further quantity of the blood-serum of the animal, but not with that of any other animal. For the detection of horse-flesh, beef, or mutton, in sausages, etc., portions of the meat which are suspected to be other than pork are extracted with 0·7 per cent. sodium chloride solution for one hour, and then filtered. Portions of 2 c.c. each of the filtrate are then placed in test-tubes containing blood-serum from rabbits which have been inoculated with horse, ox, or sheep blood-serum, respectively. Should the sausages contain horse-flesh, a flocculent precipitate will form in the test-tube containing the rabbit-horse blood-serum after the tubes have been kept in an incubator for one hour at 37° C. Mutton will be indicated by a precipitate in the rabbit-sheep blood-serum tube, and so on. The active sera are obtained by injecting 10 c.c. of the necessary blood-serum into a healthy rabbit at intervals of two days, followed by three further injections at intervals of eight days. After the lapse of a week from the last injection, the rabbit is bled from the ear, and the serum separated from the blood. Certain antiseptic substances interfere with the test: acetone, formaldehyde, and sulphurous acid inhibit the reaction; thymol has less influence; whilst naphthalene, menthol, and camphor, retard slightly the formation of the precipitate.

W. P. S.

Precipitin Reaction. D. A. Welsh and H. G. Chapman. (*Zeitsch. Immunitatsforsch. exper. Therap.*, 1911, **9**, 516-529; through *Chem. Zentralbl.*, 1911, II., 38-39.)—The greater part of the precipitate obtained in this reaction consists of the constituents of the antiserum, and the weight of the precipitate is strictly proportional to the amount of the antiserum. In the case of complete precipitation the weight of the precipitate does not depend on the quantity of the other substances, and it is not correct to consider these substances (antigens) as being precipitable, or to assume that they are precipitated by the precipitin of the antiserum. Retarding effects cannot be explained by assuming that a precipitoid is formed, but at the same time heated antisera have a direct solvent action on the precipitate. The precipitin reaction is, in the author's opinion, of great practical importance, as it aids in the identification of proteins, allows closely allied proteins to be separated, etc.

W. P. S.

Use of the Quantitative "Precipitin" Reaction in Honey Analysis. J. Thöni. (*Mitt. Lebensmittelunters. u. Hyg.*, 1911, **2**, 80-123; through *Chem. Zentralbl.*, 1911, I., 1888.)—The author has investigated the method proposed by Langer, who found that von Riegler's antiserum could be employed for the quantitative examination of honey solutions. This antiserum produces a precipitate with the proteins of genuine honey, the quantity of which may be measured by volume, and thus forms the basis of a new "constant," of great utility from an analytical point of view. The formation of the precipitate for quantitative purposes is governed by certain conditions—*e.g.*, concentration of the honey solution, the relative quantities taken, and the working equivalent and quantity of the antiserum preparation. Tests carried out with ninety samples of honey and sugars showed that the sugars gave no precipitate; that artificial honeys reacted either as the sugars or else gave only traces of precipitate—*e.g.*, a sediment 2 mm. in height with 10 to 15 per cent. solutions; that genuine honeys with the same quantities of antiserum gave precipitates settling within a very narrow range of heights, and always gave a precipitate even when diluted to 1 per cent. Mixtures of genuine and artificial honey showed diminished heights of precipitate according to the extent of the adulteration. Sugar-fed honeys gave smaller precipitates than genuine pure honeys. Fermenting honeys showed no decrease in the volume of precipitate as compared with honeys in the natural condition. According to the author, the serological method is destined to prove of greater analytical value than the chemical and physical methods of examination. J. F. B.

Sterilisation of Drinking Water by Means of Ultra-Violet Rays. J. Courmont. (*Chem. Zeit.*, 1911, **35**, 806.)—It is shown that the bactericidal effect of exposure for a few seconds to the rays from a mercury vapour lamp constructed of quartz is due to the direct action of the rays, and not to the action of ozone or hydrogen peroxide. No detectable trace of ozone is formed during the few seconds' exposure required for complete sterilisation, nor even in a full minute, and the effect is shown to be independent of the presence of oxygen. The practical utility of the process is limited to ordinary drinking water, which must be free from turbidity. Whereas the rays can penetrate a foot or more of clear water and destroy all bacterial life wherever they reach, a very small proportion of any colloid causes the complete absorption of the rays by the layers of liquid nearest the lamp. Perfectly brilliant wort, beer, must, or wine, when allowed to flow over the lamp in a layer but a few millimetres in thickness, is incompletely sterilised, and it was found impossible to sterilise some broth and peptone solutions even in films less than 1 mm. thick.

G. C. J.

ORGANIC ANALYSIS.

Estimation of Amino Groups in Amino Compounds and in Urine, and a Method for the Analysis of Proteins. D. D. van Slyke. (*Ber.*, 1911, **44**, 1684-1692.)—In a previous paper (ANALYST, 1911, 17) the author described a method for the estimation of amino acids based on the measurement of the volume of nitrogen evolved in the reaction with nitrous acid. Most of the naturally occurring amino acids react quantitatively, but glycocol yields regularly 103 per cent. of the theoretical volume of gas, whilst cystine yields 107 per cent. Lysine differs from the other amino acids in the fact that it requires half an hour for complete reaction, whereas in most other cases the reaction is complete in five minutes. Among other anomalous amino compounds are included guanosine, which yields 1·25 molecules of gas, and guanine, which is so sparingly soluble that even after several hours only a portion of its amino nitrogen is evolved. With methylamine, ammonia, and the purines, about two hours are required for complete reaction. It would appear that the method under the conditions described, with a reaction period of five minutes, is only applicable quantitatively for those acids in which the amino group occupies the α-position with respect to a carboxyl group. It is not necessary to agitate the liquid during the whole time of the reaction; agitation at the end, in order to liberate the gas dissolved in the liquid, is sufficient.

In the analysis of urine, the method is applicable for the estimation of amino groups derived from proteins, peptides, hippuric acid, etc. The urea, however, reacts very slowly, complete decomposition being effected only after eight hours; but the rate of decomposition is fairly uniform, and if two experiments be made, one for six minutes and the other for twelve minutes, the difference between the two results gives a figure for the rate of decomposition of the urea which may be deducted as a correction from the first value. Normal human urine generally contains less than 1 per cent. of its total nitrogen in the form of free amino acids. The ammonia is first expelled by passing a current of air at the ordinary temperature through the liquid previously made alkaline with sodium hydroxide. The author has further developed his method for the analysis of proteins, and gives in detail the complete scheme adopted in the case of fibrin. Ten grms. of fibrin are hydrolysed with 100 c.c. of 20 per cent. hydrochloric acid, portions of 1 c.c. being withdrawn at intervals for the estimation of the amino nitrogen. When this value ceases to increase after about twenty-six hours, the hydrolysis is finished. The hydrochloric acid is then evaporated by concentration of the solution *in vacuo*, and the liquid is diluted to 250 c.c. After estimation of the total nitrogen, the various groups are dealt with separately. The amide nitrogen is estimated by distillation with milk of lime and alcohol under reduced pressure. The melanine bodies are filtered off together with the residual lime, and the nitrogen is estimated by the Kjeldahl process. The filtrate is neutralised with hydrochloric acid and concentrated. The precipitation of the hexone bases by phosphotungstic acid is carried out as previously described (*loc. cit.*), but in presence of 3·5 per cent. hydrochloric acid instead of sulphuric acid. The washed precipitate is dissolved in sodium hydroxide under certain prescribed conditions, and the phosphotungstic acid is precipitated by barium chloride, whilst the bases remain in the filtrate, which is concentrated to a volume of 50 c.c. The amino nitrogen of the bases in the solution is estimated by the author's method, allowing half an hour for the complete decomposition of the lysine. The arginine is estimated by boiling for six hours with potassium hydroxide, as described in a previous paper. After decomposition of the arginine, the remainder of the base-nitrogen is estimated by Kjeldahl's process. The sulphur contained in the cystine is estimated by the method of Benedict and Denis. In the filtrate from the bases, the total nitrogen is estimated by the Kjeldahl process, and the amino nitrogen by the author's process. If the above process for the estimation of the amino nitrogen be compared with the known processes based on the isolation of the individual amino acids, it is found in most cases that the latter processes account for barely more than half the amount of amino acids shown by the former process to be present.

J. F. B.

Reaction of Aromatic Inner Anhydrides depending on their Influence on the Crystalline Form of Iodoform. B. Bardach. (*Zeitsch. anal. Chem.*, 1911, **50**, 545-548.)—In presence of aromatic inner anhydrides and certain closely related complexes, iodoform assumes an unstable acicular form in place of the normal hexagonal plates and stars. Certain of these anhydrides give rise to this reaction direct, whilst others yield only the ordinary hexagonal crystals unless previously treated with iodine solution.

To the not too concentrated and not far from neutral solution of the substance in tap-water (the reaction only proceeds in dissociated solution), a 2 per cent. alcoholic solution of iodoform is added drop by drop. If iodoform separates in needles, aromatic inner anhydrides are present, and this reaction is especially characteristic of compounds of the type of euxanthon and its derivatives. Albumin must be removed, if present, as it acts similarly.

If hexagonal crystals are obtained under the above conditions, 3 c.c. of iodine solution (4 iodine, 6 potassium iodide, 100 water) are added to a fresh portion of the solution, and excess of ammonia (1 to 2 c.c.) added. If the ammonia completely decolorises the solution, iodine solution is added drop by drop to restore the colour. At the expiration of an hour, and after filtration if necessary, iodoform solution is added, and the solution examined microscopically. Acicular crystals of iodoform indicate the presence of aromatic inner anhydrides, such as coumarin, or of aromatic hydroxy-acids with long side-chains, or of polyhydroxyketones. G. C. J.

Estimation of Active Hydrogen in Organic Molecules. B. Oddo. (*Ber.*, 1911, **44**, 2048-2052.)—The author has introduced a gravimetric modification of Zeriwitinoff's method for the estimation of active hydrogen atoms in organic compounds by means of organo-magnesium iodides. The method depends on the reaction between ethyl-magnesium iodide and organic compounds containing OH, NH_2, NH, or SH groups, both reagents being dissolved in anhydrous solvents. For the magnesium compound the author uses isoamyl ether as the solvent, whilst for the substance to be tested anhydrous pyridine generally gives the most reliable results. In the preparation of the magnesium compound it is advisable to take rather less than the theoretical quantity of ethyl iodide, so that there may be no danger of an excess of this reagent passing away with the ethane. The apparatus employed for the estimation consists of two thin, short-necked flasks of about 50 c.c. capacity. The first flask holds the solution of the substance under examination, and is connected with the second flask by means of a tube leading from the top of the first flask to the bottom of the second. The second flask, containing the solution of the magnesium compound, is also connected with a bulb-absorption apparatus having a filter of tightly packed glass wool next to the flask, and charged with concentrated sulphuric acid. The whole apparatus is tared, together with the solutions of the reagents, and is then connected up with a U-tube containing potassium hydroxide and calcium chloride, to the further end of which is attached a bottle containing alkaline pyrogallol solution, to exclude atmospheric oxygen. A small amount of air is sucked out of the apparatus by means of the mouth, so that when the suction is relieved some of the magnesium solution passes up the tube from the second flask into the first. Reaction takes place, with evolution of ethane, and when the evolution subsides a further quantity of the magnesium reagent is passed over into the first flask. The second flask is cooled in an ice-bath, and the heat of reaction in the first flask is moderated by occasional application of cold water. Finally the reaction is completed by immersing the first flask in water at 50° to 60° C. The apparatus is cooled, disconnected from the U-tube and weighed again, the loss of weight representing the quantity of ethane evolved. This method possesses the advantage that larger quantities of the substance may be taken for the estimation than with the gasometric method. The values obtained agree sufficiently closely with the theoretical, and are calculated in terms of hydroxyl or "active hydrogen." The method is applicable in the case of oximes, camphoroxime showing 1 atom of active hydrogen. J. F. B.

Characteristic Colour Reaction of Ovolecithin. C. Casanova. (*Boll. Chim. Farm.*, 1911, **50**, 309-313; through *Chem. Zentralbl.*, 1911, II., 231.)—For the detection of lecithin the liquid under examination is heated for some time at 50° to 60° C. (to expel any alcohol which would interfere with the reaction), and extracted with ether, and the ethereal extract concentrated and treated with 2 c.c. of 10 per cent. ammonium molybdate solution, and then with concentrated sulphuric acid. In the presence of lecithin there is produced a cherry-red zone which gradually changes through greenish-yellow into deep blue. Cholesterol and phytosterol do not interfere with the reaction. In the presence of oxygen lecithin may be decomposed, through the absorption of one molecule of water into the ester of glycerophosphoric acid and choline, and by further absorption of water glycerophosphoric acid is liberated. Upon these facts is based a method of detecting adulteration, the total acidity being first estimated, and then the glycerophosphoric acid as phosphoric acid by means of uranium acetate in the ash of the ethereal extract. In an aqueous solution of lecithin the acidity rises considerably under the influence of light and oxygen, whilst in an alcoholic solution no such action takes place.

C. A. M.

Estimation of Pentosans and Methylpentosans in Cereals and Wood-Fungi. M. Ishida and B. Tollens. (*J. f. Landw.*, 1911, **59**, 59; through *Wochensch. Brau.*, 1911, **28**, 300.)—Most plant tissues contain both pentosans and methylpentosans, which yield a mixture of furfural and methylfurfural on distillation with hydrochloric acid. These bodies are estimated by precipitation as phloroglucides. But the methylpentosans yield less methylfurfural on distillation than the pentosans yield furfural; consequently, the value for methylpentosans is low if calculated by the same factor as that used for the pentosans. The methylfurfural phloroglucide is estimated by extracting it from the mixture of phloroglucides by means of hot alcohol, in which it is soluble, whereas the furfural phloroglucide is insoluble. The authors have estimated the pentosans and methylpentosans separately in a number of cereal grains and wood-fungi, and have arrived at the conclusion that if the mixed phloroglucides be calculated in terms of pentosans, as was formerly the custom, the value so obtained when multiplied by 1·1 will give the sum of the pentosans and methylpentosans present in the substance. J. F. B.

Titration of Potassium Cyanide in Presence of Potassium Ferrocyanide. W. D. Treadwell. (*Zeitsch. anorg. Chem.*, 1911, **71**, 219-225.)—Liebig's method for the titration of cyanide in presence of chloride and thiocyanate breaks down in presence of potassium ferrocyanide, which tends to dissolve silver cyanide and leads to high results. Denigès (*Ann. Chim. Phys.*, 1895, [VII.] **6**, 381) and Sharwood (*J. Amer. Chem. Soc.*, 1897, **19**, 400) have stated that addition of ammonia and a trace of potassium iodide greatly increases the sharpness of Liebig's method. The author finds the addition of the large quantities of ammonia recommended by Denigès and Sharwood are unnecessary, and even inadvisable. The conditions of success are faint alkalinity and sufficient dilution. The solution of cyanide to be titrated should not be above decinormal strength. If to such a solution, rendered faintly alkaline, 1 grm. of potassium iodide be added, the cyanide may be estimated with accuracy by titration with silver nitrate, even in presence of ten times its weight of ferrocyanide. A smaller quantity of potassium iodide (*e.g.*, 0·1 grm.) serves equally well if ferrocyanide be the only disturbing substance present, but the use of the larger quantity is recommended if thiosulphate may be present. The use of 1 grm. of iodide renders the estimation of cyanide exact in presence of half its weight of thiosulphate, but the disturbing effect of higher concentrations of thiosulphate cannot be wholly overcome by addition of iodide. The author advances a theory of the titration in support of which he adduces experimental proofs. G. C. J.

Phosphotungstic Acid Precipitation of Proteins. E. Wechsler. (*Zeitsch. physiol. Chem.*, 1911, **73**, 138-143.)—The author states that phosphotungstic acid precipitates of proteins can be readily decomposed by means of barium hydroxide if the precipitate be treated previously with acetone and water. The precipitate is completely or partially brought into solution in the mixture of acetone and water, and the barium hydroxide is then added. In some cases it is necessary to grind the precipitate in a mortar with the acetone, water, and barium hydroxide, in order to decompose it completely, whilst in other instances it is sufficient to add a small quantity of acetone to the precipitate mixed with water to obtain a readily filterable solution from which the phosphotungstic acid may be precipitated by barium hydroxide. The precipitates obtained with different proteins require various proportions of acetone and water, but a mixture of 4 volumes of acetone with 3 volumes of water will generally answer the purpose. W. P. S.

Composition of Mineral Lubricating Oils of High Boiling-Point. J. Marcusson. (*Chem. Zeit.*, 1911, **35**, 729-731; 742-744.)—The chief constituents to which mineral machine oils owe their lubricating power are those that do not react with formaldehyde and sulphuric acid. The constituents which do combine to yield "formolites" have a higher sp. gr. and refractive power, but a lower viscosity than the original oils. In applying the formolite test, 27 grms. of the oil are dissolved in 50 c.c. of normal petroleum spirit (benzine), and the solution treated, without shaking, with 30 c.c. of concentrated sulphuric acid. The mixture is cooled in ice-water, and, after the addition of 15 c.c. of 40 per cent. formaldehyde solution, it is shaken and cooled until no further evolution of heat is perceptible. The contents of the flask are allowed to stand for thirty minutes and then poured into a litre flask containing 200 c.c. of ice-water, the acid liquid neutralised with ammonia and the precipitate separated, washed with petroleum spirit until free from oil, and then with water until free from ammonia, and dried at 105° C. until constant in weight. The constituents of the oil that do not react with formaldehyde and sulphuric acid are estimated by evaporating the petroleum spirit solution and weighing the residue. They may include olefines, naphthenes, polynaphthenes and paraffins. The results thus obtained in the examination of American and Russian machine oils showed that in general the yield of formolite increased with the rise in the viscosity, in the case of refined oils. The American oils gave higher yields than the Russian oils, as is shown in the following table:

	Formolite Precipitate.	Residual Oil.	Sp. Gr. at 15° C.		$[N]_{D15°}$ C.		Viscosity at 20° C. (Engler's).	
			Original Oil.	Residual Oil.	Original Oil.	Residual Oil.	Original Oil.	Residual Oil.
	Per Cent.	Per Cent.						
American oil, refined	28·9	74·3	0·8910	0·8856	1·4962	1·4883	11·0	14·9
,, ,, ,,	30·0	75·2	0·9207	0·9064	1·5168	1·5022	24·4	28·4

,, ,, ,,	24·4	78·7	0·9108	0·9070	1·5015	1·4968	62·0	70·8

As a rule, American machine oils contain more unsaturated hydrocarbons than Russian oils, the higher iodine value of the former being due, not only to unsaturated alicyclic hydrocarbons, but also to aliphatic hydrocarbons. On the other hand, Russian oils contain a greater proportion of saturated hydrocarbons not attacked by fuming nitric acid than do American oils. Both oils yield dinitro derivatives containing about 7 per cent. of nitrogen. The optical activity of machine oils is due, in the main, to saturated hyrocarbons, probably condensed naphthenes.

C. A. M.

Detection of Petroleum Pitch in Fat Pitch. J. Marcusson. (*Zeitsch. angew. Chem.*, 1911, **24**, 1297-1302.)—If the saponification value of a pitch-like distillation residue is lower than 33 (the minimum recorded for fat pitches), the presence of petroleum pitch or other foreign body is indicated, whilst a value of about 100 (106 highest limit for fat pitches) indicates that the product is pure. In the case of mixtures with saponification values between these limits, information is afforded by an examination of the unsaponifiable matter. Thus, if it is a powder and not viscid like the orginal material, the sample consisted of fat pitch free from petroleum residues. The same conclusion may be drawn when the oily constituents obtained after treatment with petroleum spirit and sulphuric acid do not exceed 15 per cent. of the original pitch, and have an $[N]_{D 15°}$ C. of less than 1·510. A still more reliable test may be based upon the separation of the double compound formed with mercuric bromide by the organic sulphides in petroleum pitch. Mixtures of petroleum pitch and fat pitch yield this compound, but the presence of free fatty acids retards its formation. For the detection of small quantities of petroleum pitch the following modification of the test of Malencovic is recommended: 10 grms. of the sample are dissolved in 25 c.c. of hot benzene, and the cold solution treated with 30 c.c. of $\frac{N}{2}$ alcoholic potassium hydroxide solution, and then rapidly diluted with about 200 c.c. of 96 per cent. alcohol. After standing for a short time, the solution of saponified fatty acids is decanted, and the residual pitch washed with a little alcohol, the last traces of which are afterwards removed as completely as possible with the aid of a water-pump, and by drying the residue at 105° C. The pitch is then dissolved in 100 c.c. of ether, heated beneath a reflux condenser, whilst a little calcium chloride is added to absorb any water. The solution is cooled and filtered, and the filtrate treated with 20 c.c. of mercuric bromide solution (5 grms. in 250 c.c. of ether), and allowed to stand overnight. Any deposit is collected, washed with ether, and dissolved off the filter by means of hot benzene, which will leave undissolved any mercuric bromide that may have separated at the same time. The benzene solution is evaporated, and the mercuric bromide double compound will be left as a dark brown or black spongy mass, which when heated in a tube decomposes with the formation of a spongy mass of carbon, and in which sulphur may be detected by the usual method (distinction from mercuric bromide.) Coal-tar pitch forms a similar compound, but may be distinguished from petroleum pitch by methods previously described (see ANALYST, 1911, 227), whilst brown coal-tar pitch may be recognised by Graefe's diazobenzene chloride reaction (ANALYST, 1906, **31**, 204; 1908, **32**, 477; 1911, *loc. cit.*). C. A. M.

Estimation of Rosin in the Residues from the Distillation of Coal Tar. Holde and F. Meister. (*Chem. Zeit.*, 1911, **35**, 793-794.)—From 10 to 20 grms. of the mixture of coal-tar distillation residue and rosin (or 2·5 to 5 grms. when the amount of rosin exceeds 4 per cent.) are extracted with 200 c.c. of ether beneath a reflux condenser, and the insoluble residue washed three times with ether. The filtrate is shaken with successive portions of 30 c.c. of $\frac{N}{10}$ sodium hydroxide solution until the aqueous layer appears colourless, the resulting soap solution shaken twice with 50 c.c. of ether, and the united ethereal extracts once more shaken with 30 c.c. of the alkali solution. The united alkaline extracts containing the colophony are shaken with ether and an excess of dilute sulphuric acid in a separating funnel, the ethereal solution of the liberated abietic acid is washed free from mineral acid, after the addition of concentrated sodium sulphate solution, then filtered, concentrated to 100 c.c. on the water-bath, heated for about ten minutes with 0·5 grm. of dry bone charcoal to remove the dark resinous substances derived from the coal tar, and filtered. The filtrate and washings are evaporated, and the residue dried for five minutes at 105° C. and weighed. An addition of 8 per cent. is made for the substances in the colophony not soluble in the sodium hydroxide solution. This correction has been empirically determined. The results thus obtained with test mixtures containing from 1·5 to 14 per cent. of rosin were in close agreement with the theoretical amounts. C. A. M.

Detection of Salicylic Acid. H. C. Sherman and A. Gross. (*J. Ind. and Eng. Chem.*, 1911, **3**, 492-493.)—The ferric chloride reaction for salicylic acid is not characteristic of this substance, the compounds maltol and iso-maltol, present in small quantity in certain foods, giving a similar coloration. Jorissen's reaction has been found useful for distinguishing these substances, the authors' modified method of carrying out the test in the case of small quantities of salicylic acid being as follows: To the solution to be examined 4 or 5 drops of sodium or potassium nitrite solution (10 per cent.), the same quantity of acetic acid (50 per cent.), and 1 drop of copper sulphate solution (1 per cent.) are added, shaking after addition of each reagent. The solution is heated for forty-five minutes in a boiling-water bath, the liquid in the tube being completely immersed in the hot water. After allowing to cool, the tube is examined against a white background both vertically and horizontally, and is compared with a blank test with water to which the reagents have been added. By this test 0·005 to 0·010 mgrm. of salicylic acid can be detected. If considerable amounts of salicylic acid are present, a stronger solution of copper sulphate may be used, and for qualitative results a shorter time of heating is sufficient. The red colour of this test is stable, and the results are quantitative. The authors confirm Allen's observation that benzoic, cinnamic, and tartaric acid do not give a coloration, and find that maltol, iso-maltol, methyl-ethyl-aceto-acetate, orcin, arbutin, resorcin, and phlorizin, all of which give some coloration with ferric chloride, do not respond to this test. A. R. T.

Analysis of Shellac and Shellac Varnish. A. C. Langmuir and F. S. White. (*J. Soc. Chem. Ind.*, 1911, **30**, 786-789.)—The authors return to the question as to the comparative merits of the Hübl and Wijs methods of determining the percentage of iodine absorbed by mixtures of shellac and rosin. Both methods are shown to be affected by time and temperature of the reaction. The authors adhere to previously published figures as to the iodine values for these substances, and hold that the Wijs method is more accurate, since there is a difference of 210 units between its values for shellac and rosin (228 and 18), while in the case of the Hübl method this difference is only 115 (125 and 10). (*Cf.* ANALYST, 1905, **30**, 164). The Hanus modification possesses no advantage over these methods. Endemann's condensation method (ANALYST, 1907, **32**, 425) for the determination of the purity of shellac is stated to be unreliable.

The authors determine the proportion of *wax* in shellac as follows: 100 grms. of the sample are dissolved in 500 c.c. of water containing 20 grms. of sodium carbonate. The liquid is decanted from insoluble matters, and the suspended wax taken out of the liquid by adding a known weight (about 15 grms.) of paraffin wax to the boiling liquid. After standing till cold, the paraffin cake is removed, dried, and weighed. Small detached particles of paraffin wax are recovered by filtering the liquid, drying the residue, washing the wax through the filter by means of petroleum spirit, and evaporating the solvent, when the residue is weighed and the weight added to the main portion. The increase in weight of the paraffin gives the amount of shellac wax.

Arsenic may be determined by the two following methods, according as it is present in large or small amounts:

1. Two grms. of shellac are boiled with 50 c.c. of strong sulphuric acid and

15 grms. of potassium sulphate until all organic matter is destroyed, when the solution is diluted and hydrogen sulphide passed through the liquid. The precipitated arsenic sulphide is filtered, dissolved in ammonium carbonate, and the solution acidified, when the pure sulphide is dried and weighed. Some arsenic is dissolved by fused shellac, and the above method gives the total arsenic. Orpiment may be estimated by dissolving 100 grms. of shellac in alcohol, and washing by decantation. The residue is then oxidised by nitric acid, and the solution evaporated with sulphuric acid till fumes are evolved. Hydrochloric acid and ferrous sulphate are then added and the liquid distilled as usual, and the arsenic determined in the distillate.

2. The detection of traces of arsenic may be made by a modification of the Gutzeit or Marsh-Berzelius method. Ten grms. of the shellac are dissolved by heating with 50 c.c. of arsenic-free nitric acid, and, after a few minutes' boiling, 15 c.c. of arsenic-free sulphuric acid are added, and the liquid boiled till fuming. A practically dry mass of carbon is left. This is evaporated with 50 c.c. of saturated sulphurous acid solution to dryness, and 60 c.c. of water are then added, the liquid boiled down to 40 c.c., and the solution filtered and made up to a known bulk (75 c.c.). An amount of solution corresponding to 2 grms. of shellac is taken, and the arsenic determined by colorimetric comparison in the Gutzeit or similar apparatus.

Careful sampling from a large bulk of shellac is shown to be necessary, different portions frequently containing widely different proportions of rosin. The sp. gr. of an orange shellac was found on immersion to be 1·1141, and by floating 1·1350, at 15·5°/15·5° C. The difference is due to the presence of numerous "air-cells" in shellac.

Shellac Varnish.—Wood spirit and denatured grain alcohol are the usual solvents. The boiling-point of varnish prepared with the former, determined by heating the varnish in a large test-tube and holding the thermometer just above the liquid, will approximate 68° C., and 78° C. for denatured grain spirit.

To detect methyl alcohol in grain alcohol, the presence of acetone from the wood alcohol added to the grain alcohol is relied on. The alcohol is distilled from 150 c.c. of sample, and then redistilled, using a Linnemann fractionating tube, collecting the first 5 c.c. This is diluted to 100 c.c. with water, and 4 c.c. of the solution heated in a boiling water-bath for ten minutes with 4 c.c. of a solution of 5 grms. of precipitated mercuric oxide in 100 c.c. water and 20 c.c. sulphuric acid. A white precipitate, appearing in a few minutes, is produced in the presence of acetone. One per cent. of denatured alcohol in the grain alcohol may be detected, and 2 per cent. gives a distinct reaction.

The weight or body of shellac varnish is expressed in pounds of shellac per gallon of alcohol taken. It may be determined by weighing 0·5 to 1 grm. in a weighing-bottle, transferring with alcohol to a weighed dish containing 10 grms. ignited sea sand and a stirring-rod, and heating for just one hour at 110° C. Since even at this temperature shellac holds some water, the weight of residue is multiplied by 0·96 in the case of white shellac, and 0·98 for orange shellac.

The addition of water or "benzine" to the alcohol in shellac varnish may be determined by taking the sp. gr. of the distillate, or by diluting the varnish, when the "benzine" will separate. Spirit-soluble copals, sandarac, and rosin are added to shellac varnish as adulterants. Wijs's iodine solution, diluted with 2 parts by volume of glacial acetic acid, may be used to detect these substances. A few drops of varnish are added to 2 to 3 c.c. of this diluted Wijs's solution. Pure shellac remains unchanged in colour, except on long standing. Rosin gives an immediate reddish coloration. Copal and sandarac yield a red colour (less pronounced than in case of rosin) and a curdy precipitate. This precipitate is also formed when an alcoholic solution of copal or sandarac is diluted with glacial acetic acid, or when a large excess of alcohol is added. Shellac wax settles after dilution, but it can be distinguished from the above precipitate. The odour of copal and sandarac, when the varnish is rubbed between the fingers, is characteristic. If rosin alone is present with the shellac, a rough approximation of its amount, by comparison with standards, may be made with the above colour test. An alcohol-soluble casein preparation, met with as an adulterant, was detected by means of the high proportion of ash, which contained boric acid. A. R. T.

INORGANIC ANALYSIS.

Estimation of Arsenic and Iron Salts in Mineral Waters. F. Ageno and N. Guicciardini.—(*Gazz. Chim. Ital.*, 1911, **41**, 473-478.)—The author describes an indirect method of estimating arsenic and iron salts in mineral waters by means of acid permanganate. C. A. M.

Detection and Estimation of Calcium Cyanamide in the Presence of Other Fertilisers. L. Vauflart. (*Ann. Falsif.*, 1911, **4**, 321-324.)—Calcium cyanamide may be detected in mixtures containing organic and other substances by the odour of acetylene which is evolved when the mixture is moistened (calcium cyanamide usually contains traces of calcium carbide), by the black carbonaceous residue remaining after extraction with water, and by the yellow precipitate which is formed when an aqueous solution of the fertiliser is treated with silver nitrate; this precipitate is insoluble in ammonia, soluble in nitric acid, and frequently contains a small quantity of silver acetylide, which remains as a black powder when the yellow precipitate is dissolved in nitric acid. Treatment of the fertiliser with mineral acids also affords information of the presence of calcium cyanamide and of the character of some of the other constituents. As regards the estimation of cyanamide, the author finds that, whilst Brioux's method (ANALYST, 1910, **35**, 486) yields satisfactory results in the case of cyanamide itself (on an average, 87·3 per cent. of the total nitrogen is found to be present as cyanamide nitrogen), the results obtained in the case of mixtures are much too low. This is due to the fact that the rate at which cyanamide is converted into dicyandiamide is considerably accelerated in the presence of such substances as superphosphate, etc. If, however, both the cyanamide nitrogen and the dicyandiamide nitrogen be estimated as described by Brioux (*loc. cit.*), the result obtained will be a measure of the calcium cyanamide in a mixture, it being taken into account that only 87·3 per cent. of the cyanamide nitrogen is thus found. For instance, a fertiliser consisting of phosphate, potassium salts, calcium cyanamide, and dried blood, and stated to contain equal quantities of the two latter substances, yielded 5 per cent. of total nitrogen. The cyanamide (*plus* dicyandiamide) nitrogen amounted to 2·3 per cent., corresponding with 17·7 per cent. of calcium cyanamide. As 17·7 per cent. of calcium cyanamide containing 15 per cent. of total nitrogen would yield 2·65 per cent. of nitrogen, the difference between the latter figure and the total nitrogen represents the organic nitrogen; this amount, 2·35 per cent., corresponds with 19·5 per cent. of dried blood containing 12 per cent. of nitrogen (*cf.* ANALYST, 1911, 429). W. P. S.

Oxidation of Ferrous Salts. C. Baskerville and R. Stevenson. (*J. Amer. Chem. Soc.*, 1911, **33**, 1104-1106.)—Experiments are described which show that the tendency of ferrous salts in acid or neutral solution to undergo oxidation by the air has been greatly exaggerated. In one experiment a stream of air was passed for three hours through a solution containing 0·7 grm. of ferrous iron, and at the end of that time only 0·1 mgrm. of ferric iron was found. Addition of chromium, copper, manganese, nickel, titanium, vanadium, and tungsten, and of the ordinary dust of the laboratory air, had no measurable accelerating influence on the oxidation. The conclusion is drawn that ferrous iron, in acid and neutral solution, at room temperature, is so slowly oxidised, and that this oxidation is so slightly affected by such substances as are apt to be present, that expulsion of air after reduction by zinc is unnecessary, and the titration may be performed at leisure in ordinary determinations of iron by means of permanganate. G. C. J.

Volumetric Estimation of Lead Peroxide. J. F. Sacher. (*Chem. Zeit.*, 1911, **35**, 731.)—The method of Lux (*Zeitsch. anal. Chem.*, **19**, 153), in which red lead is decomposed with nitric acid, the liquid boiled with oxalic acid to dissolve the lead peroxide, and the excess of oxalic acid titrated with permanganate, gives too low results, owing to the fact that a portion of the lead peroxide is dissolved by the nitric acid. To the same cause must also be attributed the errors in the electrolytic estimation of lead as peroxide from a nitric acid solution, whereas by adding oxalic acid prior to the nitric acid the method is satisfactory. The lead may also be precipitated by means of sulphuric acid before the titration with potassium permanganate, as suggested by Tocher (*Farben-Zeit.*, 1899-1900, 214). There is no need to separate the lead sulphate, and the analysis may be completed in twenty to twenty-five minutes. Forestier's gravimetric method of estimation (*Zeitsch. angew. Chem.*, 1898, **11**, 176), which is based upon a treatment of the red lead with hot acetic acid and estimating the insoluble residue of lead peroxide either gravimetrically or volumetrically, gives inaccurate results, since lead peroxide is reduced by hot acetic acid. C. A. M.

Estimation of Nitrate. G. Romijn. (*Zeitsch. anal. Chem.*, 1911, **50**, 566-570.)—Dilute solutions of nitrates are reduced quantitatively to nitrite by pure zinc dust in presence of ammonia and an ammonium salt. The nitrite is then determined volumetrically, or, if present in minute amount only, colorimetrically. Iron salts must be absent, or partial reduction to ammonia may result. Into a 100 c.c.

measuring flask there is placed 5 c.c. of a solution made by dissolving 100 grms. of ammonium sulphate in water, adding 100 c.c. of ammonia (sp. gr. 0·96), and diluting to 300 c.c. The flask is next filled to the mark with the water to be tested, which should not contain more than 400 mgrms. NO_3 per litre. A mixture in equal proportions of pure zinc dust and kieselguhr (200 mgrms.) is added, the whole well shaken, and allowed to stand five minutes. The solution is filtered, the first runnings rejected, and 50 c.c. of the clear filtrate taken for the determination of nitrite. If this be large in amount, 10 c.c. of $\frac{N}{10}$ permanganate and 5 c.c. of sulphuric acid (sp. gr. 1·124) are shaken with the solution in a stoppered flask, which is then set aside for fifteen minutes. Potassium iodide (0·5 grm.) is then added, and the liberated iodine, equivalent to the excess of permanganate taken, is estimated by means of thiosulphate. Smaller amounts of nitrite are determined colorimetrically, and for this purpose the author recommends the use of a dry mixture of α-naphthylamine (1 part), sulphanilic acid (10 parts), tartaric acid (100 parts). This mixture keeps indefinitely, and, when using it, no other acid need be added. G. C. J.

Rapid Method for the Estimation of Nitrates. A. Quartaroli. (*Staz. sperim. agrar. Ital.*, 1911, **44**, 157-164; through *Chem. Zentralbl.*, 1911, II., 49-50.)—The method depends on the action of anhydrous formic acid on nitrates, according to the equation:

$$2KNO_3 + 6H.COOH = N_2O + 4CO_2 + 5H_2O + 2H.COOK.$$

From 0·1 to 0·3 grm. of the nitrate is gently heated with 5 c.c. of formic acid in a test-tube of 15 c.c. capacity; this tube is provided with a cork and delivery-tube, and the evolved gases are collected over mercury in a nitrometer. After the volume of the gas has been noted, 2 c.c. of concentrated potassium hydroxide solution are introduced into the nitrometer, the latter is shaken, and the volume of the gas is again noted. The first reading gives the volume of the nitrous oxide and carbon dioxide, the second that of the nitrous oxide alone. The temperature and pressure being known, the quantity of nitrate in the sample may then be calculated. The results obtained agree closely with those found by the Schulze-Tiemann method.

W. P. S.

Action of Hydrazine Sulphate on Nitrites, and a Method for the Estimation of Nitrite Nitrogen. B. B. Dey and H. K. Sen. (*Zeitsch. anorg. Chem.*, 1911, **71**, 236-242.)—When excess of hydrazine sulphate is allowed to act on a solution of any ionised nitrite, nitrogen, nitrous oxide, and ammonia result, in accordance with the following equation:

$$2NH_2.NH_2 + 3ON.OH = NH_3 + 2N_2O + N_2 + 4H_2O.$$

If the reaction be allowed to take place in a nitrometer, the ammonia and a considerable proportion of the nitrous oxide (depending on the amount of water present) remain in solution. If the gas be washed three or four times with 20 c.c. of water, the last of the nitrous oxide may be removed and the residual nitrogen measured. This nitrogen is two-thirds of that originally present as nitrite. The method has been applied successfully to some fifty nitrites including tetramethylammonium nitrite, benzylamine nitrite, as well as the nitrites of the alkalis, alkaline earths, and heavy metals. On the other hand, amyl nitrite, and, in general, non-ionised nitrites, do not give rise to any evolution of gas when brought in contact with hydrazine sulphate. G. C. J.

Analytical Examination of Commercial Oxygen. C. Baskerville and R. Stevenson. (*J. Ind. and Eng. Chem.*, 1911, **3**, 471-476.)—The compressed oxygen from a cylinder was first passed through a trap to catch any solids and liquids, and in this trap were contained red and blue litmus-paper and starch-potassium-iodide paper, for the detection of acids, alkalis, halogens, and ozone. Moisture was determined quantitatively by means of two weighed U-tubes next in order in the series, these tubes containing phosphorus pentoxide on glass-wool, and the second one being a check on the accuracy of the first tube. A calcium chloride tube was then interposed to protect these moisture-tubes from the moistening-bottle. This bottle, next in order, contained a moist, porous, cotton rope, through which the gas is passed, the rope being at its lower end immersed in the water in the bottle. The moisture in the rope is insufficient to absorb impurities from the gas, but it allows of a repeat test on *moistened* gas with the previously-mentioned reaction papers, which in the form of three successive cones were placed in the tube leading from the moistening-bottle. The gas was next passed through nearly-saturated caustic baryta solution, which showed the presence or absence of carbon dioxide, and at the conclusion of the test was divided into three parts for the following tests: (1) SO_3, after addition of hydrochloric acid; (2) for halogens and halogen acids and oxides of chlorine, by addition of nitric acid and silver nitrate; (3) this was set aside. Caustic soda solution (2:3) was in the next container, and after the experiment this was tested as follows, after division into three parts: (1) for CO_2, SO_2, and SO_3, by addition of barium chloride, and hydrochloric acid in excess; (2) for SO_2, H_2S, halogens, halogen acids, and chlorine oxides, by acidification with nitric acid, addition of ammonia till alkaline, then silver nitrate, and reacidification with nitric acid; (3) this was mixed with the reserved portion of the baryta solution, and tested for hydrocyanic acid and cyanogen by the Prussian blue test.

The gas was next passed through silver nitrate solution, which repeats some of the previous tests, and also shows PH_3, SbH_3, and AsH_3. Next two calcium chloride tubes were used to dry the gas, which was then passed through the CuO furnace, thus oxidising the hydrogen and any organic compounds. Two weighed calcium chloride tubes take up the water formed, and the carbon dioxide was obtained by weighing the next apparatus containing baryta solution. Solid caustic soda in the next tube served as a guard for the baryta apparatus. The gasometer received the gas after passing through the various items of the apparatus, and the oxygen was there measured, 10 to 18 litres passing in three to six hours.

A separate experiment was made for the following: A trap containing litmus-paper and starch-KI paper repeated the previous observations. Next the gas passed through starch-KI solution as a test for ozone, and portions of this solution were tested before and after with methyl-orange and phenolphthaleïn to indicate acids and bases in the gas. A slightly acid solution of ferrous sulphate was next in order, and this was titrated before and after the passage of the oxygen to determine active oxidising compounds, oxygen having no effect under these conditions. Very dilute permanganate solution, lastly, served to detect reducing agents. Oxygen itself was determined direct by alkaline pyrogallol solution, and the nitrogen and rare atmospheric gases obtained by difference. N_2O could not be tested for. Organic matter was generally absent. Carbon dioxide was separately determined by absorption in sodium hydroxide solution (2 : 3) saturated with oxygen. Analyses of seven samples of commercial oxygen gave results showing 92·8 to 99·2 per cent. of oxygen, 0·25 to 6·9 per cent. of nitrogen and inert gases, moisture up to 0·15 per cent., CO_2 up to 0·11, hydrogen 0·14 per cent. (only in one sample), and all other impurities absent.

A. R. T.

Detection of Perborates and Similar Compounds. W. Lenz and E. Richter. (*Zeitsch. anal. Chem.*, 1911, **50**, 537-544.)—To distinguish sodium perborate from borax, a little potassium bichromate solution is added to the aqueous solution, which is then shaken with ether. In presence of perborate the ether is coloured blue by perchromic acid. The reaction is due to hydrogen peroxide, and is given by potassium percarbonate, but not by ammonium persulphate, potassium perchlorate, or periodic acid.

Solutions of perborates (which are alkaline, owing to partial decomposition by water) decolorise permanganate with separation of manganese peroxide. In presence of acid no separation of peroxide occurs, but the colour of the permanganate is discharged. Percarbonates (and hydrogen peroxide) behave similarly, and perborates and percarbonates can be titrated with permanganate. Ammonium persulphate in acid solution has no action on permanganate in the cold, and the action is feeble at higher temperatures; in alkaline solution it slowly decomposes permanganate in the cold, with separation of manganese peroxide, and the action is increased by heating. Potassium perchlorate in acid solution has no action on permanganate; in alkaline solution it slowly transforms the violet colour to blue, the action being more marked at higher temperatures. Periodic acid has no action on permanganate.

When silver nitrate in not too small amount is added to a solution of sodium perborate, a heavy, black precipitate separates at once. This is easily washed by decantation, and is then insoluble in 10 per cent. ammonia. Solutions of perborates acidified with nitric acid give no reaction with silver nitrate. In ammoniacal solution, silver nitrate gives no immediate precipitate, but on standing, and more quickly on warming, gas is evolved, a silver mirror deposited, and the solution acquires the blue colour of molecular silver. Potassium percarbonate gives a white precipitate with silver nitrate in the cold, but the colour passes through yellow to grey on warming. The precipitate is insoluble in 10 per cent. ammonia. In nitric acid solution, percarbonates give no reaction with silver nitrate, nor do they give any reaction in an ammoniacal solution until this is boiled, when the blue colour of molecular silver appears. Ammonium persulphate gives this blue colour in neutral solutions, whilst in nitric acid solution it is coloured yellow, and in ammoniacal solution silver nitrate decomposes it with evolution of gas, but without the formation of any precipitate. Potassium perchlorate is unacted on by silver nitrate. In aqueous solution, periodic acid gives with silver nitrate a yellow precipitate, consisting of doubly refractive rhombohedra, which are soluble in ammonia, but not in a cold solution of thiosulphate and sulphurous acid. In cold ammoniacal solution, periodic acid gives, with silver nitrate, a faint brown coloration, which gives place to a dark brown precipitate on warming.

The capacity to peroxidise manganous hydroxide was determined as follows: Into each of a number of test-tubes, 3 to 5 c.c. of a 1 per cent. solution of manganous sulphate was placed, dissolved oxygen expelled by boiling, the solution cooled to 60° C., covered with petrol, and allowed to cool completely. A few drops of caustic soda solution were then added to the contents of each tube, when a nearly white precipitate resulted. To one tube 3 to 5 c.c. of ordinary distilled water, not freed from air, was added as control, and to the others 3 to 5 c.c. of each of the solutions to be tested. Sodium perborate and percarbonate in 0·08 per cent. solution caused a distinct darkening of the precipitate; potassium persulphate and periodic acid in 0·02 per cent. solution produced an equal darkening, whilst potassium perchlorate had no effect.

Cobalt hydroxide, similarly protected from aerial oxidation, was tried as reagent, 3 to 5 c.c. of a 0·25 per cent. solution of the nitrate being precipitated by caustic soda. In a blank experiment the precipitate passes from blue to pale pink, and darkens very slowly. Two drops of a 1 per cent. solution of sodium perborate produce a distinct brown colour, and the same tint is given by 6 drops of potassium percarbonate or 1 drop of ammonium persulphate (all in 1 per cent. solution). Potassium perchlorate and periodic acid are without effect.

A 1 per cent. solution of nickel sulphate, treated in a similar manner to the cobalt nitrate, gave no reaction with perborate, percarbonate, perchlorate, or periodic acid. On the other hand, it proved a very sensitive reagent for ammonium persulphate, as little as 2 drops of a 0·1 per cent. solution giving rise to a black precipitate.

Sodium perborate and potassium percarbonate and perchlorate give no reaction with basic lead acetate solution, whereas periodic acid gives a heavy, white, microcrystalline precipitate, even in very dilute solution. Ammonium persulphate in concentrated solution gives after a time a yellow precipitate with basic lead acetate. Hydrogen peroxide renders basic lead acetate solution turbid and dark, but the reaction is not given by dilute solutions, and disappears on boiling.

Solutions of cerous chloride, to which a few drops of ammonia have been added, are coloured yellow by hydrogen peroxide, sodium perborate, and potassium percarbonate. The reaction will detect 0·03 mgrm. hydrogen peroxide, 0·5 mgrm. perborate, or 2 mgrms. percarbonate. Ammonium persulphate, potassium perchlorate, and periodic acid, give no reaction.

In absence of free acid, only ammonium persulphate of the salts here considered liberates iodine from potassium iodide. In presence of sulphuric acid, perborate and percarbonate act similarly, but perchlorate is without effect. None of the salts liberate bromine from potassium bromide.

Sodium perborate and potassium percarbonate decolorise a solution of 0·05 grm. fuchsin and 12 grms. sodium acetate in 100 c.c. water. The colour is not restored on dilution, but the decolorised solution acquires a yellow tint when acidified with acetic acid. Ammonium persulphate slowly decolorises fuchsin, but to observe the reaction the fuchsin solution must be added drop by drop to a large bulk of the persulphate solution. Potassium perchlorate is without action on fuchsin.

When a 1 per cent. solution of sulphuric acid is saturated with aniline, filtered, mixed with an equal bulk of a 1 per cent. solution of perborate or percarbonate, and heated to boiling, a faint yellow colour is developed. Ammonium persulphate in 1 per cent. solution gives rise to a dark brown when tested in a similar manner, and as little as 0·5 mgrm. may be detected by means of aniline sulphate. The reagent is unaffected by perchlorate. G. C. J.

Volumetric Estimation of Phosphoric Acid. J. Rosin. (*J. Amer. Chem. Soc.*, 1911, **33**, 1099-1104.)—Of the methods depending on the precipitation of phosphoric acid by silver nitrate, with subsequent estimation of the excess of silver by Volhard's method, that of Holleman (*Zeitsch. anal. Chem.* 1895, **34**, 85) is the best; but the results are too high owing to co-precipitation of silver acetate if a large excess of sodium acetate is used, and too low if only a small excess of sodium acetate is used. In contradiction to the statements in the textbooks, the reaction between silver nitrate and sodium phosphate is shown to proceed in accordance with the equation: $3Na_2HPO_4 + 6AgNO_3 = 2Ag_3PO_4 + 6NaNO_3 + H_3PO_4$. This phosphoric acid must be neutralised if its precipitation by silver is to be complete, and zinc oxide serves well for the purpose, but the use of a great excess must be avoided. The solution in which phosphoric acid is to be estimated is neutralised (to phenolphthaleïn) by means of caustic soda free from chloride or of known chloride content, and an excess of $\frac{N}{10}$ silver nitrate is added, and the mixture well shaken in a 200 c.c. measuring flask. The amount of silver nitrate added should be at least 30 per cent. in excess of that required, but the addition of two or three times the theoretical amount introduces no error. Zinc oxide, or a suspension of it in water, is next added little by little, shaking vigorously for two or three minutes after each addition, and testing for free acid each time by dropping in a fragment of blue litmus-paper. When the colour of the litmus-paper is no longer affected, the solution is made up with water to the mark, well mixed, and allowed to subside for a few minutes only, as zinc oxide acts slowly on silver nitrate, precipitating it as oxide. The mixture is filtered, and the excess of silver determined in 100 c.c. of the filtrate by Volhard's method. The extreme error of the method is ± 0·1 c.c. of $\frac{N}{10}$ solution. The degree of dilution within the limits 100 to 250 c.c. has no measurable influence on the results.

The phosphoric acid in precipitated calcium phosphate may be determined with an accuracy of 1 in 500 by shaking for a few minutes with at least twice the theoretical amount of $\frac{N}{10}$ silver nitrate, adding zinc oxide, again shaking, making up to known volume, filtering and determining the excess of silver in an aliquot portion of the filtrate. Addition of zinc oxide is unnecessary if the sample consists wholly of tricalcic phosphate, but this is rarely the case. Chloride, if present, must be determined separately, and a correction made. Nitrates and sulphates do not interfere, but the method cannot be used for the determination of total phosphoric acid in presence of more than traces of iron and aluminium. G. C. J.

Titration of Phosphates. W. Strecker and P. Schiffer. (*Zeitsch. anal. Chem.*, 1911, **50**, 495-499.)—The authors have investigated two methods for the volumetric estimation of phosphoric acid in phosphates, namely, titration with uranium acetate and with silver nitrate. A solution containing a known amount of pure sodium phosphate was employed in the experiments, and the results obtained were compared with those yielded by the gravimetric molybdate method; the quantities of phosphoric acid found by the three methods in equal volumes of the phosphate solution were: Molybdate method, 0·0605 grm.; uranium method, 0·0604 grm.; silver nitrate method, 0·0604 grm. These results show that the volumetric methods are not less accurate than the gravimetric method. W. P. S.

Rapid Determination of Silver and Cadmium by Means of the Gauze Cathode and Stationary Anode. R. C. Benner and W. H. Ross. (*J. Amer. Chem. Soc.*, 1911, **33**, 1106-1112.)—The use of the gauze cathode with stationary anode, which was found to be so efficient in the determination of nickel and cobalt (ANALYST, 1911, 307), has been extended to include silver and cadmium. The range of electrolytes from which these elements could be deposited on the gauze in adherent form, when strong currents were used, was found to be much less than in the case of nickel and cobalt. The deposits obtained for each metal with potassium cyanide as electrolyte were entirely satisfactory.

For the deposition of silver, the electrolyte should contain about 7 grms. of potassium cyanide and 2 grms. of potassium hydroxide in 50 c.c. The potassium hydroxide prevents the appearance of a red colour due to the decomposition of cyanide, and in the amount named has but little effect on the rate of deposition. If it be desired to deposit more than 0·3 grm. of silver, more cyanide must be employed to insure an adherent deposit, but increasing the amount of cyanide decreases the rate of precipitation to a marked extent. Under the conditions named, with a current of 5 ampères, 0·15 grm. silver may be deposited in ten minutes. Before breaking the current the electrolyte is replaced by water, otherwise an error of − 0·4 mgrm. may result. The extreme error of the method is ±0·5 mgrm.

For the deposition of cadmium the electrolyte may contain 2 to 5 grms. of potassium cyanide and 1 to 2 grms. potassium hydroxide and 0·1 to 0·3 grm. cadmium in each 60 c.c.; or Stoddard's directions (*J. Amer. Chem. Soc.*, 1909, **31**, 385) may be followed and potassium cyanide added in amount just sufficient to dissolve the precipitate first formed, potassium hydroxide being next added until the solution is distinctly alkaline. When working according to Stoddard's directions the deposition of 0·2 grm. of cadmium is complete in twenty-five minutes using a current of 4 ampères. When the larger quantities of potassium cyanide and hydroxide are used, it is necessary to wash before breaking the current. The extreme error of the method is ±0·6 mgrm. G. C. J.

Colorimetric Method for Vanadium in Iron and Steel. C. R. M'Cabe. (*Chem. Engineer*, 1911, **13**, 243-247.)—In absence of chromium or tungsten 2 grms. of the steel are dissolved in 40 c.c. of hot strong hydrochloric acid, 5 c.c. of nitric acid

(1 : 1) are added, and the mixture evaporated to about 10 c.c. and transferred to a separator, the dish or beaker being washed with hydrochloric acid (1 : 1) until the liquid in the separator amounts to 20 c.c. Ether (50 c.c.) is added, and the mixture shaken and allowed to separate. The lower layer and 1·5 c.c. of the ethereal layer are then drawn off and diluted with 200 c.c. of boiling water, after which ammonia is added. The bulk of the iron remains in the ethereal layer in the separator, but drawing off 1·5 c.c. of this layer with the aqueous layer insures the presence of about 0·1 grm. of iron, which is desired. When addition of ammonia has precipitated the iron, a further 10 c.c. of ammonia are added and boiling continued for half a minute. The whole of the vanadium and iron is precipitated, whilst manganese remains almost wholly in the solution, when this is heated to boiling before addition of ammonia. The iron and vanadium precipitate is filtered off and, if nickel is present, is redissolved in hot dilute hydrochloric acid and reprecipitated. In absence of nickel the filter containing the precipitate is opened in a dish and treated with 3 c.c. hydrochloric acid (1 : 1) and 7 c.c. water, warming moderately and rocking until solution is complete. The contents of the dish are transferred to a stoppered glass tube, until with washings this contains about 40 c.c., and then 0·5 c.c. of hydrofluoric acid, previously diluted with water, is added, when the ferric solution loses its colour. Hydrogen peroxide (5 c.c. of a solution containing 0·5 per cent. H_2O_2) is next added, and the solution diluted until its brown colour is exactly equal to that of a solution of vanadic acid of known strength. Directions for the preparation of vanadic acid, which is not obtainable commercially, are given. The standard solution contains 0·2 mgrm. vanadium in each c.c., and in preparing dilute solutions for colour comparisons a measured quantity of a dilute ferric solution containing about 0·1 grm. iron is acidified with 3 c.c. hydrochloric acid (1 : 1), decolorised by hydrofluoric acid, a measured quantity of the standard vanadium solution (usually 15 c.c. at first) is added, and the whole diluted to five times the measure of the vanadium solution taken.

In presence of chromium the acid solution, after ether separation of most of the iron, is evaporated almost to dryness, 50 c.c. of nitric acid are added to the residue, and the solution boiled until fumes are all expelled and the solution is a clear green. To the boiling nitric acid solution 2 or 3 grms. potassium chlorate are added to precipitate manganese and oxidise chromium. Boiling is continued for a few seconds, after which 200 c.c. of boiling water are added, and the iron and vanadium precipitated by means of ammonia. The iron and vanadium are separated from manganese, nickel and a trace of chromic acid by resolution in hot, dilute hydrochloric acid and reprecipitation by means of ammonia in dilute boiling solution. A trace of chromium usually remains with the iron and vanadium, but does not interfere.

In presence of tungsten the filtrate from the tungsten determination is used for the estimation of vanadium. Since the evaporation to dryness in the tungsten determination leads to partial reduction of vanadium, it is necessary to re-oxidise this by adding 5 c.c. nitric acid (1 : 1) during evaporation of the filtrate preceding the ether separation of iron. Sulphuric acid must not be used in the tungsten determination.

Titanium and molybdenum do not interfere with the above method.

G. C. J.

Simultaneous Volumetric Estimation of Iron and Vanadium. E. Müller and O. Diefenthäler. (*Zeitsch. anorg. Chem.*, 1911, **71**, 243-249.)—Campagne (*Ber.*, 1903, **36**, 3164) described a method for the estimation of vanadium, which consisted in reducing V_2O_5 to V_2O_4 by repeated evaporation with hydrochloric acid, finally evaporating to fuming with sulphuric acid, after which the solution was diluted and titrated with permanganate at 60° C. The authors obtained results which were from 5 to 10 per cent. low when following Campagne's directions, and conclude that he omitted some detail of importance from his description. The following method gives results which are accurate within less than 1 drop of $\frac{N}{10}$ permanganate: To the solution of vanadate, contained in an Erlenmeyer flask, 15 c.c. of hydrochloric acid and 50 c.c. of alcohol (or 15 to 20 c.c. of an alcoholic solution of hydrogen chloride) are added, and the mixture boiled until of a pure blue colour. It is then transferred to a basin and evaporated to dryness on the water-bath, and the residue heated for a further ten to fifteen minutes on the water-bath, with frequent trituration with a rod. This treatment eliminates organic matters which, on treatment with sulphuric acid, would yield substances having a reducing action on permanganate. The dry residue is covered with 5 c.c. sulphuric acid, which is then heated until it fumes. The solution is then allowed to cool, diluted and titrated with permanganate.

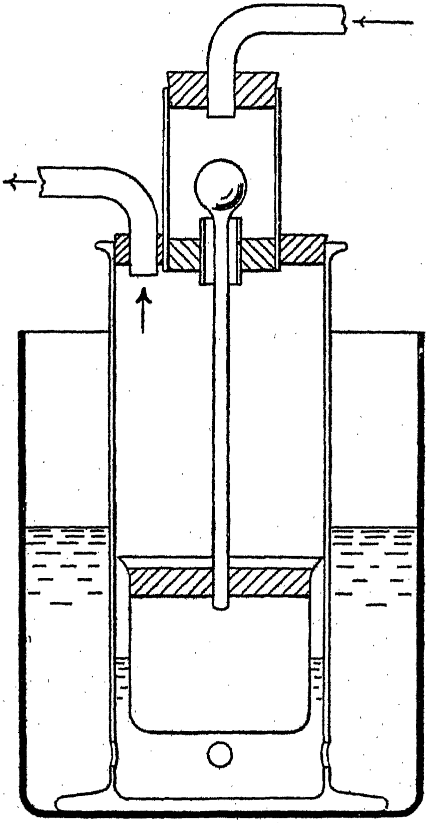
Applied to ferro-vanadium, the above method leads to high results, as in presence of much solid matter it is impossible to eliminate the whole of the organic matter after the evaporation. As this organic matter has no measurable reducing action itself on permanganate, but only gives rise to reducing substances on heating with sulphuric acid, the use of sulphuric acid should be avoided in presence of iron, and may with advantage be avoided in every case if Reinhardt's solution (phosphoric acid and a manganese salt) is available. The alloy (1 grm.) is dissolved in a little nitric acid, the excess of which is partially evaporated and the last traces of it destroyed by addition of hydrochloric acid and further evaporation. Hydrochloric acid and alcohol are then added, and the mixture boiled in a flask until the vanadic acid is all reduced, and finally evaporated in a basin to 5 c.c., not to dryness. The solution is made up to known volume, and, in an aliquot portion, vanadium is estimated by titration with permanganate in presence of Reinhardt's manganese mixture. In another portion of the solution iron and vanadium may be estimated together, after reduction by means of sulphurous acid; or the iron may be estimated somewhat less accurately, but more conveniently, by an iodometric method with which the reduced vanadium solution does not interfere. G. C. J.

Determination of Vanadium in Vanadium and Chrome-Vanadium Steels. J. R. Cain. (*J. Ind. Eng. Chem.*, 1911, **3**, 476-481.)—As the result of disagreement between the results obtained on the same sample by the staff of the United States Bureau of Standards and several other chemists, an investigation of the methods most in use for the estimation of vanadium was undertaken by the Bureau, and the results communicated to the other chemists, with whose co-operation the true vanadium content of the sample was soon agreed on, and certain sources of error in the determination of vanadium traced. These sources of error are set out fully in the present paper, in which it is stated that methods requiring the use of ferrocyanide as indicator for ferrous salts, where quadrivalent vanadium and ferric salts are also present, must of necessity be very uncertain. An error in all methods where final titration is made against permanganate may arise by failure to deduct the blank caused by the presence of other elements than vanadium. This error may amount to 100 per cent. in the case of low-vanadium products. The temperature of titration, which should be as near 80° C. as can be arranged without risk of exceeding that temperature, is also important if a sharp end-point is to be secured. In methods in which iron is removed by ether extraction, ferrous salts are apt to be formed, and must be re-oxidised. If the evaporation of a solution of quadrivalent vanadium with strong sulphuric acid to eliminate hydrogen chloride, be too prolonged or conducted at too high a temperature, oxidation may occur. In methods in which, after an ether separation, the remainder of the iron, as well as any chromium, etc., is to be separated from vanadium by pouring into a boiling solution of caustic soda, there are several sources of possible error. Vanadium is almost always carried down with the hydroxides of iron and chromium, and two or three precipitations are necessary. Another source of error is due to manganese, which tends to become oxidised to peroxide during the boiling with soda, and this peroxide oxidises chromium salts to chromate, the separation of which is so difficult that the following new method is recommended:

The borings (2 to 4 grms.) are dissolved in 40 to 60 c.c. of dilute (1 : 10) sulphuric acid in a covered Erlenmeyer flask. The insoluble matter, which may contain most of the vanadium, is fused for a few minutes with bisulphate, and the aqueous solution of the fusion added to the main solution. The solution is nearly neutralised with sodium carbonate (saturated solution), and then finely-divided cadmium carbonate is added in small portions, at intervals of four or five minutes, to the solution, which is kept boiling and covered. One or 2 grms. of cadmium carbonate should remain undissolved. About fifteen to twenty minutes' boiling suffices. The precipitate, which contains all the vanadium and chromium, very little iron, and no manganese, is allowed to settle, filtered rapidly, and washed (twice only) with hot water. It is then dissolved in the minimum quantity of nearly boiling dilute sulphuric acid (1 : 10), catching the filtrate in the original flask. The cooled solution is nearly neutralised with ammonia, leaving only so much free acid as will prevent any iron from precipitating on boiling. Cadmium is next removed by heating the solution to boiling and passing hydrogen sulphide, and, after allowing to settle, filtering. The precipitate is washed two or three times with hot water, and the filtrate and washings concentrated to 60 to 70 c.c. and electrolysed, using a mercury cathode and a current of 5 to 6 ampères at 6 to 7 volts. The solution is tested for iron by ferricyanide, and absence of iron is usually a safe indication that all chromium as well as iron has passed into the mercury. With much chromium present relatively to iron, 3 to 4 c.c. of the electrolyte may be withdrawn, a few drops of hydrogen peroxide added, and the solution boiled for a few minutes after the brown colour, due to vanadium peroxide, has disappeared. If the solution remains clear and colourless on adding ammonia, the electrolysis is ended. The test portion is acidified with sulphuric acid, and added to the main solution. The exhausted electrolyte is withdrawn, and the mercury washed two or three times with 25 to 30 c.c. of water while the current is passing. To the united solutions 2 to 3 c.c. of sulphuric acid (1 : 10) is added, the mixture heated to 70° to 80° C., and permanganate added until a strong pink colour results. The vanadium is reduced by leading sulphur dioxide into the boiling solution, the excess of sulphur dioxide expelled by continuing to boil whilst passing carbon dioxide, and the solution is then filtered through asbestos, cooled to 70° to 80° C., and titrated with $\frac{N}{50}$ permanganate. With special facilities a determination may be completed in one and a half hours. G. C. J.

APPARATUS, ETC.

Simple Forms of Gas-Pressure Regulators. E. Stansfield. (*Chem. News*, 1911, **104**, 3-4.)—The author describes two patterns of regulator. In each there is (1) an outer vessel; (2) an inner cylinder open top and bottom, and which may consist (see Fig.) of a cylindrical vessel with one or more holes drilled through the sides near the bottom, or of a wide-mouthed glass-bottle with the bottom cut off; a piece of wide glass-tube could be used; (3) a float, consisting of a beaker, and weighted at the base so that it floats upright: the rim of the beaker should be an easy fit inside the cylinder; (4) gas inlet and outlet tubes; (5) a valve connected to the float: this valve consists, in the apparatus figured, of a small bulb blown at one end of a glass tube, the other end of which is fixed in a cork in the neck of the float. The valve seating is a short bit of glass tube. If the end of this tube is first made square by rubbing on emery-cloth, a little grinding of the valve on its seating will make it nearly airtight.

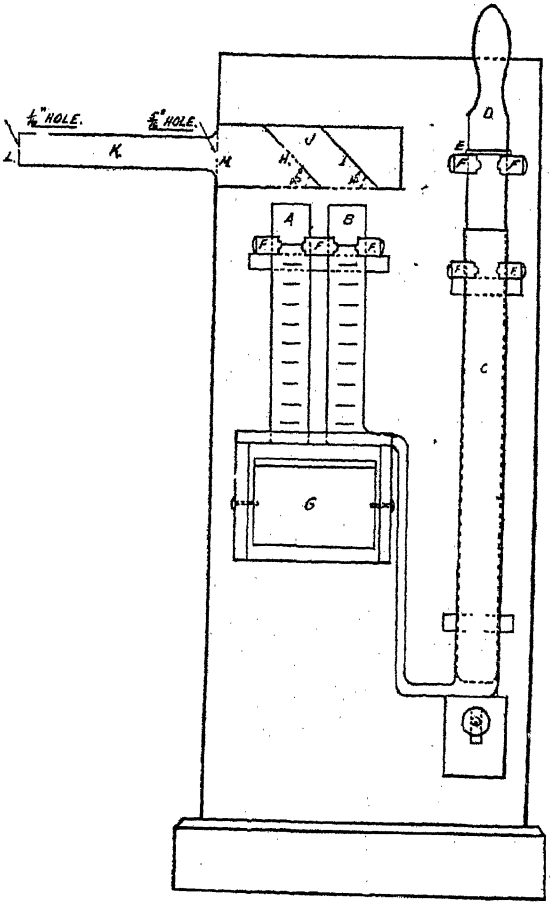


Water is poured into the outer vessel and gas passed through in the direction indicated by the arrows. More water poured into the outer vessel will give a higher pressure, and *vice versa*.

The other regulator has inlet and outlet gas tubes blown into a vertical tube. The valve is a glass rod fixed in the cork of the float at one end, and having a cylindrical cap at the other, which fits in the vertical tube closely, yet allowing free movement. A piece of glass tube with a cork in it, in which the rod is fixed, makes a suitable cap. The inner vessel and accessories of the regulators should be fixed in a cork fitted in the neck of the outer vessel, to prevent upsetting. The area of cross-section of the float should be large as compared with the valve, so that the pressure exerted on the top of the valve by the inlet gas is negligible, or a large excess of inlet over outlet pressure might permanently close the valve. The type shown in the figure gives a more constant pressure than the second form of apparatus.

A. R. T.

New Colorimeter. E. D. Campbell and W. B. Hurley. (*J. Amer. Chem. Soc.* 1911, **33**, 1112-1115.)—The unknown solution is placed in the tube A, which is 19 cm. long, 3 cm. in diameter, and graduated for 15 cm. The standard solution is placed in the tube B, which has the same dimensions as A, the graduated portion being divided into 100 divisions of 1·5 mm. each. In one piece with B are a connecting tube and a reservoir, C, in which the glass plunger D works, so that the level of the liquid in B can be controlled. The plunger has a rubber collar, E, to prevent it from descending too far and breaking the bottom of the reservoir. A, B, and C rest on wooden supports, that under A and B being provided with holes for the passage of light reflected from the adjustable mirror G. F, F are spring clips for holding the glass parts in place whilst allowing of their easy removal for cleansing. The black wooden back of the colorimeter serves the purpose of a support for the parts of the instrument, and of a screen as it is interposed between the colour tubes and the source of light (a north window). The light passing through the tubes impinges on the mirrors H and I cemented to brass plates sliding in grooves cut at an angle of 45° in the sides of the wooden box, J, which is supplied with a loose cover. The mirror H is cut vertically and cemented in such a position as to reflect one half of the circular field of light coming through A. The light passing up through B is reflected horizontally by the mirror I through a hole in the brass plate supporting H. One half of the circular field of light from B is cut off by the mirror H, the vertical



edge of which acts as a dividing line between the two halves of the circular field. The image of one half of the tube B is then observed in juxtaposition to the opposite half of the image of the tube A. The juxtaposed images are observed through a tube K, 2·5 cm. in diameter and 16 cm. long, lined with black felt and provided with an eyepiece having a hole 1·5 mm. in diameter. At the point M in the tube K is placed a diaphragm having an aperture 8 mm. in diameter. All parts inside the box J, except the mirrors, are painted black. By having the apertures in the eyepiece and diaphragm properly proportioned, only the image of the bottoms of the tubes A and B can be seen, thus preventing interference of light reflected from the vertical sides of A and B. An observer looking through the eyepiece sees a single field divided vertically by an almost imperceptible line when the two solutions are of the same intensity. By manipulating the plunger D, the level of the liquid in B can be raised or lowered, thus causing the right half of the image to assume a darker or lighter shade at will. G. C. J.

Laboratory Apparatus for the Production of a Constant Current of Ozonised Air. L. v. Liebermann. (*Chem. Zeit.*, 1911, **35**, 734.)—A stout test-tube is fixed by means of a perforated cork into one of the limbs of a U-tube which has side tubulures. This test-tube is closed by a stopper through which passes a platinum wire terminating in a piece of platinum foil. The other limb of the U-tube is closed by means of a cork, and the whole is placed in a strong glass vessel (battery jar) containing sulphuric acid of about 1·4 to 1·5 sp. gr. This acid is also introduced into the test-tube to the same level. An asbestos cover, with openings to admit the top of the U-tube, is placed over the battery vessel, and through another opening in this is passed a platinum wire also ending in platinum foil. Both wires are connected with a battery, whilst a current of dry air is drawn through the side tubulures of the U-tube. It is advisable to saturate all the cork connections with paraffin wax to prevent their being attacked by the ozone. C. A. M.

GOVERNMENT REPORT.

Report to the Local Government Board on the Nutritive Value of Bread made from Different Varieties of Flour. J. M. Hamill. (*Food Reports*, No. 14. Cd. 5831. Price 3d. 1911.)

The Report deals solely with "genuine" flours obtained by mechanical means from the wheat grain without chemical treatment or the addition of foreign substances (*vide* Food Report, No. 12, Cd. 5613, by Hamill and Monier-Williams, ANALYST, 1911, 254).

I. *Classes of Wheat Flour.*—A short account of the morphology of the wheat grain (illustrated) is followed by a discussion of milling methods and the quality and grading of flour. The whole of the complicated machinery of modern milling is devised with a view to obtaining in white flour nothing but the contents of the parenchymatous cells of the endosperm, although absolute separation is never effected in practice. Products other than flour are termed *offal.* *Bran* consists of the pericarp and aleurone layer with some adhering parenchymatous cells of the endosperm; *pollard* is bran in a finer state of division; *fluff, or fibre,* consists largely of the cellulose walls of the endosperm cells; *sharps, or middlings,* are mixtures of pollard, fluff, and germ fragments. By modern methods 70 to 73 per cent. of ordinary white flour can be obtained from an average cleaned wheat; bran and pollards account for about 20 per cent., and finer offal, sharps, and germ for 10 per cent. The extent to which all these are separated from each other depends on their market value. The old process of stone milling is only suitable for the softer or mellower wheats with tough skins, as, owing to the severe attrition to which the berries are subjected, the brittle skins of hard foreign wheats become too much disintegrated for effective subsequent separation. Flours refined to different degrees may be obtained from stone-milled wheat, but the amount of separation ordinarily obtained by this method contrasts unfavourably with that reached in roller-milling, in which the grain is reduced to flour in gradual stages, and the offal is continually removed by sifting and the use of air-currents. More efficient separation of bran and a larger yield of high grade flour thus becomes possible. Contrary to common notions, high grade flour is subjected to less grinding and coarser dressing than the lower grades, which are dressed through very fine silk. A variety of different grades of flour can be made to suit any demand by dividing the output of the roller mill in different ways as it is being produced; thus it is perfectly easy to prepare so-called "standard flour" from such mills by suitable adjustments. Much uncertainty exists on the subject of "germ" amongst millers. In stone-milling it appears certain that much of the germ passes away into the offal, only the more finely-ground particles passing through the coarse mesh used for dressing such flour. Roller-milled flour is practically free from germ. Millers generally are averse to returning the germ to flour, alleging that its presence has a detrimental effect on the baking and keeping qualities of the flour and on the stability and strength of the dough, and that it is impossible to produce a large, well-risen loaf from flour containing germ. In addition, it is declared to be unsuitable for use with aërating substances such as baking-powder, owing to the development of unpleasant flavours, and that flour containing it soon acquires a rancid flavour. The question of keeping quality cannot, however, be regarded as definitely settled, the superiority in this respect of modern flour being probably due to improved methods of milling and the use of sounder wheats. There is evidence to show that flours to which the germ is returned keep well provided they do not contain an excessive amount of moisture, and such flours, when containing germ in amounts insufficient to affect the colour of the bread, acquire a pleasant, nutty flavour. Many fancy flours contain large amounts of added germ, thereby enhancing their protein content; the germ in such cases is previously subjected to heat in order to destroy its enzymic activity and to prevent any development of rancidity. The highest grades of roller-milled flour absorb more water and produce a larger loaf with a better colour and appearance when judged by the usual criteria applied by the baker and the public than the lower grades of roller-milled flour, and, judged by the same criteria, both are superior to stone-milled flour.

As regards flavour, bread from stone-milled flour is often considered superior to that made from roller-milled. The presence of more germ in the former, and the fact that English wheat which has a good flavour is that usually employed, probably accounts for this. Subtle enzymic changes occur, due to the presence of germ, favoured by warmth and keeping. In breads made from either stone or roller milled flour, loss of flavour, as well as liability to become harsh and dry, are frequently ascribed to "over-proving"—*i.e.*, over-fermentation—in an attempt to obtain as large a loaf as possible. The greater the percentage yield of flour obtained from wheat, the darker will be the colour of the loaf, due to the presence of offal; other factors influencing colour are the mill employed (stone or roller) and the colour of the wheat used—red or white. It follows that different flours containing the same percentages (over 70 per cent.) of the total wheat may yield loaves varying much in colour. The great bulk of the flour used in this country is the product of roller mills, although stone-milled flour is still made, and there is a distinct, though limited, demand for it.

The classes of milling products from which bread may be made are as follows: (1) *Wholemeal, or "Graham," flour* is produced by grinding the entire wheat grain. Obviously, it should contain the whole of the germ and bran particles. No sieves or bolting-cloths are used in making it. (2) *"Entire" wheat flour, or fine meal,* is a product obtained by removing a portion of the bran, and finely grinding the rest of the grain. It can also be prepared from stone-rolled wholemeal by sifting. The amount of offal removed in either case varies. In the United States, flour produced from wheat with a portion of the husk removed is known as "entire" wheat flour, and this inaccurate term is used in the report, as the greater part of the experimental work quoted has been done in that country. (3) *Households* grade of flour is the commercially lower grade of flour obtained from roller mills. It is darkish in colour, contains a little finely-divided bran, and, from the baker's point of view, is inferior to high grade flour for bread-making. Flour of this type is known as *baker's grade* and *clear grade* flour in America. (4) *Patent grade* flour is the commercially higher grade flour produced by roller mills. The water-absorbing capacity of such flour, and the size and general appearance of loaves made from it, appeal strongly to bakers. Whereas a certain grade of flour may yield ninety loaves per 280 pounds of flour, one hundred loaves may be obtained from higher grades as a result of the absorption of more water. (5) *Straight-run, or patent grade,* flour is the whole of the flour produced in the roller mill. It is intermediate in appearance and baking qualities between households and patent grades. (6) *Special flours, generally sold under fancy names,* may contain added germ (usually cooked), finely ground bran, lentil flour, banana meal, etc.

II. *Nutritive Values of Various Milling Products (Meals and Flours) and Bread made therefrom.*—Numerous tables, mostly from the publications of the United States Department of Agriculture, are given, showing the chemical composition and heats of combustion of various samples of wheat, flour, and bread. A flour relatively rich in protein may, as a result of absorbing more water, yield a bread containing less protein than bread derived from flour relatively poor in protein. High grade flours have a high water-absorbing capacity. The caloric value of bread is approximately five-eighths of the caloric value of the flour from which it is made. Germ consists of about one-third protein, one-third carbohydrate, and one-sixth oil, ash and water accounting for the residue. Since wheat does not contain more than 2 per cent. of actual germ, the inclusion of the whole of it would only raise the apparent protein content of the flour about 0·6 per cent., and this last figure would fall to 0·2 or 0·3 per cent. if only such germ were returned to the flour as it is possible to separate from the branny offal. The protein in the germ contains no gliadin or glutenin, but a considerable amount of nucleic acid in combination with albumin and globulin, and the organically combined phosphorus in the nucleic acid is mainly confined to the germ. The combinations in which such elements as sulphur, phosphorus, and iron, are found in the ash gives no indication of the form in which they were present in the flour. The ash contents of bread are very variable relatively to the ash contents of the flours from which they were made, generally being about half of the mineral matter present in the original flour. It is not possible to base conclusions as to the nutritive value of different breads merely upon chemical data, physiological experiments being necessary to determine the digestibility of the different materials. It would appear that patent grade flour is more easily acted upon by the digestive juices *in vitro* than "entire," or Graham flour. Numerous tables are given, comparing the digestibility of different kinds of flours and breads, as actually determined in feeding experiments on individuals. The principal conclusion arrived at is that the differences in nutritive value between various grades of flour made from the same wheat are usually insignificant when compared with the differences in nutritive value of flours made from wheats differing widely in composition.

The mineral requirements of the body are next discussed, as are the recent experiments at Cambridge and Liverpool, where white and wholemeal breads were fed to rats and pigeons. In these two cases the animals failed to thrive on white bread and flour, but did better on wholemeal. The bearing of these experiments and those of Leonard Hill (*Brit. Med. J.*, 1911, 1310) on the connection known now to exist between polished rice and the disease of beri-beri (H. Schaumann, *Beihefte zum Archiv f. Schiffs- und Tropenhygiene*, 14; Beiheft 8) is pointed out. No conclusive evidence is available as to the relative merits of wholemeal and white flour on the teeth.

III. The question of so-called "standard flour" is touched upon, and the definition of it given—80 per cent. of the wheat, with all the germ and semolina—adversely criticised. The various methods in which it is compounded are described, and the difficulty shown of giving any definition of such material apart from a preliminary "standard wheat." Many so-called "standard flours" consist of mixtures of low grade flour with fine offal bought for the purpose, and their use results in a profit of from 2s. 6d. to 3s. per sack, as compared with 80 per cent. straight-run flour. An endeavour to obtain uniformity by prescription of physico-chemical limits, sufficiently stringent to be of value, would inevitably rule out a considerable portion of the wheat at present imported. It would seem that "standard" flour (regarded as 80 per cent. straight-run together with the germ) has advantages over the "imitation standard" in the palatability and appearance of the loaf made from it. Tables are given containing the results of analyses by G. W. Monier-Williams, which show the chemical composition of seven distinct wheats and of the various milling products as well as "standard" flour obtained from them. The differences in apparent protein and mineral matter between the "standard" and household flours obtained from the same wheat are comparatively small in all cases.

Extracts from the Conclusions.—"The records of experimental work which have been consulted for the purposes of this report, and other writings on the subject, do not permit any conclusive statements to be made regarding the exact value in nutrition of different varieties of flour."

"The notion that ordinary high grade and naturally white 'patent' flour is practically devoid of protein or nitrogenous constituents, whereas the latter are abundantly present in bread made from wholemeal and 'entire' wheat flours, is erroneous. The differences which exist in this respect are not relatively of great magnitude, and they may to a large extent be neutralised by imperfect absorption from the digestive tract. A 'patent' flour derived from one variety of wheat may contain considerably more total protein, and furnish more available 'energy than an entire' wheat or wholemeal flour from another kind of wheat. There is no reason to believe that the varities of bread which the miller and baker have accustomed us to regard as of lower quality—'households,' for example—are in any physiological sense inferior to that of the higher priced bread made from the high grade and specially white flour. On the contrary, from the point of view of available nutrient material and energy value, the advantage is on the side of the 'households.'"

"'Entire' wheat flours (including stone-ground flours and 'standard' flour) are in nearly the same position as 'households,' although when made from weak wheats they will usually contain less available protein than 'households' made from strong wheats. They possess, however, additional constituents, due to the presence of branny particles and the germ of the wheat, which appear to have a value of their own in nutrition, and may, as a result of further investigation, be shown to comprise phosphorus-containing organic compounds or other substances, the presence of which in some part of the dietary, even in minute quantity, is important in maintaining good health."

"For children who live largely on bread, or bread supplemented by jam, sugar, or other foods, which add little to the available mineral matter, proteins, organically-combined phosphorus, or other substances which possibly may be necessary for health, there appears on the balance to be advantage in the use of bread made from flour of the 'entire' wheat class, or from wholemeal in which the bran is very finely ground. It should, however, be remembered that many children whose food consists largely of bread do not get enough of it, and are really underfed in respect of such essential nutritive substances as proteins and carbohydrates. To increase the quantity of bread taken in such cases may be of greater importance than the substitution of one form of bread for another; to supplement the bread by other articles will be still more useful." H. F. E. H.

REVIEWS.

A SYSTEMATIC HANDBOOK OF VOLUMETRIC ANALYSIS. By FRANCIS SUTTON. Tenth Edition, revised by W. LINCOLNE SUTTON and ALFRED E. JOHNSON. London: J. and A. Churchill, 1911. Pp. xiv + 621. Price 21s. net.

It may seem a work of supererogation to review the tenth edition of a standard work like that of Sutton, but as the author states in his preface that at the age of fourscore years he is not equal to the task of revision, and has placed it in the hands of his son and Mr. Johnson, it is to some extent a new work.

When this book was first published, nearly fifty years ago, analytical chemistry had hardly attained the status of a scientific profession; the analyst differed from the pure chemist in his training, in his methods, and largely in his mode of thought. But as time went on the training of the analytical chemist became more and more scientific; great strides were made in both branches of the profession, especially during the interval that has elapsed since the publication of the ninth edition, and to-day the analyst fairly ranks as a scientific chemist. In 1863, Sutton was rather in advance of his times, and for many editions he kept his work up to date, and progressed with the times. He expresses himself in the preface particularly anxious that the tenth edition "should be distinguished by the most thorough and critical revision, and, in the result, by the greatest possible consonance with modern practice," and the revisers had a splendid opportunity to rewrite the book in the light of the advances of the past few years. It cannot be said that they have fully availed themselves of this opportunity.

The old conception of an indicator was that it gave an end point to a reaction; the laws of mass action teach us that it is really an equilibrium point, which will approximate more or less to the completion of the reaction according to the conditions. This idea should form the basis of volumetric analyses, and might have been simply explained quite early in the book in the section of alkalimetry by describing the modern theories of indicators; the revisers, however, simply refer to the publications of Ostwald and Noyes, and do not attempt even an abstract of their work. Had they done so, the explanation of very many methods would have been greatly simplified, such as the titration of ferrous salts with permanganate in the presence of chlorides, and the principles underlying Gay-Lussac's method for the assay of commercial silver would have followed as a matter of course, instead of being quite wrongly stated.

The nomenclature is most confused: thus, methyl-orange is described as sodium dimethylamido-azo-benzene sulphonate, and methyl-red as *p*-dimethylamino-azobenzene *o*-carboxylic acid; in various parts of the book the prefix "para" is variously denoted *p*-, p, **p**, and para; and α-β-γ- propane triol is referred to indiscriminately as "glycerol," "glycerin," and "glycerine"; such expressions as "sulphocyanate," and "dihydric potassium phosphate" occur. There is often a looseness of expression, such as "Sulphuric acid, in a dilute form, has no prejudicial effect on the pure permanganate."

There are many other annoying features of the book: the working details of the methods, which are the portions of the book that will be most often consulted, are printed in so small a type as to be a little difficult to read; the index is very incomplete and inconveniently arranged; references to figures in the text are often without the page on which they are found; and references to original papers are most unsystematic—thus, on p. 45 one finds J. S. C. I, **12.** 432, and J. S. C. I, 1899. 708; while, as a variation, on p. 48 the reference is J. S. C. I. 1900. **19.** 958, the last obviously being the best form.

There is a remarkable blemish in the section on Gas Analysis, where ethane and hydride of ethyl, as well as butane and hydride of butyl (propane presumably not existing, but only hydride of propyl) are referred to in more than one place as distinct substances of different series, C_nH_{2n+2} and $(C_nH_{2n+1})_2$, and there is a serious misprint on p. 525, which may possibly lead to accidents, it being stated that "the hydrocarbons $(C_nH_{2n+1})_2$ and C_nH_{2n+2} may be absorbed by absolute alcohol, some of which is introduced into the absorption tube, and *ignited* for a short time with the gas"; probably *agitated* is meant. Much modern work—for instance, that of Bone and his colleagues, and of Butterfield—is ignored, and no mention is made of benzene in illuminating gas.

In some cases recent methods have been overlooked—for instance, in the section on Indigo, the tetrasulphonate method of Bloxam is not given; in others, obsolete methods are described at too great a length, such as Pavy's method for the estimation of reducing sugars; and it is a debatable point whether methods like that of Polenske for the estimation of insoluble volatile acids in butter and other fats, the final stage of which happens to be volumetric, would not be better left to special textbooks.

Notwithstanding what has been said, there is very much that is good in this book. Methods, nearly all of them good, are described for the estimation of almost every substance, and no analyst, working by the directions given, which are clear and sufficient in detail without being prolix, will be misled. With this excellent ground-work, it should not be a difficult task to make the next and Jubilee edition—to which the author is looking forward, and which all chemists hope he will be spared to see published—worthy of its great reputation. If modern chemical ideas, such as the law of mass action and the ionic theory, are borne in mind; if recent work on gas analysis is studied; if a more systematic system of nomenclature, as that of the Chemical Society, is adopted; if the working details are printed in larger type, leaving the smaller for the explanations of the methods; and if the services of a competent indexer can be secured, the work will realise the ideals of its venerable author.

H. DROOP RICHMOND.

AN INTRODUCTION TO THE CHEMISTRY OF COLLOIDS. By Dr. VICTOR POESCHL. Translated by HERBERT H. HODGSON, M.A., B.Sc., Ph.D. London: Chas. Griffin and Co., 1910. Price 3s. 6d. net.

This is a translation of a small textbook, which in the original has reached a second edition, and may be useful in giving readers unfamiliar with the large works of W. O. Ostwald and of Freundlich a general view of the subject, the importance of which is certainly growing.

The first two chapters are devoted to the general characteristics, nomenclature, and properties, of colloidal solutions. These are described on lines generally received, except for a somewhat daring attempt to explain the Brownian movement (pp. 10 and 11), which takes no notice of the universally accepted results of Einstein and of Perrin, but is certainly not an improvement. Then follow two further theoretical chapters on the relations of colloidal to true solutions and to suspensions, and on classification, W. Ostwald's division into suspensoids and emulsoids—*i.e.*, systems consisting of one liquid and one solid phase and of two liquid phases respectively—being used. These theoretical considerations are now interrupted by two chapters devoted to the preparation of colloidal solutions and to research methods—viz., chiefly to ultra-microscopy. The first-named gives a brief but fairly complete survey of the various substances so far obtained in colloidal solution, as well as the methods employed in their preparation. The chapter on ultra-microscopy will, perhaps unavoidably, be almost unintelligible to readers not fairly familiar with the instrument itself. Theoretical considerations are resumed under the heading "Recent Views on the Nature of the Colloidal State," a great part of which must make very difficult and not very useful reading to students without previous knowledge of the subject. Two brief concluding chapters deal with the importance of colloids in various sciences and industries, a somewhat disproportionate amount of space being devoted to mineralogy.

As will appear from the foregoing, the arrangement of the matter is not particularly systematic, and, in addition, the language is occasionally so lax that the reader is confused or misled. As far as p. 32—*i.e.*, through about one-third of the book—the term "colloid" is used indifferently, either in Graham's sense as denoting a *form*, and in the modern as denoting a *state*, of matter. Only then the latter meaning is definitely made clear. In several places (pp. 12, 31, etc.) "fluorescence" is described as a fairly general property of colloidal solution, and is tersely explained as "colours diffusing [*sic*] by transmitted from reflected light." Even after due allowance for the obvious misprint, this is certainly an excessively careless statement.

As regards the translation, it is a glaring specimen of a too common type, in which the guiding principle is to retain all the eccentricities of German construction, while translating every word by the first English equivalent given in the dictionary. The result is a complete absence of idiom, style, and, occasionally, of sense. No reader unfamiliar with German can possibly guess what phenomenon is meant by "the scattering of colour in the ultramicroscopic image." "Through the methods worked out by R. Zsigmondy and H. Siedentopf . . . we have been able to orientate more exactly the cause of heterogeneity"; "Berthelot observed that a hundred billionths of a gramme of iodoform could still be scented"; "On heating the gels part with their adsorption ability," are a few further specimens of the method used in translating.

Until, however, some of the larger standard works are available in English translations, the book may be useful, notwithstanding some original and acquired defects, in stimulating the interest of readers unfamiliar with German.

E. HATSCHEK.

OILS: THEIR COMPOSITION, MANUFACTURE, AND ANALY
MMONS, B.Sc. (London), and C. AINSWORTH MITCHELL, B.A. (
London: Scott, Greenwood and Son. 1911. Price 7s. 6d. net.

authors say in the preface: "The aim of the present volume is to des a concise manner the properties of different edible fats and oils and their c ations, and to give an outline of the modern processes used in their preparati d purification." It is obvious that such an extensive subject can only be ver briefly outlined in the limited space of some 150 pages, part of which ha not been utilised to the very best advantage, owing to certain matters having been dealt with twice under different sections. The first chapter is clearly expressed, and contains well-selected formulæ and tables; in Chapter II. eighteen fats and oils are described in eight pages, with a very limited number of analytical "constants" and "variables," and unfortunately (with three exceptions) only one set of figures is given in each case, so that the reader does not receive the very necessary information as to how far a genuine sample may depart from these examples. In some cases, however, a few more figures are given for such of these oils as are again dealt with throughout the work, where other fats are also described.

We are told that Arachis oil is only "occasionally" used in margarine, and it is hard to understand the extraordinary statement—in several places throughout the book—to the effect that cocoa butter (or other fat) is largely used for "the *cream* of chocolate creams."

Under refining, bleaching, and deodorising, an excellent outline is given of most of the more important manufacturing methods, and it is correctly suggested that other unpublished processes are used, the secrecy of which is jealously guarded. The chapters on butter and lard are perhaps the best in the book, and contain much useful information. The authors very properly point out that "the discoveries of science . . . have led to the practice of a considerable amount of very skilful adulteration," and they express the hope "that the somewhat lengthy chapter on the analysis o od products will be useful to those engaged in the industry, in enabling such adulter to be detected and successfully combated." In the chapter in question, v analytical methods are given in a more or less detailed manner, and most of t important recent methods are described, but it is regrettable that in some value to the analyst is greatly diminished by misprints, mistakes, and omiss little practical details which are absolutely essential to one who wants to the methods from the instructions given. A few of these may be cited—the Ze tyro-refractometer number of butter-fat is given as 35° to 38° at 40° C.; t onification *value* of cocoa butter as 286 to 290, where saponification *equival* ntended. Under the Polenske process (notwithstanding the vast amount of w lished in this country and in Germany, indicating the great importance of b grade and quantity of powdered pumice, as well as the author's own warning he necessity for strictly specified conditions) there is but little excuse for uctions to add "a few fragments of pumice." There is a misprint of 100 d of 110 c.c. in the amount to be distilled in the given time. In the Kirsc s, where 10 c.c. of dilute sulphuric acid and 35 c.c. of water should be ad f dilute sulphuric acid is erroneously given and no mention is made of

Two methods for estimating boron preservative are de
would break down for boric acid, seeing that no alkali is ad
eas the more recent method of Richmond and Miller (ANALYST,
mentioned.

Under chocolate, it seems somewhat outside the scope of the work to inc
r. Booth's proposed standards and to describe even in such a sketchy and insuffici
anner methods for the estimation of various non-fatty constituents.

On considering the work generally, and more particularly from the analytical standpoint, one cannot help feeling that much of the useful data it contains is somewhat depreciated in value by the want of a little more revision and attention to detail in putting them together, while in a few cases there is a suggestion of a want of personal verification by the authors. Nevertheless, the work is full of useful information, with abstracts from a very wide expanse of scientific literature, and interesting statistics are given in the last chapter.

E. R. BOLTON.

THE PRINCIPAL STARCHES USED AS FOOD. Second Edition. Illustrated by Photomicrography. By WALDRON GRIFFITHS. Cirencester: Bailey and Woods. 1911. Price 6s.

This little book consists of some twenty-five photo-micrographs of the principal starches printed on the Kodak Company's "Vigorous Art" Velox Paper. The results may be described as very satisfactory, excellent definition having been obtained in all but one or two instances, and even in the case of very small starches the use of a hand lens will bring out all necessary detail—a device which would, of course, result in an unpleasant effect had the ordinary process-block been adopted. The magnification is, in all cases, 150 times linear, thus facilitating comparison. The author has discarded glycerol and camphor-water for making his permanent slides, and finds that Farrant's gum, used with certain precautions, answers best.

he new edition also contains illustrations of some prepared food-stuffs, of which
is the principal constituent; but a somewhat invidious choice of certain
ietary articles has been made, one of which, although stated in the text to be
, does not figure among the illustrations.

s impossible to speak in complimentary terms of the letterpress, which con-
erous orthographical errors, and in some cases, notably under the headings
" Wheat" and "Ground-Nut," has been made the vehicle for some curious
irrelevant expressions of opinion. This is the more to be wondered at since it is
ted in the preface that the author has received valuable assistance from Pr
ch, of the Royal Agricultural College, Cirencester, in revising his proof-shee
vever, it is by the illustrations that a book of this class is to be judged, and,
ady stated above, these leave little to be desired.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE DETERMINATION OF CODEINE IN OPIUM.

By ALBERT E. ANDREWS.

THE only published methods for the estimation of codeine in opium appear to be those of P. van der Wielen (*Pharm. Zeit.*, 1903, **48**, 267) and of Caspari (*Apoth. Zeit.*, 1904, **19**, 874). These are both unsatisfactory, for in van der Wielen's method the separation of codeine and narcotine depends on the complete crystallisation of the latter from an alcoholic solution of the mixed crude alkaloids, and in Caspari's method there is loss of codeine owing to its being carried down with morphine when this alkaloid is precipitated by ammonia from an aqueous liquid containing the two alkaloids. It may not be out of place to mention here that this fact does not seem to be recognised, for to it must be attributed the presence of codeine in the morphine salts met with in commerce.

The following method is the outcome of much experimental work, and has been employed in a very large number of analyses of opium carried out in the Scientific and Technical Department of the Imperial Institute.

The principal steps involved in the process are—

(1) Preparation of an aqueous extract of the opium and the addition of lead acetate solution to precipitate colouring matters, etc., and also the narcotine. (2) The addition of sodium salicylate solution to further separate resinous bodies and also thebaine. (3) The concentration of the resulting acid aqueous liquid and removal from it of ether-soluble substances. (4) The addition of a large excess of caustic soda solution to the purified aqueous liquid so as to fix the morphine and enable the codeine to be extracted with ether.

The successful carrying out of these operations depends on certain working conditions being complied with, and for this reason it is important to give the following detailed account of the method: Twelve grms. of dry opium are completely extracted with small quantities of cold water, the total filtered liquid being made to occupy 100 c.c.; 20 c.c. of a 20 per cent. solution of lead acetate are now added, and after standing over night the liquid is filtered, preferably with the aid of a water exhaust pump, through a filter paper placed in a Buchner funnel. One hundred c.c. of the filtrate representing 10 grms. of the opium are subjected to a current of sulphuretted hydrogen and the precipitated lead sulphide is filtered off, the filtrate being collected in a 200 c.c. Erlenmeyer flask and subjected to a current of air to remove the sulphuretted hydrogen. The precipitate is washed with water, the washings being collected apart and concentrated before adding them to the main liquid, since the total filtrate should not exceed about 130 c.c. in volume. The reason for evaporating the washings separately is to avoid heating the main liquid, which would thereby become considerably coloured. Twenty c.c. of a 20 per cent. solution of sodium salicylate are now added to this liquid, the flask is corked and the contents well agitated. A resinous precipitate quickly aggregates, and the liquid is then passed through a small fluted filter-paper into a beaker, into which a few crystals of thebaine salicylate are introduced. The liquid is then well stirred, and the sides of the beaker scratched with a glass rod from time to time to facilitate the separation of any thebaine as salicylate. After standing overnight the liquid is passed through the same filter, and the above treatment is repeated until no further deposition of solid matter takes place. The liquid is now finally filtered through the same filter-paper, which is then washed with a little water. The total filtrate is now concentrated over a water-bath to about 10 to 15 c.c., and whilst still warm transferred to a glass separator, using a little water to rinse out the dish, the final rinsings being transferred to a second separator. The main liquid in the separator is now freed from ether-soluble substances by agitating well with ether, which is then separated and transferred to the second separator and shaken with the aqueous rinsings contained in it. This washing of the aqueous liquid with ether is repeated at least three times, the ether each time being passed through the second separator. The aqueous portion in the second separator is now added to the main liquid in the other separator, and 10 c.c. of a 20 per cent. solution of caustic soda are added; the strongly alkaline liquid is now extracted with ether at least four times, using for each extraction a volume of solvent rather more than the aqueous alkaline liquid. Each portion of ether is in turn passed into a second separator and washed with 20 to 30 c.c. of water, then transferred to a dry flask and dried by the use of a little anhydrous sodium sulphate before being distilled. The total ether used for the extraction of the codeine is distilled in a flask down to a few c.c., which are then allowed to evaporate spontaneously, when, as a rule, the codeine separates in well-defined crystals in a nearly pure condition.

The alkaloid is then dried, preferably in an exhausted desiccator and weighed, the weight being checked by dissolving in excess of $\frac{N}{10}$ acid and titrating the excess with $\frac{N}{10}$ caustic soda solution, using litmus or methyl red as indicator. The volumetric result is usually a little lower than the gravimetric figure, and is considered the more reliable.

COMPOSITION OF PARA RUBBER-SEED OIL.

By SAMUEL S. PICKLES, D.Sc. and WILLIAM P. HAYWORTH, F.I.C.

The increase in the cultivation of the Para rubber-tree (*Hevea brasiliensis*) during recent years and the consequent production in large quantities of the seed has suggested many inquiries regarding the possibility of utilising the oil contained in the seed. The subject of the industrial application of this by-product has been dealt with in the current issue of the *Bulletin of the Imperial Institute* (1911, **9**, 35), and attention is there drawn to the fact that the seeds yield a liquid drying oil very similar in properties to linseed oil and capable, like the latter, of being used in the manufacture of paints, varnishes, rubber substitutes, oil-cloth, soft soap, etc. The kernels of Para rubber-seed were first examined at the Imperial Institute in 1902, and were found to contain a fixed oil which had marked drying properties (*Bull. Imp. Inst.*, 1903, **1**, 156). Since then various samples of the seed and oil have been received from time to time. In some cases the seeds had been decorticated previous to exportation, and perhaps also crushed, bruised, and otherwise damaged. Such treatment results in the partial hydrolysis of the oil and the production of an abnormal product, the reason being that the seed kernels contain a lipase, which has the property of hydrolysing the oil, and which is liberated when the cells containing it are crushed (Dunstan, *Proc. Chem. Soc.*, 1907, **23**, 168). The oil, of which the composition is here given, was extracted in this country from the kernels of undecorticated seeds. The kernels contained 48·8 per cent. of oil, which was pale yellow in colour, liquid at ordinary temperatures, and dried to a hard varnish in about twelve days on exposure to air.

On examination the oil was found to have the following constants:

Sp. gr. at 15°/15° C.	0·9239
Acid value	29·9
Saponification value	185·6
Iodine value	133·3
Titer test (fatty acids)	33°
Hehner value	96·4
Reichert-Meissl value	0·5

Examination of the Fatty Acids.—The liquid and solid (unsaturated and saturated) acids were separated by the usual method by taking advantage of the different solubilities of their lead salts in ether. The mixed fatty acids consist approximately of (1) unsaturated liquid acids 86·0 per cent., and (2) saturated solid acids 14·0 per cent. The mixed unsaturated acids form a brown oily liquid, having an iodine value = 154·2. The saturated acids were obtained as a hard, white cake, melting-point = 55° C.

Saturated Acids.—The mixed solid acids were fractionally crystallised from alcohol, and, after several crystallisations, were finally separated into two main fractions, both of which were crystalline.

Fraction 1, melting-point 69° C. This acid crystallised in shining plates, and was apparently pure stearic acid. On analysis 0·1742 grm. gave 0·4682 grm. CO_2, and 0·1995 grm. H_2O.

Whence C = 76·1 per cent. and H = 12·7 per cent.; $C_{18}H_{36}O_2$ (stearic acid) requires C = 76·0 per cent. and H = 12·7 per cent.

Fraction 2, melting-point 56·5° C. This acid or mixture of acids also crystallised in shining plates. On combustion the following results were obtained: 0·1710 grm. gave 0·4720 CO_2, and 0·1915 grm. H_2O.

Whence C = 75·3 per cent. and H = 12·5 per cent.; $C_{17}H_{34}O_2$ requires C = 75·5 per cent., H = 12·6 per cent.; $C_{16}H_{32}O_2$ (palmitic acid) C = 75·0 per cent., H = 12·5 per cent.

It is probable that this fraction is not a pure acid, but consists of a mixture of stearic and palmitic acids, which is extremely difficult to separate.

Unsaturated Acids.—The iodine value of the mixed liquid acids was found to be 154·2. The original oil was examined for the presence of linolenic esters, but on estimation it was found to yield only 6·66 per cent. of solid hexa-bromides, corresponding to not more than 2·5 per cent. of linolenic acid. It therefore seemed probable that the liquid acids consisted mainly of a mixture of oleic and linoleic acids, and confirmation was obtained on examining the products obtained from them on oxidation.

About 6 grms. of the mixture of unsaturated acids were oxidised with alkaline potassium permanganate, and the oxidation products were separated by means of ether. The ethereal solution yielded, on evaporation, dihydroxy stearic acid, which, when recrystallised from alcohol, was obtained in hexagonal plates, melting-point 130° C. The portion insoluble in ether was extracted many times with a large quantity of boiling water, and several lots of crystals were obtained, all melting, however, at 159° to 160° C. This was found to be a tetrahydroxy stearic acid (sativic acid) formed by the oxidation of the linoleic acid. It yielded the following results on analysis: 0·1312 grm. gave 0·2987 grm. CO_2, and 0·1250 grm. H_2O; C = 62·0 per cent., H = 10·5 per cent.; sativic acid ($C_{16}H_{36}O_6$) requires C = 62·1 per cent., H = 10·3 per cent.

The melting-point 159° to 160° C. is lower than that given for sativic acid by Hazura—viz., 173° C., and accordingly oxidations were conducted on pure linoleic acid obtained from Kahlbaum. The sativic acid thus obtained, however, always melted considerably below 170° C.

SUMMARY.

From the results of this examination the composition of the mixed fatty acids from Para rubber-seed oil appears to be as follows:

(*a*) *Saturated* (*solid*) *acids* = 14 per cent., consisting of *stearic acid* (melting-point 69° C.) and an acid or mixture of acids, melting-point 56·5° C.

(*b*) *Unsaturated* (*liquid*) *acids* = 86 per cent., consisting of oleic acid, 32·6 per cent.; linoleic acid, 50·9 per cent.; linolenic acid, 2·5 per cent.

COMPOSITION OF THE FAT FROM THE SEEDS OF LOPHIRA ALATA (BANKS).

By SAMUEL S. PICKLES, D.Sc., and WILLIAM P. HAYWORTH, F.I.C.

Lophira alata (Banks) is a tree found native in Central and West Africa. It is widely distributed in Sierra Leone and through the coastal districts of West Africa.

The fat, which is obtained from the seeds, and is known as "Niam fat," or "Meni oil" in West Africa, and "zawa" oil in the Sudan, is used by the natives for culinary purposes and also as a hair oil.

During the last few years several consignments of the seeds of *Lophira alata* have been received at the Imperial Institute for investigation from Sierra Leone and also from the Sudan. Descriptions of the seeds and particulars regarding the general characters of the oil and its value have already been given in the *Bulletin of the Imperial Institute* (1908, **6**, 243; 366). In addition, Lewkowitsch (*J. Soc. Chem. Ind.*, 1907, **26**, 1265) has examined the Sudan and Sierra Leone oils, whilst amongst other workers who have examined the oil are E. Heckel (*Ann. de l'Instit. Colon. Marseilles*, 1903, series ii., vol. i., part ii., p. 1) and E. S. Edie (*Quart. J. Inst. Comm. Research in Tropics*, 1907, **11**, 124).

The following investigation of the nature of fatty acids contained in "Niam" fat was made on the fat extracted from *Lophira alata* seeds from Sierra Leone.

The kernels were ground up, and the fat was extracted by cold percolation with light petroleum. When the extraction was complete the petroleum was recovered by distillation, and the last traces were removed first by passing a current of CO_2 through the oil, and finally by heating it to 100° C. in vacuum until constant in weight. The fat obtained on cooling was pale yellow in colour, and of the consistency of butter. It had a somewhat rancid, though not unpleasant, taste. The proportion of fat in the kernels varied in the different specimens between 40 and 43 per cent.

Constants of Fat.—Sp. gr. at 40°/40° C.	0·9016	to	0·9044
Acid value	25·9	„	48·0
Saponification value ...	180·7		194·6
Iodine value	69·8		72·5
Reichert-Meissl value ...	0·8		0·9
Titer test	47°		49°

Examination of the Fatty Acids.—The acids were obtained by saponification of the oil and were separated into saturated and unsaturated acids by taking advantage of the difference in solubility of their lead salts in ether. On recovering the acids from the lead salts, the saturated (solid) acids and unsaturated (liquid) acids were found to be present in about equal proportions.

Saturated or Solid Acids.—The solid acids, which were obtained in the form of a white cake, were fractionally crystallised from alcohol and separated into two main fractions, the first crystallising from alcohol in shining plates, melting-point 77·5° C., and the second, an amorphous fraction, melting-point 56° to 59° C.

Identification of Arachidic Acid.—The melting-point of the crystalline acid (77·5° C.) is almost identical with that given for arachidic acid—viz., 78° C. A combustion of the acid yielded the following results: 0·1730 grm. gave 0·4868 grm. CO_2 and 0·1970 grm. H_2O. Whence C = 76·8 per cent. and H = 12·7 per cent.; arachidic acid, $C_{20}H_{40}O_2$, requires C = 76·9 per cent., H = 12·8 per cent.

The acid yielded a crystalline methyl ester, melting-point 53·5° C., and an amide, melting-point 99° C. There can thus be no doubt that this substance is arachidic acid.

The second fraction was amorphous, and melted indefinitely between 55° to 59° C. Repeated recrystallisation failed to bring about a separation, although it was obviously a mixture. The acids were then converted into their ammonium salts, and the dilute aqueous solution of the ammonium salts was boiled for a short time. Slight decomposition took place, some ammonia passing off; and, on cooling, a cloudiness in the solution indicated the liberation of some fatty acid. On extracting the solution with ether and evaporating the ethereal solution, an acid was obtained which had the crystalline form and melting-point (62·5° C.) of palmitic acid.

On analysis it gave the following results: 0·1755 grm. gave 0·4815 grm. CO_2 and 0·2015 grm. H_2O. Whence C = 74·9 per cent. and H = 12·7 per cent.; palmitic acid ($C_{16}H_{32}O_2$) requires C = 75·0 per cent. and H = 12·5 per cent.

Liquid or Unsaturated Acids.—On liberation from the lead salts the unsaturated acids were obtained as a yellow oily liquid having an iodine value = 139. On treatment with bromine no hexabromides were obtained; linoleic acid therefore must be regarded as absent. The iodine value appeared to indicate a mixture of oleic acid and linoleic acid in about equal proportions, and this was found to be the case.

The presence of linoleic acid was proved by the fact that on bromination linoleic tetrabromide (melting-point 114° C.), was obtained, and also by the production of a sativic acid (melting-point 160° C.) on oxidation with potassium permanganate. Confirmatory evidence of the presence of oleic acid was obtained on examination of the products of oxidation. They contained the characteristic dihydroxystearic acid, which, after crystallisation from alcohol, was obtained in hexagonal plates melting at 130° C., identical with that obtained under similar conditions from pure oleic acid. This acid was separated from the sativic acid present by repeated extraction with ether, in which the latter is insoluble.

SUMMARY.

The composition of the mixed fatty acids from the fat of *Lophira alata* seeds is approximately as follows:

Saturated (Solid) Acids: Fifty per cent., consisting of arachidic acid (melting-point 77·5° C.), palmitic acid (melting-point 62·5° C.), and probably a lower melting acid in small quantity.

Unsaturated (Liquid) Acids: Fifty per cent., consisting of about equal parts of oleic acid and linoleic acid.

FOOD AND DRUGS ANALYSIS.

Detection of Thujone in Absinthe. H. Enz. (*Schweiz. Woch. Chem. u. Pharm.*, 1911, **49**, 337-340; through *Chem. Zentralbl.*, 1911, II., 576.)—After destruction of aldehydes by boiling with aniline phosphate, the absinthe is diluted with water to a strength of 30 per cent. by volume, and 500 c.c. of the liquid are distilled with the aid of a rectifying column, 30 to 40 cm. in length, so as to obtain 9 fractions of 25 c.c. each. Where possible, it is preferable to dilute the absinthe to 60 per cent. strength, and to separate it into fractions of 50 c.c. The very delicate test of Duparc (ANALYST, 1908, **33**, 473) shows that thujone is present in the fractions 6 and 7, which contain much water, but are free from acetaldehyde and constituents of high boiling-point, such as anisol. Since, however, various oils, such as hyssop, vervain, and savin, and also carvone and citral, give the thujone reaction, a positive result in this test is not a certain proof that the liqueur was prepared from the absinthe plant. On the other hand, the non-occurrence of the reaction proves the absence of absinthol. C. A. M.

The Chemical Behaviour and Preservative Action of Sulphites in Beer. J. L. Baker and F. E. Day. (*J. Inst. Brewing*, 1911, **17**, 465-477.)—The beer was distilled with hydrochloric acid in an atmosphere of carbonic acid, the liberated sulphurous acid being collected in a little $\frac{N}{10}$ iodine and titrated with thiosulphate. Except in the case of very acid beers, only a negligible trace of other substances were carried over capable of reducing the iodine solution, the volumetric method being frequently checked by precipitating the oxidised distillate with barium chloride. It was noticed that beers to which no addition of sulphite had been made contained on the average from 20 to 25 parts per million of sulphurous acid, due to the finings and hops. This amount was deducted in all cases from the results obtained, an untreated control beer being used for the purpose in each experiment. Samples of several different kinds of ales and stouts were treated on the laboratory scale with known amounts of potassium hydrogen sulphite and calcium sulphite, and in casks with bisulphite of lime, and with a mixture of the bisulphites of magnesium and potassium (Phylax). The rate of disappearance of the sulphurous acid was then followed at intervals for seventeen weeks, as well as changes in the acidity and attenuation. It was found that potassium bisulphite rapidly lost 25 to 30 per cent. of its sulphurous acid, whilst calcium bisulphite only lost 10 to 12 per cent. A distinctly retarding effect on acid formation was shown during the first sixteen days—an effect in some cases reversed when once the beer had become strongly acid. The after fermentation was arrested to a degree roughly proportional to the sulphite present. It was observed that the greatest loss of sulphurous acid (10 to 40 per cent.) occurred during the first ten days, and usually in the first five. The acidity was found to be retarded as much by 1 ounce to the barrel of any of the sulphite preparations as by larger quantities—in fact, with heavily treated beers, acidity, when once started, proceeded more rapidly. That some combination occurs between certain constituents of the beer and the added sulphurous acid is evidenced by the fact that direct titration of the beer with iodine gave lower values than when distillation was employed. If soda were first added in excess, and then acid more than sufficient to neutralise the soda, amounts even higher than by distillation were sometimes obtained. Experiments showed that combination of the sulphite occurs, not only with beer, but separately with maltose, alcohol (methylated spirit), and dextrin, the bodies so formed possessing considerable stability, since they are not decomposed by hydrochloric acid in the cold. A considerable amount of the sulphurous acid added as a preservative to beer is thus withdrawn from chemical activity, since it is improbable that such stable compounds possess antiseptic value. Since these compounds are decomposed by alkali and water, it is suggested that they may be of the nature of unstable sulphonates or sulphurous esters. The maximum beneficial effect on beer as regards acidity prevention is obtained by the employment of sulphite preparations in such proportions that about 50 parts per million of sulphurous acid are present; double this amount is actively prejudicial. The keeping qualities of the pale ales tested were not affected by sulphites, and it is suggested that their addition to such beers may be dispensed with advantageously.

H. F. E. H.

Detection of Fat in Beeswax, Paraffin, Spermaceti, etc. M. Wagenaar. (*Pharm. Weekblad*, 1911, **48**, 479-481.)—The material is saponified, acidified, and filtered. The filtrate is then rendered alkaline, 5 drops of cupric sulphate solution are added, the mixture is boiled, and again filtered. Should this filtrate be blue in colour, it indicates that glycerol is present, and that the material under examination contains a fatty glyceride.

Estimation of Formic Acid in Foods. H. Fincke. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 88-104.)—Further experiments show that the gravimetric mercuric chloride method recommended previously for the estimation of small quantities of formic acid (ANALYST, 1911, 103) is quite trustworthy; when only 2 or 3 mgrms. of the acid are present, the average error is 0·04 mgrm. In only a few exceptional cases is the accuracy of the method affected by the presence of other substances. It has been shown (*loc. cit.*) that the interfering action of salicylic acid may be prevented by the addition of sodium chloride, and sulphurous acid, if present, may be detected readily, and due precautions taken. Glyoxylic acid is the only other substance which is likely to be met with in foods; it is found in unripe fruits, is volatile, its calcium salt is soluble, and it reduces mercuric chloride. Before estimating the formic acid, the glyoxylic acid must be destroyed by reduction with zinc and sulphuric acid. The author finds that ordinary vinegar contains but traces, if any, of formic acid, whilst wine vinegars contain appreciable quantities of this acid (up to 3·1 mgrms. per 100 c.c.), due to the fact that the wines contained formic acid. Almost all the samples of vinegar "essence" (products containing from 50 to upwards of 80 per cent. of acetic acid) contained formic acid. For the purpose of comparison, the quantities of formic acid found are calculated as parts of the total acid; on this basis, two samples yielded less than 1 part of formic acid per 1,000 parts of total acid, five samples contained more than 10 parts, whilst twenty-one other samples contained from 1·78 to 8·94 parts. W. P. S.

Estimation of Small Quantities of Water in Lard. E. Polenske. (*Untersuch. Nahr. Genussm. Kaiserl. Gesundheitsamte,* 1911, **1**, 30-36.)—The following method is proposed for estimating the small quantities of moisture which are not infrequently present in refined lard; it depends on the fact that lard containing less than 0·45 per cent. of water melts to form a clear liquid when heated to a temperature of 95° C., but becomes turbid when cooled at temperatures varying with the proportion of water present. The semi-fluid lard is placed in a test-tube fitted with a cork carrying a thermometer and heated to a temperature of 52° C. by immersing the test-tube in a water-bath; the tube is then removed from the bath and shaken until the temperature falls to 40° C.; if the lard is clear at 52° C., and does not become turbid at 40° C., it contains less than 0·15 per cent. of water. Should it become turbid at 40° C., its water-content lies between 0·15 and 0·2 per cent. If turbid at 52° C., the lard is heated to 95° C.; a turbidity at this temperature indicates the presence of more than 0·45 per cent. of water, and the amount must be estimated by heating the lard while a current of carbon dioxide is passed through it. Should the lard be clear at 95° C., it is gradually cooled until a turbidity appears, the quantity of water present being then ascertained by reference to the following table:

Water-Content.	Temperature at which Lard becomes Turbid.
Per Cent.	° C.
0·45	95·0
0·40	90·8
0·35	85·0
0·30	75·2
0·25	64·5
0·20	53·0

Of course, if the lard is not clear at a temperature of 95° C., it should be ascertained whether the turbidity is actually due to the presence of water.

W. P. S.

Analysis of Liquorice-Juice. L. and J. Gadais. (*Bull. Soc. Chim.,* 1911 [iv.], **9**, 741-743.)—The sample should be carefully prepared, by grinding, if possible; or by slicing. The moisture is determined by drying 2 grms. at 100° C. to constant weight. The insoluble matter is found by dissolving 5 grms. of the sample in 200 c.c. of cold water, settling for twenty-four hours, decanting the clear solution, adding 100 c.c. of water, settling again for twenty-four hours, again decanting, collecting the residue on a tared filter, washing, and drying at 100° C. The insoluble matter may be incinerated. The total ash should be determined on 2 grms. of the sample. For the estimation of the glycyrrhizin, 5 grms. of sample are placed in a beaker having a mark at 50 c.c., and dissolved in hot water. The cooled solution is made up to 50 c.c., and 100 c.c. of 95 per cent. alcohol are added, with thorough stirring. The deposit is allowed to settle for twenty-four hours, the liquid is decanted off into a basin, the precipitate is collected on a small tared filter, and washed three times with 15 c.c. of dilute alcohol. When all the liquors have been collected in the basin, they are evaporated down to 25 c.c. This extract is transferred to a small tared beaker having a mark at 50 c.c., and made up to the mark; 5 c.c. of water containing 1·8 c.c. of hydrochloric acid (sp. gr. 1·18) are added. The mixture is placed aside for twelve hours so that the precipitate may settle, and the clear liquid is decanted off. The deposit is washed three times with 10 c.c. of water cooled to 2° C., 0·5 c.c. of ammonia (sp. gr. 0·922) is added, and the beaker and its contents are dried at 100° C., the glycyrrhizin being weighed as its ammonia compound. The gums, etc., insoluble in alcohol are weighed on the filter on which they were collected.

A more rapid procedure is as follows: Ten grms. of the sample are dissolved in a flask gauged at 301 c.c. and having a mark at 100 c.c. The 100 c.c. of aqueous solution are mixed with about 170 c.c. of 95 per cent. alcohol; the liquid is cooled again, and made up to 301 c.c. with alcohol. After standing for two hours 150 c.c. of the clear liquid are taken for treatment as described above. It is assumed that the volume of the precipitate is generally about 1 c.c. (*cf.* ANALYST, 1911, 409-410).

J. F. B.

Polarimetric Method for the Determination of Malic Acid, and its Application in Cane and Maple Products. P. A. Yoder. (*J. Ind. and Eng. Chem.*, 1911, **3**, 563-574.)—The author has worked out a polarimetric method for the estimation of malic acid based on the increase in its lævo-rotatory power in presence of uranium acetate. This increase, when the maximum effect is obtained, is 229-fold; it should be noted, however, that the dextro-rotation of tartaric acid is also increased by uranium salts to the extent of 28-fold. If a sufficient quantity of uranium salt be used (at least 1·25 atom of uranium per mol. of malic acid), the increased rotation is independent of the concentration of malic acid—at all events, in dilute solutions. The maximum effect is not produced in presence of a high degree of acidity or concentration of hydrogen ions; mineral acids inhibit the specific action of uranyl salts, but acetic acid may be present in moderate quantities; certain hydroxy-acids, such as citric or lactic, combine with the uranium salt, so that a larger quantity of the latter is required. The simplest method of procedure presumes the absence of interfering substances, the acids being in the free state and present only in small quantities. The concentration of malic acid should be reduced to between $\frac{N}{10}$ and $\frac{N}{5}$. To an aliquot portion of the solution methyl orange and phenolphthaleïn are added, and the liquid is titrated with $\frac{N}{10}$ potassium hydroxide until the methyl orange tint lies between that shown by $\frac{N}{5}$ acetic acid and the same acid neutralised to the extent of one-fourth by potassium hydroxide. The titration is next carried farther to the neutral point with phenolphthaleïn (total acidity). The original solution is polarised in the 200 mm. tube; this liquid is returned to the main bulk, 20 c.c. are measured out, powdered uranyl acetate is added in quantity equal to about 1 atom of uranium to every atom of replaceable hydrogen of the total acids (0·046 grm. of uranyl acetate containing 51·6 per cent. of uranium for every 1 c.c. of $\frac{N}{10}$ potassium hydroxide required for complete neutralisation). The salt is dissolved in the liquid, and sufficient potassium hydroxide is added to establish the degree of neutrality to methyl orange specified above; the solution is made up to 25 c.c., filtered if necessary, polarised, and the reading corrected for the extra dilution. From the difference between the two polarisations the malic acid is calculated on the basis that for a 1 per cent. solution of malic acid in the 200 mm. tube at 20° C. the increase in lævo-rotation with white light is 29·6° Ventzke (10·25° circular), and with sodium light 28·8° V. (9·99° circular). For temperatures other than 20° C. the reading in °V. should be multiplied by $1+0{\cdot}001\ (t-20)$. If the organic acids are not all in the free state, the quantity of uranyl salt to be added cannot be accurately deduced from the phenolphthaleïn titration, and its sufficiency must be ascertained by trial, adding small increments of fully soluble uranyl acetate to the solution contained in a tubulated polarimeter tube, calculating 0·04 c.c. increase in volume per 0·1 grm. of the salt added. By the use of a tubulated polarimeter tube the method of trial may also be used to ascertain the correct degree of acidity necessary to produce the maximum increase of rotation. A measured quantity of the solution, containing a sufficient quantity of uranium, is placed in the tube, and $\frac{N}{2}$ potassium hydroxide or acetic acid, whichever may be necessary, is added from a burette through the tubulure until the maximum effect is produced, the readings being corrected for the extra dilution. This procedure may be adopted for coloured solutions where methyl orange cannot be used.

For the estimation of malic acid when interfering substances are present—for instance, in the examination of maple or cane products—the author has worked out two processes based on the preliminary precipitation of the malic acid:

1. *Lead Acetate Method.*—Weigh out 50 grms. of syrup, or 33·3 grms. of sugar and 16·7 grms. of water; add sufficient alkali to neutralise the acidity ascertained by a separate titration. Add further water to make, with the alkali solution used, 15 c.c. Mix, add 10 c.c. of lead acetate solution (sp. gr. 1·25), then 150 c.c. of neutral 95 per cent. alcohol; shake, and set aside for three hours. Decant off the clear liquid through a suction filter, remove the filtrate, bring the rest of the liquid on the filter, and return it until it filters clear; use the clear filtrate to rinse the flask, and finally wash slightly with 75 per cent. alcohol. Return the precipitate and filter to the flask, heat with water, and fully decompose the precipitate with hydrogen sulphide, filtering and washing with the usual precautions. Concentrate the filtrate, make up in a flask to 50 c.c., and determine the malic acid as described above. For 20 c.c. of such a solution about 0·7 grm. of uranyl acetate should be ample.

2. *Barium Acetate Method.*—This is preferable for cane products, owing to the possible presence of phosphoric and sulphuric acids. Weigh out half the quantities of the sample as prescribed for the lead method; neutralise with 0·0157 grm. of powdered barium hydroxide for every 1 c.c. of $\frac{N}{10}$ alkali required by titration. Add 7·5 c.c. of a 20 per cent. solution of barium acetate, mix, and allow the ingredients to dissolve. Add 220 c.c. of 95 per cent. alcohol, warm to incipient boiling in an Erlenmeyer flask fitted with a condenser. The precipitate should settle in an hour; decant the clear liquid hot through a filter, dilute the remainder with hot alcohol (1 part of

water to 14 parts of 95 per cent. alcohol), transfer to filter, rinse with this alcohol a few times (complete washing unnecessary), return precipitate and filter to the flask, dissolve in about 20 c.c. of hot water, filter, and wash with hot water. Add 1 c.c. of $\frac{N}{5}$ acetic acid to the filtrate, concentrate to 10 c.c., add further 2 c.c. of acetic acid, transfer to a 25 c.c. flask, filtering if necessary, and determine the malic acid by the method of trial (above), adding more acetic acid until the maximum effect is obtained. Maple syrups contain 0·25 to 0·5 per cent. of malic acid, cane products only 0·01 to 0·04 per cent.

Estimation of Tartaric Acid.—The uranium method may be similarly applied for the estimation of tartaric acid. The specific rotatory power, using white light and quartz compensation, of free tartaric acid is 16·3° at 27·5° C., and that of the uranyl compound is 453°; hence the percentage of tartaric acid, using the Ventzke scale, may be calculated by the formula, $\frac{P' - P}{25{\cdot}16 \times \frac{1}{2}L}$. Mixtures of tartaric acid and malic acid may also be analysed by the uranium method, using combined formulæ, provided the total quantity of the two acids present in the solution be known in terms of normal alkali.
J. F. B.

Determination of the Specific Gravity of Very Small Quantities of Milk. A. Kreidl and E. Lenk. (*Biochem. Zeitsch.*, 1911, **35**, 166-168.)—When milk is added directly to either benzene or chloroform, none of the fat present is dissolved by the solvent, the casein appearing to form a protective colloidal coating around the fat globules. The sp. gr. of any milk may, therefore, be determined by preparing a mixture of benzene and chloroform having a sp. gr. equal to that of the milk under examination, as is ascertained by adding a drop of the milk to the mixture. If the sp. grs. of the mixture and the milk be not the same, the drop of milk will either float to the surface or sink to the bottom, according as to whether it is lighter or heavier than the mixture. When the two sp. grs. coincide, the drop of milk will remain suspended in the mixture for a considerable length of time, provided that the temperature remains the same, and no fat is dissolved from the milk even after several hours' contact. The method may be applied to the determination of the sp. gr. of sour milk, and is stated to yield trustworthy results.
W. P. S.

Estimation of Starch in Brewers' Grains. C. Kreuzer. (*Zeitsch. ges. Brauwesen*, 1911, **34**, 277-280, 290-293; through *Chem. Zentralbl.*, 1911, II., 307.)—As none of the usual methods, such as treatment with malt extract, give accurate results in the estimation of the quantity of starch remaining in brewers' grains, the following iodometric process is proposed: An average sample of the grains is ground as finely as possible in a Seck (cutting) mill, and 2·5 grms. of the powder are mixed thoroughly with 10 c.c. of water. Twenty c.c. of sulphuric acid of sp. gr. 1·7 are then added, with stirring, and, after the lapse of fifteen minutes, the mixture is rinsed into a 100 c.c. flask with sulphuric acid of sp. gr. 1·3, this acid being used to dilute the whole to a volume of 100 c.c. after 5 c.c. of an 8 per cent. phosphotungstic acid solution have been added. The contents of the flask are now shaken, filtered through a double filter, and 50 c.c. of the filtrate are cooled in a stoppered 200 c.c. flask to a temperature of 0° C. Five c.c. of $\frac{N}{100}$ iodine solution are then added, the mixture is shaken, again cooled in ice water, 100 c.c. of petroleum spirit cooled to 1° C. are added, the contents of the flask are shaken for one minute, cooled in ice water, and the excess of iodine is then estimated by titrating 50 c.c. of the petroleum spirit with $\frac{N}{100}$ thiosulphate solution, starch solution being added as an indicator towards the end of the titration. The amount of iodine which has combined with the starch in the grains may then be calculated, and from this the quantity of starch present is obtained, 1 c.c. of $\frac{N}{100}$ iodine solution corresponding with 0·025 grm. of starch. The author finds that brewers' grains of various origin contain from 0·99 to 4·80 per cent. of starch. W. P. S.

Method for the Separation of Starch and Glycogen. E. Baur and E. Polenske. (*Untersuch. Nahr. Genussm., Kaiserl. Gesundheitsamte*, 1911, 1, 25-29.)—In the ordinary method of estimating starch in sausages by treatment with alcoholic potassium hydroxide solution, the glycogen is precipitated together with the starch, and is weighed with the latter. The following method of separating these two substances is given, advantage being taken of the greater solubility of glycogen in ammonium sulphate solution: A quantity of about 0·5 grm. of the mixed starch and glycogen separated from the material under examination is dissolved in 30 c.c. of water, and 11 grms. of finely powdered ammonium sulphate are added; the starch is precipitated, and, after the lapse of thirty minutes, is collected on a filter, and washed with a solution containing 11 grms. of ammonium sulphate in 30 c.c. of water. The filtrate, 30 c.c. in volume, is diluted with five times its volume of water, and 500 c.c. of alcohol are added; the glycogen thus precipitated is collected on a filter, washed with 5 per cent. alcohol, then with absolute alcohol, dried at 100° C., and weighed. The starch precipitate is washed with 50 per cent. alcohol to remove the ammonium sulphate, then dried at 100° C., and weighed.

W. P. S.

Preparation of the Copper Solution used in Bang's Sugar Titration Method. I. Bang. (*Biochem. Zeitsch.*, 1911, **32**, 443; through *Chem. Zentralbl.*, 1911, II., 307.)—The thiocyanate solution is made by dissolving 100 grms. of potassium bicarbonate in 1,300 c.c. of water, and then adding the other salts. To this solution are added 150 c.c. of a solution containing 166·67 grms. of crystallised copper sulphate per litre (*cf.* ANALYST, 1907, **32**, 180). W. P. S.

Estimation of Theobromine and Caffeine. C. Monthule. (*Ann. Chim. anal. appl.*, 1911, **16**, 137-138.)—The author describes the method in which the mixed alkaloids are dissolved in ammonia, silver nitrate is added, and the mixture is neutralised exactly with acetic acid. A gelatinous precipitate is thus obtained which contains all the theobromine, whilst the caffeine remains in solution.

Identification of Veronal. A. Jorissen. (*J. Pharm. Chim.*, 1911, **3**, 478-481.)—Three grms. of potassium hydroxide are fused in a nickel crucible and

0·3 grm. of veronal is added slowly; after being heated for two minutes, the mixture is cooled and dissolved in 10 c.c. of water. Five c.c. of this solution are treated with a few drops of ferrous sulphate solution, allowed to stand for five minutes, and then acidified with hydrochloric acid; a blue precipitate forms gradually if the substance under examination be veronal. The remaining 5 c.c. of the solution are acidified with sulphuric acid, shaken out with ether, and the ethereal extract is evaporated; on dissolving the rancid-smelling residue in water and adding a few drops of ferric chloride solution, a yellow precipitate is formed.

Estimation of Organic Substances in Water by Means of Permanganate. H. Noll. (*Zeitsch. angew. Chem.*, 1911, **24**, 1508-1518.)—This paper relates to an investigation of the reactions taking place when organic substances are oxidised with permanganate in the presence of sulphuric acid. W. P. S.

Estimation of the Volatile Acids in Wine. K. Windisch and T. Roettgen. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 155-170.)—The authors have investigated the conditions governing the distillation of the volatile acids present in wine, and, as the result of numerous experiments with wines and aqueous solutions of various volatile organic acids, come to the conclusion that in the official (German) method for estimating these acids the total quantity of volatile acids is found in the prescribed 200 c.c. of distillate only when the wine contains not more than 0·2 grm. of the acids. It is not permissible to distil over more than 200 c.c., as the distillate will then contain considerable quantities of lactic acid. If the wine under examination contains more than 0·2 grm. per 100 c.c. of volatile acids, it should be diluted with an equal volume of water, and the estimation is carried out on 50 c.c. of the diluted solution. It is recommended that the steam used in the distillation be admitted to the distillation-flask through a tube 4 mm. in diameter the lower end of which is bent at a right angle. During the distillation the current of steam, etc., should be so regulated that the 50 c.c. of wine in the distillation flask are evaporated to 25 c.c., and maintained at this volume until the distillation is completed; the steam should be under the lowest possible pressure, and about thirty minutes taken for the distillation. At the same time, wine distillates always contain some lactic acid, the quantity depending on the amount present in the wine, the pressure of the steam, and the volume of the distillate; lactic anhydride is more volatile with steam than is lactic acid. The distillation of lactic acid is considerably decreased by the use of a still-head filled with glass beads; for instance, a solution containing 1·4825 grms. of lactic acid per 100 c.c., yielded only 0·043 grm. in 100 c.c. of distillate. Only traces of formic acid and aldehyde are formed when lactic acid is submitted to steam distillation. W. P. S.

Portuguese Standards for Wines, Vinegar, and Olive Oil. (Extract from the Official Methods of Analysis. (*Ann. Falsif.*, 1911, **4**, 399-403.)—The following limits are given for certain constituents, etc., of wine, vinegar, and olive oil:

Wine.—Total solids, not less than 20 grms. per litre in the case of red wine and 16 grms. per litre for white wine. Alcohol, 7·5 to 10 per cent. Ash, not less than

1·6 grms. per litre. Volatile acidity, not more than 2 grms. per litre, calculated as acetic acid; the difference between the total solids and the total acidity (as tartaric acid) should be not less than 13 for red wine or 11 for white wine. The ratio of the glycerol to alcohol (by weight) varies from 1 : 20 to 1 : 8·5. Wines must not contain added glycerol, sucrose, or dextrin, but the presence of traces of copper, introduced accidentally, is not considered as adulteration.

Vinegar.—Wine vinegar must contain at least 4 per cent. of acetic acid and be free from mineral acids, added organic acids, poisonous metals, empyreumatic substances, etc.

Olive Oil.—Sp. gr. at 15° C., 0·915 to 0·918; refractive index, 1·4660 to 1·4670; the free acid should be not more than 1·6 per cent.; iodine value, 75 to 85; saponification value, 182 to 202; solidifying-point, 2° to 4° C. The oil must be free from arachidic acid, and not yield reactions for sesame and cottonseed oils.

W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Chemistry of Anæsthetics. III. : Nitrous Oxide. C. Baskerville and R. Stevenson. (*J. Ind. Eng. Chem.*, 1911, **3**, 579-582.)—The authors give a long list of impurities which may be suspected in a cylinder of nitrous oxide, and describe the methods in use in their laboratory for the detection of each. From an examination of the contents of several cylinders supplied by American manufacturers, the authors feel justified in recommending that nitrous oxide which is to be used for anæsthetic purposes should contain at least 95 per cent. of that gas (many commercial samples contain 99 per cent.) and no solids, liquids, combustible organic matter, chlorine, or other oxides of nitrogen. The last two impurities may be tested for by slowly passing 10 litres (three hours) through silver nitrate and ferrous sulphate solutions.

None of the well-known methods for the determination of nitrous oxide in a gaseous mixture of which it is the principal constituent is quite satisfactory. Explosion with hydrogen may lead to results fully 2 per cent. below the truth. The following method is recommended: A combustion-tube 100 cm. long is packed for 70 cm. of its length with rolls of copper gauze, one end of the tube being drawn out to small bore and connected by rubber to a calcium chloride tube, and this to a second similar tube and a bubbler, to show the rate of passage of the gas. The other end of the combustion-tube is fitted with a rubber stopper which carries a tee, one limb of which connects with a source of pure dry hydrogen, the other with the sample of nitrous oxide confined over mercury in a vessel in which it can be measured and its pressure and temperature observed. Hydrogen is passed through the combustion-tube at the rate of 3 or 4 bubbles a second until the copper is completely reduced and the calcium chloride tubes have reached a constant temperature. The calcium chloride tubes are weighed, replaced in position, the current of hydrogen stopped, and about 800 c.c. of the gas sample passed through the combustion-tube at the rate of 2 bubbles per second. This requires about an hour. Hydrogen is then passed through at the rate of 3 or 4 bubbles a second until all the copper oxide is reduced and all the moisture driven over into the calcium chloride tubes, this process requiring about forty-five minutes. The combustion-tube is then ready for a second determination, to begin with the passage of the nitrous oxide through the tube. A trap is used to catch any mercury and prevent its entrance to the combustion-tube. Since this is a determination of nitrous oxide indirectly by the direct determination of the oxygen present, the water from other oxygen compounds and also the moisture present in the gas must be subtracted. In the samples examined the moisture ranged from 0·13 to 0·16 per cent., and no compounds of oxygen other than nitrous oxide were detected. Oxygen itself could be detected in every sample, but the amount was too small to estimate (less than 0·1 per cent.). G. C. J.

Direct Estimation of Creatine in Pathological Urine. G. Stanley Walpole. (*J. Physiol.*, 1911, **42**, 301-308; through *Chem. Zentralbl.*, 1911, II., 394.) —The method depends upon the fact that diacetyl reacts with creatine, but not with creatinine. Albumin, which also gives a positive reaction, must first be removed by treatment with trichloracetic acid, whilst the influence of the other constituents in the urine is eliminated by making the colorimetric estimation in the following manner: Two c.c. of the urine under examination are treated with 2 c.c. of a saturated solution of sodium carbonate and 3 drops of diacetyl solution, then diluted with water to 6 c.c., and heated for one minute in boiling water. At the same time four standards for comparison are prepared by adding 0·0 mgrm., 0·2 mgrm., 0·5 mgrm., and 0·8 mgrm., of creatine to a normal urine. After the whole of the solutions have stood for thirty minutes, they are filtered, and the urine under examination is treated with a solution of 2 c.c. of normal urine and 2 c.c. of sodium carbonate solution diluted to 6 c.c., whilst to each of the standard tubes an addition is made of 2 c.c. of the urine under examination and 2 c.c. of sodium carbonate solution diluted to 6 c.c. The diacetyl reagent is obtained by distilling 50 c.c. from a mixture of 1 grm. of dioxime with 100 c.c. of 20 per cent. sulphuric acid. The diacetyl in the distillate cannot be used after a month, owing to the formation of products which give with alkali a brown pigment interfering with the reaction. For the same reason it is necessary to avoid an excess of diacetyl. The reaction is more intense in water than in urine, probably owing to the restrictive influence of ammonium salts. There is also another substance with a retarding action. This is insoluble in ether and may be removed by means of animal charcoal.

C. A. M.

Dihydroxystearic Acid in Good and Poor Soils. O. Schreiner and E. Lathrop. (*J. Amer. Chem. Soc.*, 1911, **33**, 1412-1417.)—The frequent occurrence of dihydroxystearic acid in poor soils has led to the conclusion that it is either a principal or contributory factor in infertility, and the following method is recommended for its estimation: Five to 10 pounds of the soil are extracted for twenty-four hours with 5 to 10 litres of 2 per cent. caustic soda solution. The supernatant extract is syphoned off, acidified with dilute sulphuric acid, filtered and shaken out with ether. The ethereal extract is evaporated to small bulk, and the watery residue boiled vigorously and filtered hot through a wet filter. The filtrate containing the dihydroxystearic acid is allowed to cool and is again extracted with ether, the solution being treated as before. The aqueous solution, after evaporation to small volume, deposits the acid in star-like clusters of white plates or needles, which melt when pure at 99°. One-third of the sixty soils examined showed the presence of the acid, but only two of the "good" class contained it. Of the thirty poor soils, just half the number contained the compound, which was found in virgin soils as well as in those long cultivated. Its distribution is universal throughout the United States.

H. F. E. H.

Quantitative Estimation of Volatile Fatty Acids in Fæces. R. S. McCaughey. (*Zeits. physiol. Chem.*, 1911, **72**, 140-150; through *Chem. Zentralbl.*, 1911, II., 643.)—The vacuum steam distillation method of Welde is fairly accurate for the estimation of free volatile fatty acids if a correction be made in titrating for the error introduced by the large volume of liquid and the action of carbon dioxide. For the estimation of total acidity, however, Welde's method is not very suitable. The hydrolysable substances contained in the fæces must be removed before distilling with phosphoric acid. The author extracts the fæces with boiling alcohol, makes the alcoholic extract alkaline with N. sodium hydroxide, and evaporates it to dryness on the water-bath. The residue is taken up with water, phosphoric acid is added, and the mixture is distilled with steam under vacuum. The distillate is measured and titrated with $\frac{N}{10}$ sodium hydroxide, using phenolphthaleïn as an indicator. From the number of c.c. used is deducted the correction necessary for the presence of carbon dioxide and the volatility of the phosphoric acid. This amounts to about 1 c.c. of $\frac{N}{10}$ sodium hydroxide per 1,400 to 1,500 c.c. of distillate.

J. F. B.

Bacteriological Examination of Honey. A. Sartory and E. Moreau. (*Ann. Falsif.*, 1911, 4, 259-263.)—The following micro-organisms were found in various samples of honey: Bacteria: *Bacillus subtilis*, *B. megaterium*, *B. ærophyllus*, *Sarcina lutea*, *Micrococcus radiatus*, *Staphylococcus pyogenes*, and Friedländer's *Pneumobacillus*; moulds and yeasts: *Penicillium glaucum*, *Rhizopus nigrans*, *Saccharomyces-cerevisiæ*, *Mucor racemosus*, *Aspergillus gracilis*, and *Sterigmatocystes nigra*. A new bacillus was also discovered which yielded golden-yellow colonies on plate cultures; it liquefied gelatine, the liquid portion being covered with a yellow skin. The authors place this bacillus between *B. luteus Flügge* and *B. flavus Macé*.

Preparation of Menthylglycuronic Acid. I. Bang. (*Biochem. Zeitsch.*, 1911, **32**, 445; through *Chem. Zentralbl.*, 1911, II., 307.)—The urine of rabbits, after administration of menthol, is one-half saturated with ammonium sulphate, boiled, and filtered. Ammonium menthylglycuronate separates out quantitatively on cooling the filtrate, and the acid itself may be obtained by treating the ammonium salt with acidified water or alcohol.

W. P. S.

Germicidal and Insecticidal Values of Different Soaps, with or without Associated Active Agents. H. C. Hamilton. (*J. Ind. and Eng. Chem.*, 1911, **3**, 582-584.)—The insecticidal value of soap alone is considerable, while its germicidal value is small. The nature of the glyceride present has some effect, since linseed-oil soap is found to have a greater germicidal action than cotton-oil soap (1 : 300 dilution of the former equal to 1 : 200 dilution of the latter, using the Rideal-Walker method). Further tests showed that cocoanut-oil soap has the highest value as a germicide, a dilution of 1 : 40 killing the *B. typhosus* (twenty-four-hour culture) at 20° C. in five minutes, while a dilution of only 1 : 20 was required in the case of castor- and olive-oil soaps to produce the same results. Insecticidal tests, using the bed-bug, *Cimex lectularius*, as the experimental organism, showed that little difference exists in the action of the potassium soaps of the different glycerides. The same soaps mixed with a high-boiling tar acid and caustic potash yielded some unexpected results, as shown in the following table. In each case the ingredients of the mixtures were present in equal proportions, and the specified dilutions are for each ingredient. The heading "coefficient" signifies the number of times the preparation can be diluted, as compared with carbolic acid:

OLIVE-OIL SOAP.

Combination.	Effective Dilution.		Coefficients.	
	Germicidal.	Insecticidal.	Germicidal.	Insecticidal.
Soap alone	1 : 20	1 : 100	0·17	5·0
Soap + cresylic acid	1 : 500	1 : 300	4·0	15·0
Soap + alkali	1 : 1100	1 : 50	9·0	2·5
Soap + cresylic acid + alkali ...	1 : 1000	1 : 300	8·3	5·0
	COCOANUT-OIL SOAP.			
Soap alone	1 40	1 : 100	0·33	5·0
Soap + cresylic acid	1 1000	1 : 100	8·3	5·0
Soap + alkali	1 1100	1 : 200	9·0	10·0
Soap + cresylic acid + alkali ...	1 1000	1 : 300	8·3	15·0
Cresylic acid + alkali	1 400	1 : 25	3·3	1·25
Alkali (KOH) alone	1 1200	1 : 25	10·0	1·25

The above results show that the *B. typhosus* is very susceptible to the germicidal action of caustic potash.

A point of importance is the effect of hydrolysis on the germicidal value of the soap solution. A freshly made dilution of 1 : 300 of an olive-oil soap with cresylic acid killed the test-organism under the above-specified conditions in less than one minute, while after standing eighteen hours the same dilution required between three and four minutes to produce this effect. A. R. T.

Detection of Poisonous Ricinus Constituents in Fodder-Stuffs. W. Mooser. (*Landw. Vers.-Stat.*, **75**, 107-134; through *Chem. Zentralbl.*, 1911, II., 638-639.)—By the intravenous injection of ricin into rabbits, the author has prepared an antiricin serum which serves as a precipitation reagent for the detection of *Ricinus* poison in fodder-stuffs, due to the presence of castor-oil seeds. Other bodies besides ricin are capable of giving a precipitate with the antiserum; for instance, arachin, a constituent of earth nut meal. But, since these bodies are soluble in alcohol, whilst ricin is insoluble in that medium, it is possible to eliminate the interfering substances. The procedure for the detection of ricin is as follows: Ten grms. of the suspected fodder are digested for twenty-four hours at 37° C. with 100 c.c. of pure glycerol, the extract is filtered and poured into about ten times its volume of a mixture of equal parts of alcohol and ether. The precipitate is filtered off, washed first with alcohol and then with ether, and dried at 37° C.; it is then stirred up with about 20 c.c. of 10 per cent. sodium chloride solution, and further digested with 100 c.c. of salt solution in the thermostat, the volume being finally made up to 200 c.c. before filtration. One c.c. of the clear filtrate is treated with 0·1 c.c. of the active serum, the latter being allowed to remain on the surface of the liquid, and the whole is placed in the thermostat for several hours. If ricin be present a precipitate or turbidity is produced. Only the poisonous principles of the castor-oil seed show the reaction; the presence of the harmless constituents has no effect. Meissner's statement that the poisonous principle of the seeds becomes inactive under the action of moist heat at 90° C., and is destroyed by dry heat at 130° C., is not confirmed by the authors.

J. F. B.

ORGANIC ANALYSIS.

Detection and Estimation of Methyl and Ethyl Alcohols and Formic Acid. R. F. Bacon. (*Circular, U.S. Dept. of Agriculture,* 1911.)—Substances containing small quantities of alcohol, or dilute solutions of alcohol, may be treated for the concentration of the contained spirit by distilling the material after first dissolving in them a considerable quantity of calcium or sodium chloride, and re-distilling the distillate after again adding salt. A concentration of ten times and a resulting solution containing 2 to 4 per cent. of alcohol may thus be obtained. The material should be neutralised, using phenolphthaleïn as indicator, before distilling. The sp. gr. and Zeiss immersion-refractometer reading are then determined, an agreement between these tests as to the amount of alcohol being evidence of the identity of the alcohol with ethyl alcohol. This result is confirmed by preparing the ester of paranitrobenzoic acid (Baumann-Schotten method) or of benzoic acid. To the solution a slight excess of paranitrobenzoyl chloride and an equivalent amount of sodium hydroxide are added. The liquid is shaken till the odour of the chloride disappears. The ester is a crystalline substance melting at 57° C. The benzoyl ester, prepared similarly with benzoyl chloride, is obtained quantitatively, and may be recognised by its odour and its b.-pt. (212° C.). Ethyl alcohol may be detected by the iodoform reaction and the production of ethyl benzoate. Methyl benzoate has a similar odour, but does not give the iodoform reaction.

Methyl alcohol may be detected by distilling 100 c.c. of liquid with 5 to 8 grms. of chromic acid, and testing the first 10 c.c. of distillate for formaldehyde by the usual methods. If other oxidisable substances are present the material is neutralised and one-third distilled, the distillate being oxidised as described. One part of the alcohol in 100,000 parts of water can thus be detected, and smaller amounts by previous concentration. If it is required to detect the alcohol in ethyl alcohol, the liquid is first diluted to 30 per cent. strength, and then oxidised after distillation.

Formic acid may be detected by its reduction to formaldehyde with magnesium. The solution is strongly acidified with phosphoric acid and one-third distilled. Dilute sulphuric acid and magnesium filings are added to the distillate, a vigorous evolution of hydrogen taking place. According to the amount of formic acid present, a reaction for the aldehyde will be obtainable in from five minutes to one hour. Formic acid is determined by distilling the solution containing it with phosphoric acid until the distillate is no longer acid. The distillate is evaporated after neutralisation, if necessary, to convenient volume, and an excess of platinum chloride and acetic acid equal to 1 to 2 c.c. of glacial acid for less than 1 grm. formic acid are added. The mixture is then boiled under a reflux-condenser for one hour, and the reduced platinum collected and weighed, when $Pt \times 0{\cdot}472 =$ formic acid.

A. R. T.

Separation and Estimation of Ammonia and Pyridine. M. Delépine and R. Sornet. (*Bull. Soc. Chim.*, 1911, [IV.], 9, 706-710.)—The authors have established that ammonia may be separated from pyridine by a modification of the method proposed by François for its separation from volatile amines. The ammonia is precipitated in combination with mercuric oxide, the amines remaining in the filtrate and the ammonia being liberated by distilling the mercury precipitate either with potassium iodide or with sodium thiosulphate. The mixture of ammonia and pyridine, in combination with a slight excess of hydrochloric acid, is first obtained from the sample by distillation. To this solution are added in the order named: 50 to 100 c.c. of a solution of mercuric chloride (30 grms. per litre), 30 c.c. of sodium carbonate (200 grms. per litre), 5 to 10 c.c. of sodium hydroxide (400 grms. per litre). A precipitate is formed, the liquid is made up to a known volume (500 c.c. or 1 litre) and allowed to settle. An aliquot portion (eight or nine-tenths) of the liquid is filtered rapidly, and the pyridine is distilled off in 150 c.c. of distillate, being collected in presence of hydrochloric acid. A slight excess of gold chloride is added, and the excess of the reagent, after evaporation, is removed from the pyridine aurichloride by means of anhydrous ether free from aldehyde. If evaporation be insufficient the pyridine compound yields some of its gold chloride to the ether, whereas if heating be continued too long some of the excess of gold chloride becomes insoluble in ether. Good results are obtained by evaporating the liquid to a small bulk on the water-bath and completing the evaporation by exposure in the vacuum desiccator for some days. Platinic chloride is more convenient than gold chloride, since the liquid may then be evaporated without danger. The excess of the reagent is removed by treatment in the cold with a mixture of 1 part of absolute alcohol and 3 parts of dry ether. The residue of pyridine platinichloride is incinerated.

For the estimation of the ammonia, the mercury precipitate is washed three or four times on the filter with a liquid containing 10 grms. of sodium carbonate and 10 grms. of sodium hydroxide per litre. The filter and precipitate are then transferred with water to a distillation flask, 50 c.c. of a solution of thiosulphate (200 grms. per litre) are added, 200 c.c. of distillate are collected in an excess of hydrochloric acid, and the solution is evaporated on the water-bath in a glass vessel, the residue being dried at 105° C. and weighed as ammonium chloride. J. F. B.

Estimation of Caoutchouc as Tetrabromide. D. Spence and J. C. Galletly. (*Le Caout. et la Guttapercha*, 1911, 8, 5313-5316.)—Having shown (ANALYST, 1911, 361) that the decomposition of caoutchouc tetrabromide by nitric acid involves a serious error, the authors advocate the following procedure: From 0·1 to 0·5 grm. of the tetrabromide is weighed out in a platinum crucible, and intimately mixed with 1 grm. of sodium carbonate, the amount of halogen in which has been previously determined. The whole is covered with a layer of fusion mixture sufficient to prevent any loss of hydrobromic acid during the combustion. The crucible is heated gently and gradually for half an hour up to a red heat; the contents should never be allowed to fuse completely. After cooling, the mass is dissolved in water, the solution is filtered, and the halogen is estimated gravimetrically. The combustion may be carried out equally well by using sodium carbonate alone instead of the fusion mixture. Under certain conditions the results tend to be slightly too high, owing to the presence of some silver salt which remains undecomposed if the solution to be precipitated is merely acidified with nitric acid; it is necessary, therefore, to add a considerable excess of nitric acid and to precipitate the bromide in a strongly acid solution. The caoutchouc tetrabromide should be reduced to powder in order to obtain a uniform and intimate mixture with the alkali; it is desirable that not less than 0·3 to 0·4 grm. be weighed out for analysis. A temperature corresponding to that of incipient fusion with sodium carbonate alone gives the best results in practice, this being sufficient to decompose all traces of organic matter tending to make the results too high; an excessive temperature leads to low results. J. F. B.

Estimation of Halogens in Organic Compounds. T. St. Warunis. (*Chem. Zeit.*, 1911, **35**, 906-907.)—The author describes the following method for the estimation of halogens in organic compounds: 0·2 to 0·3 grm. of the finely powdered substance is stirred up in a nickel crucible with a mixture of 10 grms. of powdered potassium hydroxide and 5 grms. of sodium peroxide, some of the mixture being placed as a covering layer on the top of the portion containing the organic substance. The crucible is covered and placed in a drying oven at a temperature not exceeding 85° C. until the contents have caked together. The crucible is then heated at first with a very small flame, the heat being increased as fusion proceeds. After the melt has cooled it is dissolved in water, and dilute nitric acid is added drop by drop until the solution is acid, care being taken to avoid a rise of temperature. The liquid is filtered, and the halogen is estimated either gravimetrically or volumetrically by means of silver nitrate. In the case of iodo compounds a little iodate may be formed, in which case it is advisable to add sulphurous acid to the solution of the melt. The method is rapid and gives accurate results in the case of solid and not very volatile halogen compounds; in the case of nitrogenous substances there appears to be no danger of the formation of cyanide. J. F. B.

Estimation of Lecithin. C. Virchow. (*Chem. Zeit.*, 1911, **35**, 913-914.)—The following method is stated to yield accurate results and to be more convenient and satisfactory in its manipulation than the methods hitherto employed: The main feature consists in the treament by which the filtration of the ethereal solution of the lecithin is accelerated; the portion of the extract, which is insoluble in ether, is no longer of a slimy consistence, and a clear filtrate is obtained. One grm. of the lecithin preparation is placed in a narrow-necked flask of about 20 c.c. capacity and boiled with three successive quantities of 10 c.c. of absolute alcohol. The alcoholic extracts are filtered into a weighed flask, and the insoluble portion is washed with alcohol so that the volume of the total filtrate is about 60 c.c.; this alcoholic extract is evaporated, the residue is dried, weighed, and then extracted with three successive quantities of 10 c.c. of ether. The ethereal solution is filtered through asbestos, the insoluble portion is washed three times with ether, and the united filtrates and washings are evaporated. After being weighed, the dry residue is dissolved in fuming nitric acid, the solution is transferred to a platinum crucible, and evaporated to dryness. One grm. of anhydrous sodium carbonate is now added, then 5 grms. of a mixture consisting of 2 parts of potassium nitrate and 1 part of crystallised sodium carbonate, and the contents of the crucible are fused. The fused mass is dissolved in water, acidified with hydrochloric acid, then neutralised with ammonia, and the phosphoric acid is estimated by the magnesia method in the usual way.

W. P. S.

Lecithin. R. Cohn. (*Zeitsch. öffentl. Chem.*, 1911, **17**, 203-217; through *Chem. Zentralbl.*, 1911, II., 304-305.)—The author has investigated the conditions governing the extraction of lecithin from substances containing it. That lecithin cannot be extracted completely by ether from yolk of egg, etc., is due to the adsorption of lecithin by the albumin. Cold alcohol extracts the whole of the lecithin, and there is no necessity to use hot alcohol, as further treatment with the latter only removes very small quantities of substances (phosphatides) which are insoluble in cold alcohol. There does not appear to be any chemical combination between the lecithin and the albumin. It is not possible to extract the whole of the lecithin by means of ether, alcohol, or other solvent, when the original material has been heated. For the estimation of lecithin in preparations containing added phosphoric or glycerophosphoric acids, the sample is extracted first with ether and then with alcohol; the alcohol extract must next be extracted with chloroform, which dissolves the lecithin from quantities of the above-mentioned acids which are found in the alcoholic extract. The nitrogen-content of the alcoholic extract should also be estimated in order to prove the actual presence of lecithin; if this substance be present alone the ratio of nitrogen to phosphorus will be approximately 1 : 1. W. P. S.

Estimation of Naphthalene in Crude Coal Gas. A. Albrecht and F. Müller. (*J. für Gasbeleuchtung*, 1911, **54**, 592-594; through *Chem. Zentralbl.*, 1911, II., 493.)—Rutten's picric acid method, which usually gives excellent results, is not suitable for crude coal gas, with which it yields too low values. With regard to other methods, experiments showed that only the purification of the gas with sulphuric acid and with alkali solution is applicable. Traces of tar left behind do not interfere with the sharpness of the change of colour. All rubber tubing employed should be old and as short as possible. Estimations of the naphthalene in the coal gas from horizontal and upright retorts indicated that the higher proportion in the latter is due to the higher temperature at which the gas leaves the retort. The three kinds of coal tried yielded gas containing practically the same amounts of naphthalene (*cf.* ANALYST, 1910, **35**, 74). C. A. M.

Characteristics of Conifer Fatty Oils. C. Grimme. (*Chem. Zeit.*, 1911, **35**, 925-927.)—With the exception of *Pinus Gerardiana*, which is a commercial product from the East Indies, the whole of the seeds examined were obtained from European plants. The results are summarised in the following table:

OILS.

Seeds of—	Yield of Oil.	Sp. Gr. at 15° C.	Solidification Point.	$[N]_D$ 35° C.	Acid Value.	Saponification Value.	Iodine Value (Wijs).	Fatty Acids.	Glycerol.	Unsaponifiable Matter.
	%		° C.					%	%	%

All the oils had aromatic odours and possessed strong drying properties. The oil from *P. cembra* contained palmitic, oleic, linolic, and hydroxy acids, with traces of myristic acid. The oils of *P. picea* and *P. abies* are known in commerce as pitch-tree oil and pinaster (or red pine-seed) oil respectively. C. A. M.

Examination of Coprah. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 195-196.)—In order to obtain uniformity in the analytical results the following process of analysis has been agreed upon and tested by the Association of German Oil-Millers: The commercial samples of coprah, weighing about 2 kilos., are broken in half, and only half of each used for the analysis. These portions are broken by hand into pieces about the size of a nut, which are then crushed in a mill so constructed that it yields small fragments without causing any separation of oil. About 500 grms. of the thoroughly mixed material are now introduced into a flask provided with a ground-in stopper. Ten grms. are weighed and placed in a filter-paper cartridge, any oil that exudes during the weighing being taken up with a plug of cotton-wool, which is also introduced into the cartridge. The latter is extracted beneath a reflux condenser with petroleum spirit (with a boiling-point up to 60° C.) in a Soxhlet apparatus, the highest point of the siphon tube of which is only 1 cm. above the top of the cartridge. The extraction is continued for four hours, the temperature of the water-bath being meanwhile not allowed to exceed 75° C., after which the cartridge is removed from the apparatus, and, after expression of as much of the solvent as possible by means of a glass rod, is dried for half an hour in a hot-water oven. Its contents are then ground up with quartz sand, replaced in the cartridge, and again extracted for two hours. Provided that the material has been sufficiently finely ground, a second grinding-up and third extraction are unnecessary. The solvent is evaporated from the united extracts, and the residue of oil dried in the oven at 105° to 106° C. and weighed. C. A. M.

[The essential part of this process appears to be the fine grinding of the sample after the bulk of the oil has been extracted by the solvent and completion of the process by further extraction of the fine powder. The necessity for this has long been recognised in England, and is enjoined for the analysis of all agricultural feeding stuffs in the official regulations of the English Board of Agriculture and Fisheries.—Ed.]

Neats-Foot Oil. **W. Fahrion.** (*Collegium*, 1911, 209-212; through *Chem. Zentralbl.*, 1911, II., 397-398.)—Eleven samples of commercial neats-foot oil and five samples of bone oil gave the following values:

	Acid Value.	Saponification Value.	Hehner Value.	Iodine Value.	Melting-Point of Fatty Acids.	Mean Molecular Weight of Fatty Acids.
					° C.	
Neats-foot oil ...	2·4 to 10	189 to 197·6	94·7 to 95·6	59·7 to 85·2	21 to 37	275·4 to 288·6
Bone oil ...	2·4 to 9	186·7 to 196·1	95 and 95·7	67·4 to 79·8	13 to 34	279·0 to 294·8

Since the fluidity in the presence of cold is reduced by a rise in the acid value, the author advocates the adoption of 6 (= 3 per cent. of oleic acid) as the highest limit for the acid value of neats-foot oil. The saponification value recorded by different observers for pure oils ranges from 194 to 199, and only in the case of commercial samples does it fall as low as 189. Holde and Stange found ten samples with iodine values of 78·3 to 85·2 to be adulterated. This value may be raised a few units by subjecting the oil to cold. The mean molecular weight of the fatty acids ought not to be outside the limits of 275 and 284, and their melting-point should be as low as possible. For the detection of vegetable oils, valuable information is afforded by a determination of the iodine value of the liquid fatty acids. Thus, three samples of neats-foot oil gave liquid fatty acids with iodine values of 94·9, 96·9, and 92·7, whilst in the case of one which was undoubtedly adulterated the corresponding value was 105·4.

C. A. M.

Estimation of Nitric Nitrogen in Gun Cotton, Nitroglycerine, and the Like. H. Pellet. (*Ann. Chim. anal. appl.*, 1911, **16**, 294-296.)—In handling nitroglycerine and some other products it is necessary to proceed rather differently to Schloesing's original method in order to avoid too rapid action. The acid solution of ferrous sulphate is boiled in the flask to expel air from the apparatus, and the nitroglycerine in more or less dilute solution is then added at any desired rate. (*Cf.* ANALYST, 1911, 243.)

G. C. J.

Composition of Soya-Bean Oil. S. Keimatsu. (*Chem. Zeit.*, 1911, **35**, 839-840.)—The oil examined gave the following analytical values: Sp. gr. at 15° C., 0·9265; viscosity (Engler) at 20° C., 8·9 to 9·0; melting-point, −7° to −8° C.; solidification-point, −15° to −16° C.; saponification value, 190; iodine value, 132 to 135; melting-point of fatty acids, 23° to 24° C.; and solidification-point of fatty acids, 16° to 17° C. It contained about 12 per cent. of saturated fatty acids, chiefly stearic and palmitic acids, and about 80 per cent. of unsaturated fatty acids, about half of which consisted of an acid isomeric with linolic acid, and yielding a hydroxy acid melting at 158° to 159° C. They also contained ordinary linolic acid (yielding satavic acid melting at 173° to 175° C.) and oleic acid (with a dihydroxy acid melting at 126° to 127° C.). Together these two acids formed about 15 per cent. of the unsaturated fatty acids. The unsaponifiable matter contained 0·2 per cent. of phytosterol, in which no stigmasterol could be detected. (*Cf.* ANALYST, 1911, 358.)

C. A. M.

Detection of Hydrocarbon and Resin Oils in other Oils. A. E. Outerbridge, jun. (*Chem. Eng.*, 1911, **14**, 347-348.)—The author has observed that both fluorescent and de-bloomed mineral oils, and also resin oils, are so affected by the ordinary enclosed electric-arc light as to have this fluorescence enormously increased, rendering it possible to detect the presence of these adulterants in linseed or other non-fluorescent oils, even if present to the extent of only 0·1 per cent. If the plain glass cover of this light fits well, the air inside is rarefied and a faint reddish light is given out. In the path of these rays the above phenomena are produced. Standards may be prepared and the amount of adulteration of non-fluorescent oils determined by means of the fluorescent scale thus obtained.

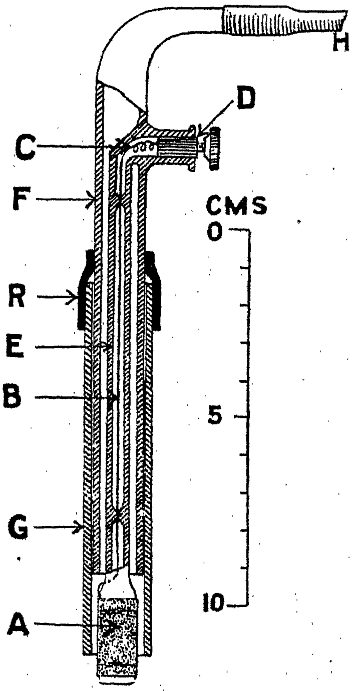
A. R. T.

Estimation of Ketones in Essential Oils. E. K. Nelson. (*J. Ind. and Eng. Chem.* 1911, **3**, 588-589.)—One to 2 grms. of the substance are heated in a water-bath under a reflux condenser with 35 c.c. of hydroxylamine reagent (prepared by dissolving 20 grms. hydroxylamine hydrochloride in 30 c.c. water, and adding 125 c.c. of alcohol free from aldehydes) and 2 grms. of sodium bicarbonate, and the liquid cooled, made acid by the addition of 6 c.c. of strong hydrochloric acid through the condenser, and the whole diluted with water to 500 c.c. The solution is filtered, and an aliquot part of the solution neutralised with $\frac{N}{2}$ caustic soda to methyl-orange. The excess of hydroxylamine is then titrated with $\frac{N}{10}$ caustic soda and phenolphthaleïn. The results are fairly satisfactory, showing a percentage equal to about 96 to 102, as compared with theory, with most ketones except fenchone, with which low results (86 per cent.) were obtained. The method serves for the assay of oils containing carvone, camphor, pulegone, and thujone as the chief constituent. (*Cf.* H. E. Burgess, ANALYST, 1903, **29**, 78.) A. R. T.

Use of Triketohydrindene Hydrate for the Detection of Proteins and their Derivatives. E. Abderhalden and H. Schmidt. (*Zeitsch. physiol. Chem.*, 1911, **72**, 37-43; through *Chem. Zentralbl.*, 1911, II., 640-641.)—Triketohydrindene hydrate (Ruhemann, *J. Chem. Soc.*, 1910, **97**, 2025) gives a blue coloration with α-amino acids, polypeptides, peptones and proteins. Exceptions are—proline, hydroxyproline, and pyrrolidone carboxylic acid. A blue coloration is only formed when a free amino group and a free carboxyl group are present simultaneously. For carrying out the test a solution of 0·1 grm. of the reagent in 300 c.c. of water is employed; 1 to 2 drops of this reagent are added to 1 c.c. of the liquid to be tested, and the mixture is heated to boiling. The liquid to be tested must have a neutral reaction. Glycocoll and alanine show a perceptible reaction at a dilution of 1 : 10,000; tyrosine at 1 : 5,000. Urine always gives a positive reaction; blood, from which the proteins have been removed by ferric hydroxide, reacts in nearly all cases, owing to the presence of products of proteolysis. By means of the method of titration in presence of formaldehyde, the authors have been able to prove the presence of amino nitrogen in blood deprived of its proteins; amino acids could not, however, be isolated. J. F. B.

An Inner Anhydride Reaction of Proteins. B. Bardach. (*Chem. Zeit.* 1911, **35**, 934.)—A reaction for inner anhydrides and groups capable of forming anhydrides has been described previously by the author (ANALYST, 1909, **34**, 326; 1911, 458). The fine, needle-like crystals obtained in the test consist of pure iodoform; proteins, such as peptone, gelatin, etc., possessing the property of causing iodoform to crystallise from its solution in the form of needles instead of the usual hexagonal prisms. This change in the crystalline form of iodoform by proteins takes place when an alcoholic solution of iodoform is mixed with a protein solution, and also when the protein has been treated previously with iodine. The effect on the iodoform is not due to the colloidal nature of the proteins, as colloidal solutions of silica, sulphur, and starch do not behave in a similar way, but is probably owing to the presence of the complex—CO—O—in the protein molecule. In general, the reaction may be used for the detection of aromatic inner anhydrides, aromatic hydroxy acids with long side-chains, and aromatic polyhydroxy-ketones. It is possible to distinguish these hydroxy-acids from phenols by using the test in conjunction with Millon's reagent; a positive result with the latter and a negative reaction for anhydrides indicates the presence of phenols. W. P. S.

Electrometric Method for the Estimation of the Acidity of Tan Liquors. Part II. J. T. Wood, H. J. S. Sand, and D. J. Law. (*J. Soc. Chem. Ind.*, 1911, **30**, 872-877.)—In the first description of this method (ANALYST, 1911, 121) several details were left open, notably the form of hydrogen electrode most suitable for the purpose. After trying other forms, the authors recommend the electrode here illustrated, which combines rigidity with rapidity of saturation and ease of manipulation.



The platinum plate consists of a piece of very thin foil which is wrapped round a cylindrical body of glass, A, and is held to the latter by some platinum wire, which passes through the glass and up the stem, E, where it is continued in the copper wire, B, the platinum wire, C, and finally in the terminal D. The stem, E, is fused in the manner depicted into a wider glass tube F which can be connected to the rubber supply-tube, H, for the hydrogen. The tube, F, ends a short way above the platinum foil, and over it is slipped the tube, G, which is just wide enough to allow it to slide up and down F readily. A piece of thick-walled rubber tube, R, holds G firmly, and F sufficiently to keep G in position without hindering it from being pushed up and down when desired. During the operation of platinising, G is pushed up completely. While the electrode is in use, G is adjusted to be a few mm. above the bottom of the foil, thus allowing the latter to dip into the liquid by this amount, whereas during the time the electrode is left filled with hydrogen when not in use, G is pulled down as far as possible, and at the same time the rubber delivery-tube, H, is clipped as close to the electrode as possible. The dimensions of the cylinder of platinum foil are 16 to 20 mm. high by 11 mm. diameter. The electrode is conveniently suspended from a ring fixed to the burette-stand by a piece of string, so as to be a few mm. above the bottom of the beaker containing the liquor to be titrated, which is then stirred by hand by the electrode itself. A solution of gallotannic acid may be neutralised completely with $\frac{N}{10}$ alkali without any appreciable darkening when the hydrogen electrode is employed, as the escaping gas hinders oxidation, whereas oxidation and darkening always occur at the neutral point during ordinary titration and the degree of oxidation affects the consumption of alkali. Unlike ordinary indicators, the hydrogen electrode is unaffected by large quantities of protein matter such as may be present in tan liquors.

The voltmeter attached to the potentiometer box gives readings to one-fifth centivolt. Seeing that other sources of error, such as contact potential, are greater than the error of reading the potentiometer, this is quicker and more convenient than the method in which the slide wire is used. Hydrogen voltages determined for various pure acids occurring in tan liquors are given, and the differences between calculated and experimentally determined values do not exceed 1 centivolt in any case except that of lactic acid, where the difference is 2·1 centivolts. Noyes, in his paper on the theory of indicators (ANALYST, 1910, **35**, 415), recommends that the ratio between the hydrion concentration corresponding to the correct neutralisation of an acid and that shown by the indicator employed in the titration should, if possible, be kept within the limits 3·5 and 1/3·5. Translating this into terms of the electrometric method, this would require an accuracy of ± 3·1 centivolt, which it is shown is attainable. G. C. J.

Use of Nickel Hydroxide in Tannin Estimation. P. Singh. (*J. Soc. Chem. Ind.*, 1911, **30**, 936-937.)—In a preliminary note the author proposes the substitution of nickel hydroxide for hide-powder in tannin determinations. The preliminary operations are carried out as in the hide-powder method. One hundred c.c. of the optically-clear tannin liquor are shaken with about 100 c.c. of a paste-like mass of freshly prepared nickel hydroxide (washed free from alkali and sulphate) made by suspending this reagent in water. After thorough shaking, the mixture is made up to 250 c.c., and filtered, when the filtrate is quite clear and gives no tannin reaction. Fifty c.c. of this filtrate are then evaporated, dried, and the residue weighed. The non-tannins are calculated on 100 c.c. of the original liquor. Experiments show that the reagent can be employed with all kinds of tanning materials. A large number of analyses are given, and the results shown in comparison with the standard (hide-powder) method. A. R. T.

INORGANIC ANALYSIS.

Some Uses of Amalgamated Aluminium in Chemical Analysis. E. Kohn-Abrest. (*Bull. Assoc. Chim. Sucr. Dist.*, 1911, **28**, 938-943; through *Chem. Zentralbl.*, 1911, II., 302.)—Tannin is precipitated from its solution by the action of aluminium slightly coated (amalgamated) with mercury, and dark-coloured oak bark extracts, etc., may be decolorised completely by the same means. Five grms. of aluminium, which have been immersed for three minutes in a 0·5 per cent. mercuric chloride solution and then washed are employed for every 200 c.c. of the solution to be treated. W. P. S.

Elementary Analysis. A. Kurtenacker. (*Zeitsch. anal. Chem.*, 1911, **50**, 548-565.)—Several metallic oxides were tried in substitution for the copper oxide of the ordinary combustion tube. Of these, only cobalt oxide was found as satisfactory as copper oxide, and the author prefers it to copper oxide because of the greater speed and lower temperature at which a combustion may be carried out by means of it. To prepare the oxide in suitable form, cobalt nitrate is first dehydrated and then decomposed by gradually raising it to a bright red heat. The porous mass is easily broken to a convenient size. It is somewhat hygroscopic. It is said that a combustion may be made with so short a layer as 10 cm. of this material. Nickel oxide can be used, but has marked disadvantages as compared with cobalt oxide, whilst no satisfactory results could be obtained when using ferric oxide, oxide of manganese, tungstic or molybdic acid.

Metallic nickel, placed at the forward end of a combustion-tube, serves well for the reduction of oxides of nitrogen, but the form of the metal is important. A spiral of ordinary thin sheet is useless. Nickel oxide is first made by igniting the nitrate, and the oxide is then reduced in a current of hydrogen at not too high a temperature. A porcelain boat, 14 cm. in length, is filled with this reduced nickel and maintained at a scarcely visible heat in the forward part of the combustion-tube. Under such conditions, metallic nickel has a scarcely measurable reducing action on the carbon dioxide passing over it in the course of an ordinary combustion. But in a nitrogen estimation by Dumas' method, the error may be appreciable, and therefore, still further forward in the tube, a short boat containing cobalt oxide is placed and maintained at something less than a red heat. G. C. J.

Qualitative Analysis without the Use of Hydrogen Sulphide. E. Ebler. (*Zeitsch. anal. Chem.*, 1911, **50**, 603-614.)—In the method of analysis without the use of hydrogen sulphide previously described by the author (*Zeitsch. anorg. Chem.*, 1905, **48**, 61; *Zeitsch. anal. Chem.*, 1908, **47**, 555), the removal of arsenic at an early stage, to prevent its coming down as an insoluble arsenate of magnesium or other metal, was accomplished by a rather troublesome process. It is now recommended that the separation of arsenic should be the first operation of analysis, and that it should be accomplished by distillation with hydrochloric acid and hydrazine bromide (ANALYST, 1910, **35**, 324).

The decomposition of complex cyanides by means of sulphuric acid is not recommended, as certain metallic chlorides may be volatilised and insoluble substances of the type of chrome ironstone may be formed. It is better to effect the decomposition by boiling for half an hour with equal parts of fuming nitric and concentrated hydrochloric acid under a reflux condenser. If an insoluble residue remains, it may contain cyanogen, but the solution is free from complex cyanogen compounds and from cyanide. Any insoluble residue may now be subjected to fusion with potassium bisulphate without risk of loss or formation of insoluble substances, since mercury, tin, antimony, and chromium will have passed into the aqua regia solution, unless the chromium was originally present as chrome ironstone. The aqua regia solution is evaporated with more nitric acid until the hydrochloric acid is wholly decomposed, and the residue is taken up in dilute nitric acid, and the insoluble matter, if any, filtered off and washed. The solution is then examined by the methods described in the earlier papers.

The insoluble residue may contain lead chloride or sulphate, complex cyanides (of iron, copper, nickel, cobalt, zinc, etc.), silver halides, stannic and antimonic acids, tin phosphate, silica, and the sulphates of the alkali earth metals. Lead is first extracted by means of a hot nitric acid solution of ammonium nitrate, which does not remove any silver or antimony. A bisulphate fusion follows, and the solution of the melt is either analysed separately or mixed with the nitric acid solution obtained at an earlier stage. The silver in the insoluble residue is next reduced with zinc after grinding to a cream with water and adding dilute sulphuric acid. The silver and other insoluble matter is washed free from chloride, and the silver and excess of zinc are then dissolved in hot dilute nitric acid. Reduction with zinc is preferred to extraction with ammonia or cyanide, as it avoids risk of solution of tin, antimony, and silica. The residue, freed from silver, is fused at a low temperature with alkali and sulphur, and, in the filtered solution of the melt, tin and antimony are precipitated by addition of acid. The sulphides are filtered off, and the filtrate, which may contain phosphoric acid and silica, is boiled to expel hydrogen sulphide, filtered from sulphur, and preserved. The residue from the extraction of the sulphur fusion is fused with sodium carbonate, and the aqueous extract of the melt is filtered from the carbonates of the alkali earth metals and mixed with the filtrate from the sulphides of tin and antimony. The mixed filtrates are tested for the presence of phosphoric acid, and evaporated to dryness to render silica insoluble. G. C. J.

New Method for Separation of Cerium. C. James and L. A. Pratt. (*J. Amer. Chem. Soc.*, 1911, **33**, 1326-1330.)—The precipitation of cerium as basic ceric nitrate may be made almost quantitative by the addition of potassium bromate to the faintly acid or neutral solution of the rare earth nitrates. The nearly neutralised solution is boiled with potassium bromate in presence of a lump of marble, which is found to be the best substance for keeping the solution neutral. Powdered marble must not be used, nor must boiling be too prolonged, or the reaction will become distinctly alkaline, and the precipitate will be contaminated by didymium, if present in the solution. When a small quantity of the supernatant liquid, withdrawn for the purpose, gives no reaction with hydrogen peroxide, the lump of marble is removed, and the precipitate is filtered off and washed with a 5 per cent. solution of ammonium nitrate, since attempts to wash with water lead to the formation of colloidal sols. The filter-paper and precipitate are returned to the beaker and treated with nitric acid and a little potassium bromate, to oxidise the paper. The paper must be completely oxidised. After evaporation to expel acid, the residue is dissolved in water and treated as before with potassium bromate and marble. After removal of the marble, filtering and washing, the precipitate is redissolved in the original beaker by means of hydrochloric acid, the solution filtered and evaporated to expel acid, and cerium finally precipitated as oxalate and weighed as CeO_2. The error, usually positive when the above directions are followed, should not exceed 0·8 per cent. By a modification of the process many kilograms of cerium salts may be prepared in a few hours, and of such a degree of purity that saturated solutions of the nitrate show no absorption bands when observed in a layer 20 cm. thick. G. C. J.

Accurate Technical Estimation of Calorific Value of Anthracite. A. G. Blakeley and E. M. Chance. (*J. Ind. Eng. Chem.*, 1911, **3**, 557-559.)—The authors have found it possible to dispense with the use of soft coal or other kindler in determinations of the calorific power of anthracite, even when this contains as much as 40 per cent. of ash. The difficulty in securing the complete combustion of anthracite was found to depend mainly on the chilling of the coal by the rapid conduction of heat through the nickel capsule and heavy platinum wire of the Atwater calorimeter employed by the authors. This can be countered and complete combustion insured by the simple expedient of placing in the capsule, below the coal, a pinch of soft asbestos, which is then lightly tamped in place by some blunt instrument, so as to present a concave depression, with the centre perhaps 2 mm. lower than the edges. The mat at its thinnest point, the centre, should not be less than 2 mm. thick. The coal should at least pass a screen of 80 meshes to the inch, and the usual routine of combustion is pursued, except that a pressure of oxygen of 25 atmospheres is used. G. C. J.

Determination of Sulphur in Coal by Means of Jackson's Candle Turbidimeter. H. F. Muer. (*J. Ind. Eng. Chem.*, 1911, 3, 553-557.)—Jackson's turbidimeter (*Techn. Quarterly*, 1900, **13**, 278) consists of a glass cylinder about 28 mm. in diameter and 25 cm. high, graduated throughout its height in mm., and supported 75 cm. above the top of a carriage candle-holder, which carries a standard candle. Originally designed for measuring the turbidity of water, it has been adopted by the United States Geological Survey for field use in determining sulphate and lime in waters from the turbidity produced by barium chloride and ammonium oxalate respectively. Attempts to make use of it for the determination of sulphur in coal by precipitating the rinsings of a Mahler bomb with barium chloride, at the conclusion of a calorimetric determination, led to results which did not accord well with gravimetric results or with each other. It was found that nitrates in the solution, in quantities such as are found in coal analysis, did not affect the results, nor were variations in the size of the flame or of the distance of the top of the candle-tube from the bottom of the glass-tube of importance, though the flame should not much exceed 40 mm. in height if the deposition of soot is to be avoided, and it should be protected from draughts, since it is difficult to make accurate determinations with a flickering flame. The cause of the discordant results first obtained was found to be wholly due to the condition of the precipitate of barium sulphate, which must be produced with uniform slowness in order to get it uniformly fine. This is best effected by the use of compressed tablets of barium chloride of 1 grm. each. The washings of the bomb, amounting to about 150 c.c., are filtered if necessary, and titrated with $\frac{N}{10}$ sodium carbonate, the acidity giving a rough guide to the selection of a suitable aliquot portion for the sulphur determination. The solution is made up to 200 c.c., and 20 to 50 c.c or more, according to the supposed sulphur content, transferred to the turbidimeter cylinder, which has a mark at 100 c.c. The contents of the cylinder are diluted almost to this mark, shaken, 1 c.c. of hydrochloric acid (1 : 1) is added, water added exactly to the mark, and the mixture again shaken. A tablet of barium chloride is now added, and the tube stoppered and tilted up and down, so that the tablet rolls slowly back and forth through the solution. When precipitation appears to be complete, the remainder of the tablet may be dissolved by rapidly rotating the tube, but violent shaking must be avoided. The turbid liquid is then transferred to a beaker, the candle lighted, and a small quantity of the liquid poured into the tube and the latter put in place. More liquid is then poured down the side of the tube until the image of the flame just disappears. The height, C, of the column of liquid in centimetres is then read, and when this value lies between 2·5 and 17, the amount of sulphur, S, in milligrams in 100 c.c. of the solution under examination is given by the equation: $S = 0{\cdot}6 + \frac{15{\cdot}3}{C}$. When C is less than 2·5 or greater than 17, the value of S may be found from a table given in the paper, or preferably by means of a second experiment, using less or more of the washings of the bomb. The error of the method does not exceed ± 5 per cent. on the sulphur present.

G. C. J.

Quantitative Separation by Means of "Cupferron." O. Baudisch. (*Chem. Zeit.*, 1911, **35**, 913.)—After further experience, the author confirms his previous statement that "cupferron" affords a simple and accurate means of separating iron and copper from other metals (*cf.* ANALYST, 1910, **35**, 78, 453), and gives the following directions for preparing this substance: Sixty grms. of nitrobenzene, 1,000 c.c. of water, and 30 grms. of ammonium chloride, are shaken so as to form an emulsion, and 80 grms. of zinc dust are then added, little by little, while the temperature of the mixture is kept below 18° C. When all the zinc has been added, and the odour of nitrobenzene has disappeared (this takes about thirty minutes), the insoluble zinc hydroxide is removed by filtration, washed a few times with small quantities of water, and the filtrate and washings are cooled with ice to 0° C. The cold solution is now saturated with sodium chloride, when the phenylhydroxylamine separates out in the form of snow-white crystals. The crystals are collected, dried for one hour on filter-paper, then dissolved in 300 to 500 c.c. of ether; the solution is filtered, cooled to 0° C., and a current of dry ammonia gas is passed through it for ten minutes. A slight excess of freshly prepared amyl nitrite is now added; the ammonium salt of nitrosophenylhydroxylamine separates out immediately, and is collected on a filter, washed with ether, dried on blotting-paper, and stored in a stoppered bottle in which a small quantity of solid ammonium carbonate has been placed previously. The compound is quite stable, and its aqueous solution, when rendered ammoniacal, may be kept for months without undergoing decomposition.

W. P. S.

Ferric Sulphate as Standard for Permanganate Solutions. J. Milbauer and O. Quadrat. (*Zeitsch. anal. Chem.*, 1911, **50**, 601-603.)—Thrice crystallised ferrous sulphate is mixed with twenty times its weight of sulphuric acid, and the mixture boiled in a Kjeldahl flask until, when a portion is withdrawn and examined microscopically, it is seen to consist solely of small hexagonal tablets of ferric sulphate. From forty-five to sixty minutes' boiling usually suffices. When cool, the crystals are filtered off in a Gooch crucible in which a porcelain plate has been placed above the asbestos, washed with alcohol and anhydrous ether, and dried to constant weight in a steam oven. The crystals must be preserved in well-stoppered bottles, as they are hygroscopic, but not so hygroscopic as to require special precautions or speed in weighing. For use as a standard, about 1 grm. is accurately weighed out, 25 c.c. of water, 10 c.c. of sulphuric acid, and sufficient zinc, are added, and the mixture warmed moderately until solution is complete. The reduced solution is then titrated against the permanganate. The results agree well with those obtained by the use of the purest oxalic acid or potassium tetroxalate.

G. C. J.

Volumetric Estimation of Ferric Iron by Permanganate after Reduction with Zinc. E. Müller and G. Wegelin. (*Zeitsch. anal. Chem.*, 1911, **50**, 615-623.)—If amalgamated zinc be used for the reduction of ferric salts, it is unnecessary to dissolve the whole of it, as iron is never deposited on amalgamated surfaces. The consumption of amalgamated zinc is much smaller, about 10 per cent. more than is theoretically necessary to reduce the iron, instead of about ten times the theoretical quantity, which is the amount consumed when unamalgamated zinc is used. The use of amalgamated zinc, therefore, reduces the risk of error due to traces of iron in the zinc used. Amalgamation reduces the speed of reaction by about half, but this can be increased by the addition of a small quantity of copper sulphate. With excess of zinc always present, there is no risk of the formation of cuprous salts, which would interfere with the subsequent titration of the iron by permanganate. The decrease in speed due to amalgamation may equally well be counterbalanced by the use of larger zinc surfaces, which, as the zinc does not need to be wholly dissolved, does not greatly increase the amount of zinc passing into solution. If Blair's reductor is to be used—and the authors do not recommend it except when large numbers of determinations have to be made consecutively—the following procedure is recommended: To 100 c.c. of the ferric solution, 5 c.c. of sulphuric acid and 5 to 10 drops of a cold saturated solution of copper sulphate are added. After addition of 3 or 4 sticks of amalgamated zinc (about 5 cm. × 6 mm.), the solution is heated to 100° C. in an atmosphere of carbon dioxide. Reduction should be complete in two hours. In subsequent determinations addition of copper sulphate is, of course, unnecessary.

G. C. J.

Precipitation of Iron with Hydrazine Hydrate. E. Schirm. (*Chem. Zeit.*, 1911, **35**, 897.)—When hydrazine hydrate is added to a solution of a ferric salt, ferric hydroxide is precipitated in a flocculent condition; but on standing, or more rapidly on heating, the precipitate is converted into a fine granular black powder which settles rapidly, and can be filtered and washed very quickly. The precipitation is quantitative. In order to economise the hydrazine hydrate, the solution should first be neutralised with a 10 per cent. solution of ammonia whilst boiling, and, if the ammonia be added in large excess, the precipitation of the ferric hydroxide free from traces of sulphuric acid is insured. A few drops of hydrazine hydrate are then sufficient to convert the precipitate into the black granular form. The dried precipitate is incinerated and strongly heated over the blow-pipe; it is weighed as ferric oxide.

J. F. B.

Separation of Iron and Vanadium by Means of Ether. E. Deiss and H. Leysaht. (*Chem. Zeit.*, 1911, **35**, 869-871 and 878-879.)—The separation of vanadium from iron by Rothe's ether process, as improved by Campagne (*Compt. Rend.*, 1903, **137**, 570), is incomplete even after nine shakings of the ether with acid. With a single shaking, as recommended by Campagne, nearly 10 per cent. of the vanadium may be left in the ethereal layer with the iron, and the error exceeds 1 per cent. after nine shakings. The separation may be made quantitative by the use of a little hydrogen peroxide with the acid used to wash the ether. The solution of vanadium and ferric iron, freed from silica, is evaporated with hydrochloric acid as usual to a syrupy consistency, whereby the vanadium is reduced to the quadrivalent form, in which it is insoluble in ether. The residue is transferred to a separator by the use of the smallest possible quantity (10-15 c.c.) of hydrochloric acid (1 : 1) and the solution cooled. For every grm. of iron present there is next added about 6 c.c. of a mixture made by saturating hydrochloric acid (sp. gr. 1·19) with ether. Such acid takes up about 1·5 vols. of ether with considerable evolution of heat, and it is desired to avoid this evolution of heat in the separator, lest the ferric iron suffer partial reduction by the ether. Ether is added and the mixture shaken, allowed to stand, and separated. The ethereal layer is then shaken with 3 or 4 drops of perhydrol and 10 c.c. of hydrochloric acid (1:1), previously saturated with ether, of which it absorbs 0·3 vol., and the acid aqueous layer is shaken with ether. The acid aqueous layer is then run off, the acid used for washing the ethereal solution containing most of the iron is run into the ether used for washing the first aqueous acid layer, and the principal ethereal solution washed two or three times more with hydrochloric acid (1:1) saturated with ether, the washings being shaken with the ether containing but little iron before adding to the principal aqueous extract. The hydrogen peroxide converts the small residue of vanadium remaining in the ether with the iron after the first separation into pervanadic acid, which, like tetravalent vanadium, is insoluble in ether, but, unlike it, is not liable to become transformed into substances which can pass into the ethereal solution. Vanadium (0·1 grm.) can be separated from 5 grms. of iron with an error not exceeding ± 0·2 mgrm. G. C. J.

Analysis of Monazite Sands. G. Chesneau. (*Compt. Rend.*, 1911, **153**, 429-431.)—In the author's experience decomposition by means of hydrochloric acid is never complete, whilst the use of sulphuric acid always leads to some of the thorium remaining as phosphate in the insoluble residue. The following method works well: The mineral (2·5 grms.) is fused with 6 parts of fusion mixture for an hour, finally at a bright red heat. The product is boiled out with a 1 per cent. solution of caustic soda, which counteracts the tendency of the alkaline carbonate solution to carry some thorium into solution. The insoluble matter is filtered off, washed with cold water, and then treated with hot dilute hydrochloric acid (sp. gr. 1·025). The undissolved matter is filtered off, washed with dilute hydrochloric acid, and submitted to a second fusion, the product of which is treated as before. In this way a hydrochloric acid solution containing the whole of the rare earths, together with some titanium, zirconium, and iron, is obtained; an alkaline solution containing silica and alumina and all the phosphoric acid of the mineral;

and an insoluble residue, consisting of the dioxides of titanium and zirconium, with traces of silica and lime.

The following method for the separation of the rare earths from the hydrochloric acid solution is said to possess advantages over published methods, from which it differs only in details: The solution, freed from heavy metals if present, is evaporated until it contains exactly 4 per cent. of hydrogen chloride—that is, to four-fifths bulk, if the preceding directions have been followed. To the hot solution oxalic acid crystals are added at the rate of 4 grms. for each 100 c.c., and the mixture is allowed to stand for two days. The oxalates of the rare earths are filtered off, washed with oxalic acid solution, dried, and ignited (not above 500° C.). The oxides are dissolved in hot strong nitric acid, and the solution is cleared, if necessary, by addition of a little hydrogen peroxide solution (10 vol.). The solution is evaporated to dryness, and heated at 130° C. until acid fumes are no longer evolved. The residue is taken up in 150 c.c. of water, and the thorium separated by double precipitation with hydrogen peroxide (free from phosphoric acid), a little ammonium nitrate being used to prevent the thorium passing into colloidal solution, which it is especially apt to do in the second precipitation in absence of mineral salts. The filtrates from the thorium are made up to 500 c.c., in 100 c.c. of which the total earths are precipitated by means of ammonia, whilst in another 100 c.c. the cerium is oxidised by means of lead peroxide, and the ceric nitrate titrated with dilute hydrogen peroxide solution. In the remainder of the filtrate from thorium the yttrium earths are separated as double sulphate with potassium sulphate, and lanthanum and the phaseo- and neodidymiums are estimated by difference.

In estimating cerium by the lead peroxide method, a control experiment on an approximately equal amount of cerium should be run simultaneously. To this end a suitable quantity of cerium ammonium nitrate is digested in the cold for one hour with 10 c.c. nitric acid and 2 grms. lead peroxide, stirring from time to time. The filtrate from the thorium is evaporated almost to dryness, and the residue treated in a similar manner. The two liquids are filtered free from lead peroxide by means of asbestos, and are then titrated with hydrogen peroxide solution (0·5 vol.) until the whole of the CeO_2 has been reduced to Ce_2O_3, as shown by the disappearance of the yellow colour.

G. C. J.

Monazite Sand from Travancore, India. (*Bull. Imp. Inst.*, 1911, **9**, 103-105.)—In its natural state this was found to contain over 46 per cent. of monazite, and showed 4 per cent. of thorium dioxide and 28·3 per cent. of cerium, yttrium, and lanthanum oxides on analysis. The monazite readily separated by electro-magnet, and then showed 8·5 per cent. of ThO_2. The Travancore deposit consists, therefore, of material of considerable value in its natural state, and by concentration this can be enhanced beyond that of Brazilian and Carolina monazites (less than 4 per cent. thoria), and resembling that of Ceylon. (*Cf. Bull. Imp. Inst.*, 1905, **3**, 151.)

A. R. T.

Rare-Earth-Containing Sands ("Amang") from Malay States. (*Bull. Imp. Inst.*, 1911, **9**, 99-102.)—The term "amang" is applied to certain heavy sands obtained in the Chinese process of tin-mining in Malaya. The analytical results generally confirm previous findings (*Bulletin*, 1906, **4**, 301), though copper, not previously detected, was present in one sample (2·97 per cent., CuO) from a district where the tin ore concentrates are known to contain the same element. Tungsten was absent in every case, and chromium present in a few cases in traces only. The quantity of monazite in the present samples is uniformly small, and is in no case sufficient to render the "amangs" of value as a source of thoria. The most noticeable feature of three samples is their richness in tinstone (62·35, 67·8, and 76·5 per cent. of the ore). These should be valuable sources of tin, if they are available in quantity.

A. R. T.

Comparison of Methods for Determination of Nickel in Steel. J. J. Boyle. (*Chem. Engineer*, 1911, **14**, 288-289.)—The dimethylglyoxime method is the most accurate available, but the cyanide method is better adapted to routine work in that it occupies only half the time, avoids the use of costly chemicals, and is sufficiently accurate for most routine purposes.

Dimethylglyoxime may be recovered from the nickel salt by mixing this to a paste with water, warming with potassium cyanide, filtering hot and precipitating the oxime at once with acetic acid.

G. C. J.

Method for the Separation of Nickel and Zinc in German Silver and other Alloys. La V. W. Spring. (*J. Ind. Eng. Chem.*, 1911, **3**, 255-256.)—About 0·5 grm. of the alloy is dissolved, the tin being separated by means of nitric acid, the lead by sulphuric acid, the copper electrolytically, and the iron by ammonia. After the addition of 5 grms. of ammonium chloride, the solution is neutralised with hydrochloric acid, then rendered slightly ammoniacal, and the nickel is precipitated by the addition of dimethylglyoxime (*cf.* ANALYST, 1909, **34**, 74). The filtrate from this precipitate is boiled after the addition of hydrochloric acid in order to destroy the excess of dimethylglyoxime, 10 grms. of ammonium sodium phosphate are added, the mixture is neutralised with ammonia, heated, and the zinc phosphate collected and weighed as zinc pyrophosphate.

Estimation of Nitrate and Nitrite Nitrogen in Commercial Calcium Nitrate and Nitrite. Stutzer and Goy. (*Chem. Zeit.*, 1911, **35**, 891.)—The commercial nitrate of calcium obtained as end-product in the oxidation of atmospheric nitrogen invariably contains nitrite, and the nitrite emanating from the same works always contains nitrate. The total nitrogen cannot be estimated accurately by the use of "nitron" after oxidation of the nitrite by hydrogen peroxide. The results are always low. Nor can the nitrate nitrogen be estimated by the use of "nitron" after decomposition of nitrite by means of hydrazine sulphate, as this decomposition is never complete. Nitrite can be estimated by titration with permanganate, and the total nitrogen as nitrate determined by means of "nitron" in the oxidised solution. But the authors prefer to avoid the use of this expensive reagent and determine total nitrogen as ammonia as follows: The nitrate or nitrite (10 grms.) is dissolved in water and the solution diluted to 1,000 c.c. To 50 c.c. of this solution, 50 c.c. water, 50 c.c. caustic soda solution (1 : 2), and 2·5 grms. Devarda metal (Cu : Al : Sn :: 10 : 9 : 1) in powder, are added, and the flask connected to a condenser and receiver containing a measured volume of standard sulphuric acid. When the evolution of hydrogen slackens, the mixture is slowly warmed and the ammonia finally distilled.

G. C. J.

Some Sources of Error in Gasometric Estimation of Nitrate by Schloesing's Method and of Nitrite by Piccini's Method. O. Ruff and E. Gersten. (*Zeitsch. anorg. Chem.*, 1911, **71**, 419-426.)—In presence of arsenious acid or of hydrogen sulphide, Schloesing's method give results which are below the truth. Arsenious acid acts by reducing a portion of the nitric acid to nitrous acid, which passes over as such into the nitrometer and is absorbed by the caustic soda. Hydrogen sulphide causes some of the nitric acid to be reduced to ammonia, which remains in the acid liquid in the flask. The presence of arsenious acid does not affect the accuracy of the results obtained by Piccini's method (*Ber.*, 1881, **14**, 1168) for the estimation of nitrites by reduction with ferrous chloride in neutral solution, but hydrogen sulphide reduces a portion of the nitrous acid to ammonia, and results obtained in presence of soluble sulphides are worthless. G. C. J.

Estimation of Ozone by Means of Alkaline Potassium Iodide Solution. G. Lechner. (*Zeitsch. Electrochem.*, 1911, **17**, 412-414; through *Chem. Zentralbl.*, 1911, II., 261.)—As loss of iodine is liable to take place when ozone is passed through neutral potassium iodine solution, owing to iodine vapour being carried away by the current of gas, the author prefers to pass the gas through potassium iodide solution rendered alkaline with potassium hydroxide. Iodate is formed as the result of the reaction between the ozone and the iodide, and when the solution is acidified the iodine liberated is a measure of the amount of ozone present. The accuracy of the method was tested by estimating the quantity of ozone in an ozoniser by measuring the change in pressure at constant volume; the contents of the ozoniser were then passed through alkaline potassium iodide solution, a current of pure oxygen being employed to drive the gas out of the apparatus, and the iodate formed was titrated as described. Satisfactory results were obtained. W. P. S.

Estimation of Phosphoric Acid by Neumann's Method. I. Bang. (*Biochem. Zeitsch.*, 1911, **32**, 444; through *Chem. Zentralbl.*, 1911, II., 307.)—Instead of expelling the ammonia by heating, the phosphomolybdate precipitate is dissolved in a definite volume of $\frac{N}{2}$ potassium hydroxide solution, and the ammonia is converted into hexamethylenetetramine by the addition of 50 c.c. of neutral formaldehyde solution. The excess of alkali is then titrated. W. P. S.

Colorimetric Estimation of Phosphoric Acid. I. Pouget and D. Chouchak. (*Bull. Soc. Chim.*, 1911 [iv.], **9**, 642-650.)—The reagent employed in the colorimetric method of estimating phosphoric acid described previously by the authors (ANALYST, 1909, 34, 178) should be prepared as follows: Solution 1: Ninety-five grms. of molybdic acid and 30 grms. of anhydrous sodium carbonate are dissolved in 500 c.c. of water; after cooling, 200 c.c. of 36 per cent. nitric acid are added, and the solution is diluted with water to 1 litre. Solution 2: Two grms. of neutral strychnine sulphate are dissolved in about 90 c.c. of warm water, and the solution is then diluted to a volume of 100 c.c. Ten c.c. of solution 1 are mixed with 1 c.c. of solution 2 in order to obtain the reagent. It is not advisable to prepare the reagent from sodium molybdate, as the latter varies in its composition, some commercial samples consisting of neutral sodium molybdate and others of the acid salt. As mentioned previously (*loc. cit.*), the accuracy of the method depends on the proportion of molybdic acid, etc., present in the reagent. W. P. S.

Reduction of Potassium Platinichloride. A. Fiechter. (*Zeitsch. anal. Chem.*, 1911, **50**, 629-632.)—After washing free from sodium platinichloride salt and excess of chlorplatinic acid, the potassium hydrogen platinichloride is dissolved in 50 c.c. of hot water, a spiral of magnesium ribbon is added, and the solution heated to boiling. A few drops of dilute hydrochloric acid are next added, and the boiling continued for two minutes, after which the excess of magnesium is dissolved by addition of a little concentrated hydrochloric acid. The platinum, in fine flakes, quickly settles to the bottom of the beaker, and, if the reduction is complete, the supernatant liquor remains clear and colourless. Even when apparently colourless, it is advisable to add a further fragment of magnesium. If the solution remains clear, reduction is complete, but if more platinum separates, still more magnesium must be added. The reduced platinum is finally filtered off in a Gooch crucible and weighed.

The consumption of magnesium is reduced by keeping the spiral at the bottom of the beaker by pressure with a glass rod. When the quantity of potash to be estimated is 0·05 grm. or less, 0·2 grm. of magnesium usually suffices; with 0·2 grm. potash originally present, 0·5 grm. magnesium may be required to reduce the equivalent amount of platinum; whilst 1 grm. of magnesium will reduce the amount of platinum corresponding to 0·5 grm. potash. G. C. J.

Application of Sodium Paratungstate in the Estimation of Carbon Dioxide in Carbonates and Nitrogen Pentoxide in Nitrates by Loss on Ignition. F. A. Gooch and S. B. Kuzirian. (*Zeitsch. anorg. Chem.*, 1911, **71**, 323-327.)—Sodium paratungstate serves as well as any of the salts which have been recommended for expelling carbon dioxide and nitrogen pentoxide from carbonates and nitrates on fusion. It is more easily prepared than anhydrous borax, silica, or sodium metaphosphate, and gives rise in use to less viscous substances than do borax and silica, and fusions with it can therefore be effected at lower temperatures. The authors prefer it also to potassium bichromate, which may lose oxygen at the temperatures necessary to decompose carbonates.

Sodium paratungstate, which corresponds approximately to the formula $5Na_2O.12WO_3$, is prepared by dehydrating and fusing sodium tungstate, adding an equal weight of tungsten trioxide, previously ignited to expel ammonia and insure complete oxidation, and continuing to heat the mixture until a clear fusion results. The cooled product, which is readily powdered, is preserved in a desiccator over sulphuric acid, though it is not particularly hygroscopic. It contains approximately half its weight of tungsten trioxide, and 1 grm. will therefore displace somewhat more than 0·1 grm. of carbon dioxide or 0·25 grm. of nitrogen pentoxide. In use, the mixture of the paratungstate with carbonate or nitrate is heated at first at a very low temperature, and then kept in a state of fusion for five minutes. After weighing, the fusion is repeated, but there is seldom any measurable loss on reheating.

G. C. J.

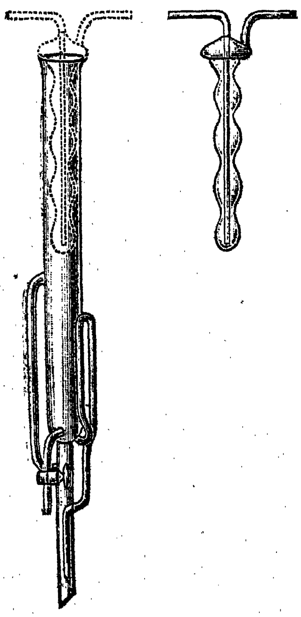
Estimation of Tin in Ores. R. J. Morgan. (*Chem. Engineer*, 1911, **14**, 289-291.)—Stick soda (6 to 8 grms.) is heated in a covered iron crucible to expel moisture, and, when it has cooled sufficiently to be once more solid, 5 grms. of the powdered ore are added, and the contents of the covered crucible heated gently at first, and afterwards to dull redness until fusion is complete. The melt is boiled out with as little water as possible, and the crucible and lid rinsed with a little dilute hydrochloric acid, which is added to the alkaline solution. Strong hydrochloric acid is added cautiously so long as there is effervescence, and when this ceases a further 20 c.c. is added and the solution heated to boiling-point and transferred to a flask. There should be nothing undissolved save, possibly, a little gelatinous silica. Three shoeing nails are bent up and pushed into the flask, the contents of which are boiled for fifteen minutes and then filtered through glass wool, the latter being washed with 50 c.c. of water. Shoeing nails being very soft, pure iron, remove copper and arsenic without risk of introducing other impurities. In the filtrate the tin is estimated by Low's method (reduction to stannous condition by metallic antimony, followed by rapid cooling in atmosphere of carbon dioxide and titration with iodine).

G. C. J.

Sampling of Coal in the Mine. J. A. Holmes. (*U.S. Bureau of Mines*, 1911, *Technical Paper I.*, pp. 16.)—The purpose of this paper is to describe the methods now followed by the Bureau of Mines and U.S. Geological Survey in an endeavour to take mine samples that fairly represent the beds of coal that are examined, and that show the commercial possibilities of the beds. It describes and illustrates the sampling kit issued by the Bureau to their collectors, as well as a simpler and lighter outfit for the use of field men who work at long distances from a base of supplies. The sampler is advised first to study a map of the mine, next to examine the mine itself, and then, having determined the number of samples to be collected, to select suitable places for taking these. The number of samples should not be less than four from any mine, nor less than one for each 200 tons of coal mined per day, and should be greater from mines in which the quality of the coal varies greatly. Detailed directions are given for cleaning off the face of the coal, cutting the sample, breaking it down and quartering it. Judgment and experience are demanded of the sampler in deciding what to include in the sample. Usually partings more than ⅜ inch thick and lenses or concretions of "sulphur" or other impurities more than 2 inches in maximum diameter and ½ inch thick are excluded, but, if in the judgment of the sampler, they are not being excluded by the miner or at the bank, they should be included. The collectors of the Bureau are required to fill in the answers to some 300 questions concerning each mine, and copies of the forms used are appended to the paper.

G. C. J.

APPARATUS, ETC.



Improved Soxhlet Condenser. O. Silberrad. (*Chem. News*, 1911, **104**, 54.)—This modified form o combined condenser and extraction apparatus avoids the unsatisfactory cork joint between the tube and condenser. A bulbous Walters condenser simply fits on to the (elongated) tube of the Soxhlet apparatus.

A. R. T.

New Type of Automatic Inflammable Gas and Vapour Detector. A. Philip and L. J. Steele. (*J. Soc. Chem. Ind.*, 1911, **30**, 867-872.)—The detector described and illustrated in the paper depends, like that of Liveing, on the catalytic action of platinum, but means are provided for preventing the platinum coils from becoming overheated, and thus fusing or having their capacity as catalyst, impaired. In its stationary form, the detector may be fixed anywhere, and air is continually drawn by means of a pump from the space (ship's bunkers, etc.) the atmosphere of which needs to be kept under observation, and is forced through the apparatus. At a certain concentration of inflammable vapour, attention is called to the fact by the ringing of a bell and the lighting up of a red lamp and the extinguishing of a white one. At the same time, the stream of air containing the combustible gas is cut off, thus preventing overheating of the platinum coils. The apparatus can be adjusted to signal when the proportion of combustible gas is one-third or any other fraction of the explosive limit. In its ordinary form, the apparatus is wholly enclosed in a massive casing which cannot be tampered with. A portable form is also described, in which not only the heavy casing but the electric motor-pump is dispensed with, the latter being replaced by a hand-pump.

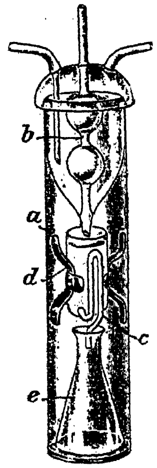
G. C. J.

Methods of Testing Safety Lamps or Other Apparatus for the Detection of Combustible Gases and Vapour. A. Philip and T. Stenhouse. (*J. Soc. Chem. Ind.*, 1911, **30**, 861-867.)—The paper describes the methods available for testing apparatus designed for the detection of inflammable vapours. The sources of combustible gas for experimental purposes are enumerated, and methods described for the mixture of the combustible gas with air, so as to obtain an atmosphere suitable for such tests as may need to be carried out. Methods are also described for determining the chemical composition of mixtures of air and inflammable vapour prepared by the methods described in the earlier part of the paper. The paper is accompanied by diagrams showing convenient arrangements of apparatus.

G. C. J.

A New Extraction Apparatus. G. A. Quincke. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 171-172.)—The apparatus shown in the illustration consists of a Jena-glass vessel, *a*, which is heated by means of a water-, sand-, or oil-bath; the vapours of the solvent contained in the flask *c* pass into the condenser *b*, which fits into the top of the glass vessel, and the drops of condensed solvent fall on to the material to be extracted, contained in the siphon vessel *e*. The latter vessel is supported at a convenient height by means of the springs *d*. Corks or rubber stoppers are dispensed with in the apparatus.

W. P. S.



Flask for Distillation of Tar. C. E. Brown and G. B. Shadinger. (*J. Ind. and Eng. Chem.*, 1911, **3**, 616.)—In order to avoid the "bumping" of wood-tar during distillation, owing to the presence of water, the authors employ an ordinary distilling-flask with side-tube and short neck, and having a thin sheet of asbestos paper wrapped once round the neck above and below the side-tube. This asbestos covering has wound over it a few turns of No. 30 Nichrome resistance wire, and a thick covering of asbestos is placed over all and securely fastened. A current of 15 to 30 volts passed through the wire furnishes heat sufficient to keep the neck of the flask at the required temperature, and to prevent condensation at this point.

A. R. T.

Apparatus for Electrolytic Estimations with Mercury Cathode. P. Baumann. (*Chem. Zeit.*, 1911, **35**, 854-855.)—The cathode (Fig. 1) consists of a flat-bottomed cylindrical vessel of Jena glass, 40 mm. wide, 70 mm. high, and 1 mm. in thickness of wall, and weighs less than 25 grms. without the mercury, of which about 60 grms. is used. A platinum wire, 0·8 mm. thick, is fused through the glass near the bottom, and penetrates 1 cm. into the mercury. The other end of the wire is bent as shown, and its point sealed to the glass about 5 mm. above the level of the mercury. The tubulus, shown on the left, is about 4 mm. above the bottom of the vessel, 6 to 7 mm. in diameter, and carries, by means of a ground-joint, the bend with bulb and glass stopcock. The inner end of the bend is again bent at right angles, and cut off short so as just not to dip into the mercury. The internal diameter of the bend is 2·5 mm., and that of the bulb 11 mm. The bulb serves to catch any mercury which may be carried over in drawing off the electrolyte or water used to wash the cathode. Before introducing the electrolyte the bend is thoroughly dried internally, to prevent the diffusion over its surface, during electrolysis, of a film of the electrolyte, which would thus escape the action of the current. When, at the end of the electrolysis, the electrolyte has been withdrawn and the cathode washed with water, the bend is replaced by a ground stopper, and the washing with alcohol and ether conducted with the help of a siphon, the cathode vessel being removed from its stand and inclined, to reduce the surface of the mercury to be washed. The apparatus is made by Schott und Gen., Jena.

An anode suitable for use with the above, and made by W. C. Heraeus, Hanau, is described in the paper.

The electrical heater (Fig. 2), also intended for use with the above, consists essentially of the platinum-wire helix, shown at the bottom of the figure, and the unshaded part of the glass tubular structure, which is filled with kerosin. The current enters and leaves the apparatus at the binding screws *a*, *a'*, which are connected to stout copper wires, 3 mm. in diameter, which pass along the horizontal glass tubes (4·5 cm. long) and down the tubes *b*, *b'*, which are 8·5 cm. by 6 mm., and sealed at *c*, *c'*. The copper wires are connected to short, stout pieces of platinum wire, 1 cm. by 1 mm., which are fused through the glass at *c*, *c'*, and connected to either end of the heating coil, which has a resistance of 0·5 ohm. The tube *d*, which serves to support the apparatus in the clamp shown, and its two branches, which contain the coil, are filled with kerosin, and the tubes *b*, *b'* are filled with mercury to above the level of the horizontal tubes. The tubes *b*, *b'* and *d* are all sealed with wax or corked. A current of 10 to 11 ampères will heat 30 c.c. of liquid to 70° C. in four or five minutes, and 6 ampères will maintain this temperature. From centre to centre *b* and *b'* are 38 mm. apart, and 28 mm. from *d*. The apparatus is made by R. Goetze, Leipzig.

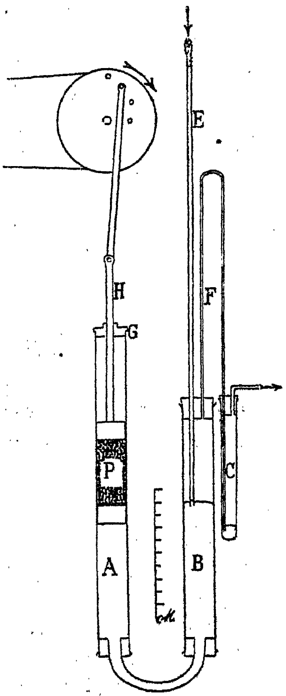
Apparatus and Methods for Sampling and Analysis of Furnace Gases. J. C. W. Frazer and E. J. Hoffman. (*U.S. Bureau of Mines, Bulletin* 12, p. 20.)—The apparatus and methods described in this Bulletin were devised by the authors in connection with their investigations on the improvement of furnace conditions and on efficiency in the use of fuel. Their gas-sampling tube is no advance on that of Huntly (ANALYST, 1910, **35**, 285), but their apparatus for instantaneous sampling is both novel and useful. Frequently it is desirable to ascertain the composition of gases at some point in a furnace at a certain definite instant, and getting an instantaneous sample from a space at a high temperature is attended with difficulty. There must be no dead space between the sampling tube and the point of collection of the sample; in other words, the sampling tube must itself be introduced into the furnace. The apparatus figured by the authors is adapted to this purpose, and is, of course, contained in a steel water-jacket. The sampling tube is exhausted, fixed in its jacket, and the whole apparatus introduced into the furnace, when the sampling tube is placed in connection with the point from which a sample is wanted by simple pressure on a knob. Pulling the knob closes the stopcock of the sampling tube again, and the apparatus is withdrawn. As it need not be in the furnace more than thirty seconds, and as the quantity of water in the jacket is considerable, it is unnecessary to provide for a circulation of water. The apparatus is somewhat complicated, but, having regard to what it accomplishes, not unreasonably complicated. It is fully illustrated and described in the Bulletin, which may be obtained free from the Director of the Bureau of Mines, Washington.

The Bulletin also illustrates and describes an apparatus for exact gas analysis, for which no claim to originality is made, its essential features—the automatic compensator of Pettersson, and Bleier's burette with two limbs, one of them bulbed—being familiar; but it appears to possess some advantages over other forms of apparatus. Experiments are described showing that 100 c.c. of gas can be measured accurately to 0·01 c.c. With volumes less than 50 c.c. the readings can be more precise. Finally, there is a description of a novel device for calibrating burettes and other measuring apparatus, by means of which some fifty observations can be made in an hour with a probable error of less than 0·01 c.c. G. C. J.

Detection of Gas in Sealed Tube Reactions. W. H. Warren. (*J. Amer. Chem. Soc.*, 1911, **33**, 1417-1418.)—When one of the products of a sealed tube reaction is a gas, this cannot be examined if an ordinary Carius tube is used, as it escapes when the tip of the tube is heated in the flame. If a suitable stopcock be sealed to the end of the Carius tube after the introduction of the reagents, any gas formed during subsequent heating may be drawn off from the cooled tube to any appropriate apparatus for identification or analysis. The stopcock must, of course, be made of similar glass to that used in the construction of the tube, and the following dimensions have been found suitable: Length of plug of stopcock 2·7 cm., taper 8 to 10 mm., bore 1·5 mm. On the side remote from the sealed tube, the cock carries a tube of any convenient dimensions for connecting with gas apparatus, that figured in the paper being 4 cm. long by 4 mm. internal diameter. From the other side of the cock springs another tube which quickly widens to 1·3 cm. internal diameter and is 2 mm. thick in the wall. This tube, which is conveniently about 7 cm. long, is sealed to the Carius tube after the latter has, if necessary, been drawn out slightly to be of the same diameter. If the joint is well annealed, accidents are not more common than with ordinary sealed tubes, and, if the stopcock is wrapped in cotton wool, it can often be saved even if the tube breaks. When the experiment is concluded and the gas drawn off, the stopcock is cut off and used again. The best lubricant for the plug is graphite. Stopcocks of the pattern described in "R" glass are made by C. Desaga, Heidelberg. G. C. J.



Simple Laboratory Suction Pump. F. Liebert. (*Chem. Weekblad*, 1911, 8, 382-383; through *Chem. Zentralbl.*, 1911, II., 329.)—In the pump here shown, the small glass receptable P is loaded with shot and has a stem H passing through the top of G. As it rises or falls in the tube A, which is charged with mercury, it causes the mercury in the tube B to fall or rise correspondingly. With the fall of the mercury in B, gas is drawn from E, whilst a rise in the mercury impels the gas through F into the test-tube C, which also contains mercury. As the mercury sinks in B, there is a rise of the mercury from C into F, which forms a sufficient seal during the suction process. On the other hand, when pressure is applied, the tube E is sealed by the rising mercury. C. A. M.

REPORTS, ETC.

Report on the Work of the Laboratories, Survey Department, Egypt (1910). A. Lucas. The work of this laboratory includes the chemical analysis of miscellaneous articles for composition, purity, etc., the physical testing of cements, bricks, etc., and the photometrical examination of illuminating gas and incandescent mantles. A total of 4,330 samples was examined during the year, 1,703 of these samples being analysed chemically, including sixty-five samples of foods. Eighteen samples of butter-fat analysed were found to be of normal composition. W. P. S.

REVIEWS.

RUBBER. By PHILIP SCHIDROWITZ. London: Methuen and Co., Ltd., 1911. Price 10s. 6d. net.

Owing to a number of causes rubber has attracted an unusual amount of attention during the past few years, and much useful work, both from the scientific and from the more purely technical sides, has been devoted to the solution of some of the more important problems connected with its production and employment. For many years prejudice and rule-of-thumb reigned supreme, and it was widely, if not universally, assumed that the various commercial rubbers had their fixed positions in the scale of quality, and that their properties—good, bad, or indifferent—were inherent and beyond the control of the technologist. Not the least useful outcome of recent work has been the recognition of the fact that this is only true to a certain extent, and that by the application of better methods much may be done to improve the inferior qualities, and so materially to lessen the distance between the best and the worst. Perhaps the most valuable portions of the work under review, and those which afford the greatest justification for its appearance, are the descriptions and criticisms of the various investigations which have, directly or indirectly, been instrumental in bringing about this improved state of affairs. The author has, himself, done good work in this fascinating and important field, and this, coupled with his first-hand knowledge of the subject in its various aspects, entitles him to claim for his views—even when, as is sometimes the case, these are decidedly speculative—the serious attention and respect of his readers. The work necessarily covers much of the ground occupied by previous authors, such as Weber, Clouth, Wright, Seeligmann, and others; but it is written in the light of the results of modern researches, and a great deal that is new and suggestive will be found even in those portions of the book where it might appear to be difficult to say much that has not already been said. The chapters dealing with wild rubber and the plantation industry are excellent, and if the same cannot be said of that referring to the production of so-called "industrial rubbers," it is clearly because the author has not felt himself at liberty to say what he knows. This is a matter for regret, since it detracts a little from the value of the book as a general survey of the whole industry. The methods adopted and the solvents employed in the winning of these rubbers are such very open secrets that probably no harm would have been done to anyone by a somewhat fuller reference to the subject. Seeing that such immense and increasing quantities of these rubbers are finding their way on to the market, it seems a pity that the whole subject should have been dismissed in the space of eight pages. A similar criticism applies to the discussion of "reclaimed" rubber.

The chapter dealing with the chemistry of crude rubber is clearly and concisely written, and in dealing with a subject where such magnificent superstructures have often been reared on such slender foundations of fact, the author cannot be blamed if he has erred on the side of condensation and exclusion. The view that the resins usually associated with the various crude rubbers are not genetically related to the rubber hydrocarbons is probably correct; but, nevertheless, they are of importance from several points of view, and their treatment is, in the opinion of the writer, scarcely adequate. The chapter on the chemical analysis of crude and vulcanised rubber is rather disappointing, in the sense that it contains little that is novel, either in the description of new methods or in the critical discussion of old ones. The prefatory remarks of the author, however, disarm criticism on this point, and it only remains for the reviewer to refer to the fact in passing. The author is, of course, right in stating that "a commercial valuation cannot be undertaken on the basis of chemical analysis alone," and that the chemical results should be supplemented by physical tests and by vulcanisation experiments. Still, one cannot help feeling that undue emphasis has been laid on the inadequacy of chemical results and on the difficulties attending the evaluation of commercial rubbers. Very large quantities of rubber are bought and sold daily on the results of simple chemical analysis, aided, of course, by the expert knowledge of the buyer, who in any case is in a better position to know what class of rubber he requires than is the chemist, no matter how expert he may be. Having said so much by way of criticism, there remains nothing but praise for the work, which is clearly written, and provides on the whole an excellent survey of the present condition of the rubber industry. The paper and printing are good, and the illustrations are excellent. There are very few typographical errors, but with a view to their correction in future editions the following, which have caught the reviewer's eye, may be noticed: "Diamethyl" for dimethyl, on p. 119; "hydriod" for hydriodic, on p. 120; "phenonema" for phenomena, on p. 124; and "adsorption" for absorption, on p. 249. "Ido-bromine," on p. 151 is, moreover, not a very intelligible expression. A. CHASTON CHAPMAN.

THE CHEMISTRY OF ENZYMES (ALLGEMEINE CHEMIE DER ENZYME). By HANS EULER. Wiesbaden: J. F. Bergmann, 1910. Pp. viii, 238. Price 5·70 m.

In this book the author aims at giving a succinct account of enzymes and enzyme action, the various chapters being devoted to the descriptive chemistry of enzymes, their physical properties, activators and inhibitants, the chemical dynamics and statics of enzyme action, enzymic synthesis, and the specific character of enzymes. This comprehensive scheme necessitates a condensed mode of treatment, but the work, in spite of this, is readable and not too greatly loaded with details. The author takes a broad view of his subject, and admits that enzymes in many cases may do more than merely accelerate or diminish the rate of a reaction; that they may not only combine with the substrate and the products formed from it, but may take part in and affect the condition of equilibrium. An examination of the numerous data quoted concerning the course of enzymic reactions shows that the due recognition of this possibility and a careful study of the various factors involved in each particular case of enzyme action are absolutely necessary if any great progress is to be made in the elucidation of the nature and mode of action of these mysterious agents.

As regards the actual chemical character of enzymes, no direct information is as yet available; in spite of many attempts at purification, no organic substance has been isolated about which it can be definitely said that it is a chemical individual and has the properties of one of the natural enzymes.

The work concludes with a short appendix containing a brief description of some of the most important methods of obtaining enzyme preparations and ascertaining their activity.

The author has undoubtedly succeeded in presenting in comparatively small space a general view of our knowledge of enzymes and enzyme action. Greater detail might appear to be desirable in several cases, notably in the discussion of the important subject of enzymic synthesis, but on the whole the relative importance of the various branches of the subject is adequately realised. The reader interested in any particular section of the subject will find here a general statement bearing on the point, and will be guided by the copious references to the literature. More than this it would be unreasonable to demand. A. HARDEN.

NOVEMBER, 1911. Vol. XXXVI., No. 428.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE monthly meeting of the Society was held on Wednesday evening, November 1, in the Chemical Society's Rooms, Burlington House. In the absence of the President, the chair was occupied by Dr. Bernard Dyer, F.I.C., Past-President.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. R. D. Carty, W. K. Walton, and G. F. Wesley Martin, were read for the second time; and certificates in favour of Messrs. Shelton Gottlieb Agar, "La Fontaine," Clifton, Guernsey, Assistant Public Analyst for Guernsey; George Stephen Barton, 8, Exhibition Road, South Kensington, S.W., analyst and bacteriologist to the Belgrave Dairy Co., Ltd.; Stanley W. Bridge, A.I.C., "Dunsmore," Park Hill Road, Croydon, assistant to Mr. E. Hinks, B.Sc., F.I.C.; Richard Victor Briggs, 4, Pollock Street (P.B. 279), Calcutta, analytical and consulting chemist; Francis Archibald Mason, 26a, Great George Street, Leeds, analytical and consulting chemist; William Bristow Saville, 117, Vassall Road, Brixton, S.W., assistant to Messrs. Harland and Brown; George Alfred Stokes, 191, Edgware Road, Paddington, W., assistant to Mr. A. W. Stokes, F.I.C.; and Francis Clifford Dyche-Teague, B.Sc. (Birmingham), A.I.C., 28, King Street, Portman Square, W., analytical and consulting chemist, were read for the first time.

Mr. H. C. Huish was elected a member of the Society.

The following papers were read: "Notes on Shrewsbury and Knapp's Process for Estimating Cocoanut Oil," by H. S. Shrewsbury, F.I.C., and Arthur W. Knapp, B.Sc., F.I.C.; "Note on the Examination of Finnish Turpentine," by L. M. Nash, F.I.C.; "Note on a Counterfeit Gold Coin," by H. S. Shrewsbury, F.I.C.; "Note on the approximate Estimation of Starch by Iodine," by L. Reed, F.I.C.; "Note on the Gravimetric Estimation of Phosphorus in Milk," by E. H. Miller; 'Kobert's Reagent as a Test for Salicylic Acid," by J. McCrae, Ph.D., F.I.C.; and "Precipitation of Nickel Compounds and Preparation of Spongy Nickel," by W. H. Low.

* * * * *

INTERNATIONAL CONFERENCE ON FOOD ANALYSIS.

As the result of some correspondence which they had had with the Foreign Office, the Local Government Board in June, 1910, addressed a letter to the President, suggesting that the Society should send a representative to the International Conference which was to be held in Paris on June 27, and succeeding days. This Conference was convened by the French Government for the purpose of discussing two main questions; first, the means to be adopted for the unification of methods of expressing the analytical results obtained in the analysis of food products; and, secondly, that of the unification of the analytical methods themselves. Mr. A. Chaston Chapman was appointed to act as the Society's representative, the other British delegates being Dr. G. S. Buchanan and Dr. G. W. Monier-Williams, representing the Local Government Board; Dr. J. J. Dobbie, Director of the Government Laboratories; Mr. E. J. Connah, Chief Chemist of the Customs Laboratory; and Dr. Nestor Tirard, Secretary of the Pharmacopœia Committee of the General Medical Council. The following countries were also represented: Argentina, Belgium, Bulgaria, China, Denmark, France, Greece, Holland, Hungary, Italy, Mexico, Norway, Portugal, Sweden, Switzerland and Uruguay, and the Meetings were held under the Presidency of Dr. Bordas, the Principal of the Laboratories of the French Ministry of Finance.

The following is a translation of the result of the deliberations of the Conference, and of the rules which have been proposed for the expression of analytical results obtained in the analysis of food products. To these recommendations all the British delegates signified their adhesion.

I. The members of the International Conference which was held in Paris on June 27, 1910, are in agreement in recognising that the unification of the methods of analysis of food products involves, in the first place, the unification of the methods of expressing the analytical results obtained conformably with the rules laid down hereafter.

II. The Conference expresses a desire that the French Government should take the initiative in considering a project for the creation of a permanent International Bureau, with laboratories attached.

The object of such laboratories would be to study the methods of analysing food products with a view to their possible unification, as well as the preparation of such tables of comparison (*concordance*) as might be considered necessary.

The Conference further expresses the hope that this project may be submitted by the French Government as soon as possible to all the countries represented at the Paris Conference.

III. The delegates agree to recommend to the recognised authorities of their respective countries the adoption of the methods suggested by the Conference. They express the wish that their decisions may be sanctioned by an International Convention, and, in particular, that measures shall be taken in the countries represented to bring into general use the manner of recording analytical results as adopted by the Conference.

RULES FOR THE UNIFICATION OF THE EXPRESSION OF ANALYTICAL RESULTS.

1. *Notation.*—The methods of notation are to be those adopted by the International Committee of Weights and Measures. The atomic weights employed are to be those established by the International Commission on Atomic Weights.

2. *Mass (Quantity of Matter).*—The practical unit of weight is the gram—the one-thousandth part of the international kilogram. This is in conformity with the definition of the General International Conferences on Weights and Measures, and introduced into the laws of those countries which have signified their adhesion to the Metric Convention.

3. For products the quantity of which is estimated by weight (*dont on évalue la quantité par des pesées*), the results of the analysis giving their composition are to be expressed in grams or milligrams per 100 grms. of the product. These results are indicated as follows:

g. %g. or mg. %g.
g/100 g. or mg/100 g.
g. p. cent. g. or mg. p. cent. g.

4. *Volume.*—The unit of volume is the litre—the volume of a kilogram of pure water under the conditions defined by the General International Conferences on Weights and Measures. The practical unit of volume measurement is the cubic centimetre, equal to the one-thousandth part of the litre.

5. The litre is represented at the temperature of t° by the volume of g grams of distilled water weighed in air with brass weights. A table giving the values for g for various temperatures is appended.

6. In the case of substances that are measured by volume, the results of the analysis are to be stated in grams or milligrams per litre of the substance. Thus—

g/L. or mg/L.

The results can at the same time be expressed in any other desired manner.

7. *Temperature.*—Temperatures are to be given in terms of the normal scale adopted by the General International Conferences on Weights and Measures—that is, the Centigrade scale of the hydrogen thermometer, which has for its fixed points—

(1) The temperature of melting ice (0°).
(2) That of the vapour of distilled water boiling under normal atmospheric pressure (100°).

As far as possible, the boiling-points should be subjected to the usual corrections. They are in that case to be followed by the letters "corr."

8. *Calorimetric Measurements.*—Thermo-chemical results must be expressed in large calories with the letters "gr. cal." (the quantity of heat required to raise the temperature of 1,000 grms. of water 1° Centigrade).

9. *Pressure.*—Pressures must be expressed in millimetres of mercury at 0° and under normal conditions of gravity.

10. *Density.*—Density is the ratio of the mass of a given volume of a body to the mass of the same volume of distilled water at 4° and under normal pressure.

11. Since the majority of existing tables contain the values at 15° compared with water at 15°, densities are in practice referred to those conditions (alcoholic solutions, and especially solutions of various acids, oils and essences).

An exception is made in the case of solid fats, but the temperature *T* at which their density has been taken, and also the temperature *t* of the water to which the density is referred, are to be stated as follows:

100°/15°, 40°/40°, etc.

12. Densities are not to be given in arbitrary units (Baumé, Tessa, Cartier, etc.).

13. The alcohol content of alcoholic liquids must be given in grams of alcohol, either per litre or per 100 c.c., and at the same time in volumes of alcohol according to the method in vogue in the particular country, but preferably in volumes of absolute alcohol contained in 100 volumes of the liquid analysed.

14. *Refractive Index.*—Refractometric measurements are to be expressed as refractive indices with reference to air, for the spectrum line D, and at a temperature of 25°, but at a temperature of 40° for fats.

When, however, it is impossible to work at the temperatures of 25° or 40° as mentioned above, the refractive index may be taken at another temperature *T*, but this must be designated by the expression "refractive index (*T*)."

15. *Polarimetric Results.*—Polarimetric readings are to be expressed in terms of degrees of arc, with centesimal fractions, for a tube of 20 cm., at a temperature of 20°, and for yellow light (D).

In the case of solids, the nature of the solvent and the concentration of the solution should be indicated.

16. *Acidity.*—Whatever the nature of the acid (whether fixed or volatile, free or partly combined), the acidity is to be expressed by the number of cubic centimetres of normal, decinormal, or centinormal solution corresponding to 100 grms. of substance or to 1 litre of liquid, the following notation being employed:

$$\text{cm}^3\text{N.},\quad \text{cm}^3 1/10\text{N.},\quad \text{cm}^3 1/100\text{N.}$$

In the case of butter and other fats, the acidity is to be referred to 100 grms. of the actual fatty matter.

Side by side with the above, results may be given in terms of acetic, tartaric, malic acid, etc., according to the nature of the product, or arbitrarily in terms of sulphuric acid, or in any other way.

In addition, the method employed and the indicator used should be mentioned whenever these have a bearing upon the results.

17. The saponification value is to be given in cubic centimetres of normal solution corresponding to 100 grms. of the fat analysed. It may be accompanied by the Köttstorfer number.

18. *Alkalinity.*—Whatever the nature of the bases, the alkalinity is to be expressed by the number of cubic centimetres of normal, decinormal, or centinormal

solution corresponding to 100 grams or to 1 litre of the substance analysed, the following notation being used:

$$\text{cm}^3\text{N.},\quad \text{cm}^3 1/10\text{N.},\quad \text{cm}^3 1/100\text{N.}$$

The alkalinity may at the same time be expressed in any other manner. The indicator used should also be stated when this has any bearing on the results obtained.

19. The alkalinity of the ash of a substance, expressed in the manner stated above, should be referred to 100 grms. or to 1 litre of the substance.

20. *Reducing Sugars.*—Reducing sugars the nature of which is not stated are to be expressed in grams of glucose per 100 grms. or per 1 litre of the substance analysed.

21. *Iodine Value, Bromine Value, etc.*—The iodine and bromine values represent the number of grams of halogen, calculated as iodine or bromine respectively, which combine with 100 grms. of the substance.

In the case of butter and other fats, the results are to be referred to 100 grms. of the actual fat.

22. *Proteins.*—When any factor other than 6·25 is used in calculating proteins from the amount of nitrogen, this factor should be given in parentheses.

23. *Analysis of Spirits (Special Regulation).*—The ethers are expressed in terms of acetic ether, the aldehydes as acetaldehyde, the higher alcohols as isobutylic alcohol or amylic alcohol, stating which of the two is taken. The volatile acids are to be expressed in terms of acetic acid.

These constituents are to be expressed in milligrams per litre of the liquid, and at the same time in milligrams per 100 c.c. of absolute alcohol contained in the liquid analysed.

The extractive matters and the fixed acidity (calculated as acetic acid) are to be expressed in grams per litre of the liquid analysed.

The letters C.I. may be used to indicate that the analytical results are expressed in conformity with the preceding rules.

* * * * *

THE PRECIPITATION OF NICKEL COMPOUNDS AND PREPARATION OF SPONGY NICKEL.

By WILSON H. LOW.

(*Read at the Meeting, November* 1, 1911.)

Textbooks on both qualitative and quantitative analysis are somewhat limited in their remarks concerning the behaviour of nickel solutions with ammonia, and there is little in them to suggest that ammonia is a possible reagent for the precipitation of nickel salts. In Roscoe and Schorlemmer's "Chemistry," however, the statement is made that nickel is precipitated as hydroxide by the fixed alkalis, that the precipitate dissolves in ammonia, *and separates out as a green crystalline powder on boiling the ammoniacal solution.*

This statement was found to be correct. The nickel separates in a form easy to filter and wash, and of course is free from fixed alkali. This would be an ideal method for determining nickel were it not for the fact that the precipitation is not complete, but the filtrate contains enough nickel in solution to be slightly greenish in colour.

Further addition of ammonia and boiling failed to produce more precipitate. With the hope that hydrazine might give better results, the original nickel solution was boiled with an excess of hydrazine hydrate. This produced a precipitate from neutral solutions of varying colour, but with an excess of the reagent the precipitate was a delicate blue-violet. This precipitate was crystalline, could be easily filtered and washed, and, except in colour, appeared physically much the same as the precipitate produced by ammonia. But here again it was found that the filtrate contained nickel, which further addition of the reagent and boiling failed to precipitate.

While neither ammonia or hydrazine hydrate gave filtrates free from nickel, it was found that if the filtrate from the ammonia precipitation was treated with hydrazine hydrate the remaining nickel was completely precipitated, as evidenced by the filtrate being clear and colourless. Operating in the opposite manner, and adding ammonia to a hydrazine hydrate filtrate, no further precipitate was formed. The explanation appeared obvious: Hydrazine will precipitate nickel completely from solutions containing ammonium salts, but ammonia will not cause a complete precipitation in solutions containing hydrazine compounds. This proved to be the case, and, starting with a nickel solution containing ammonium chloride, the hydrazine precipitated the nickel completely.

Either the precipitate produced by ammonia or hydrazine may be easily reduced to spongy nickel by heating in hydrogen. The spongy nickel is free from fixed alkali.

KOBERT'S REAGENT AS A TEST FOR SALICYLIC ACID.

By J. McCRAE, Ph.D., F.I.C.

(*Read at the Meeting, November* 1, 1911.)

KOBERT'S reagent (three drops of formaldehyde solution in 3 c.c. of sulphuric acid), so useful in the detection of morphine, gives a characteristic rose colour with salicylic acid (or salicylates).

When Kobert's reagent is added to dry salicylic acid, the colour develops fairly quickly, but the colour does not appear quite immediately. The reaction is most clearly seen when about $\frac{1}{50}$ mgrm. of salicylic acid is dissolved in two drops of sulphuric acid, and a drop of Kobert's reagent then added; the fine rose colour develops within a few minutes.

The same result is obtained with acetyl-salicylic acid (aspirin and xaxa), and also with salol; in the case of salol the colour develops more quickly.

Sulphuric acid gives a red colour with salicine, but the colour obtained with Kobert's reagent is deeper and richer. This colour reaction can be best seen by dissolving about $\frac{1}{50}$ mgrm. of salicin in three drops of sulphuric acid, and to this red solution adding one drop of Kobert's reagent in such a way that mixing does not take place; a deep red colour is produced.

Kobert's reagent gives the following characteristic colours with other substances: Phenol, red-violet; catechol, violet (redder than the morphine colour); resorcinol, deep orange-brown; quinol, dirty greenish-brown; pyrogallol, brown; α-naphthol, dirty green; β-naphthol, dirty brown; cinnamic acid, brown; mandelic acid, yellow.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Composition of Ripe and Unripe Bananas. R. Reich. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 208-226.)—The author has analysed several different kinds of bananas, and meals prepared from the same, and the following table gives a selection of typical results from the large number of analyses recorded:

	Water.	Water-Soluble Substances.	Invert Sugar.	Sucrose.	Starch.	Nitrogen.	Crude Fibre.	Acidity (as Citric Acid).	Ash.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.

It will be seen from the above results that the starch present in bananas is converted into sucrose and invert sugar during the ripening process (*cf.* ANALYST, 1911, 274).

For the manufacture of banana meals, care is taken that the fruit is collected at a period when the formation of starch is fully developed, but before the saccharification of the starch commences. W. P. S.

Composition of Roquefort Cheese. A. W. Dox. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 239-242.)—The following results were obtained on the analysis of eight samples of Roquefort cheese purchased in New York:

	Water.	Fat.	Protein. N × 6·37.	Ash.	Sodium Chloride.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Maximum	40·10	33·53	23·25	6·81	4·50
Minimum	37·49	31·50	19·94	5·48	3·64
Average	38·61	32·24	21·62	6·19	4·18

The high percentage of sodium chloride distinguishes this class of cheese from Gorgonzola (1·57 per cent.) and Stilton (0·59 per cent.). W. P. S.

Nature of the Poisonous "Cardamom" (Maratti) Fat employed in the Manufacture of "Backa-Margarine." H. Thoms and F. Müller. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 226-236.)—The recent case of poisoning by "backa-margarine" having been found to be due to the presence of maratti fat in the margarine, the author investigated the characters and sources of this fat. It seems that the fat was obtained from an Indian species of *Hydnocarpus*, probably from the most widely distributed member of the species—namely, *Hydnocarpus Kurzii Warburg* (synonym: *Taraktogenos Kurzii King*). The fat has the following constants: m.p., 22° to 24° C.; $[\alpha]_D = +54·0°$ to 58·0°; saponification value, 201 to 212; and an iodine value from 88 to 94·8. It appears to be identical with chaulmugra fat; besides palmitic acid, the fat contains hydnocarpic acid and chaulmugric acid, $C_{18}H_{32}O_2$; m.p. 68·5°. Both maratti fat and chaulmugric acid are poisonous, a dose of 0·04 grm. of the former killing a white mouse within an hour and a half. (*Cf.* ANALYST, 1911, 65.) W. P. S.

Estimation of the Reichert-Meissl Value of Fats by Means of Glycerol-Potassium Hydroxide. H. Kreis. (*Chem. Zeit.*, 1911, **35**, 1053-1054.)—The author states that butter, cocoanut oil, lard, etc., may be saponified for the estimation of the Reichert-Meissl value, by the use of 2 c.c. of 50 per cent. potassium hydroxide solution and 4 c.c. of glycerol. The saponification proceeds more rapidly than when the usual 20 c.c. of glycerol are employed, and the results obtained agree closely. The advantage of using the smaller quantity of glycerol arises from the fact that many specimens of glycerol yield considerable amounts of volatile acid substances, the Reichert-Meissl values of fats having to be corrected accordingly. W. P. S.

Estimation of Fat in Feeding Stuffs by Means of Trichlorethylene. R. Neumann. (*Chem. Zeit.*, 1911, **35**, 1025-1026.)—The use of trichlorethylene is ecommended (*cf.* L. Gowing-Scopes, ANALYST, 1910, **35**, 238) for the estimation of fat in such feeding stuffs as meals, feeding-cakes, etc. Five grms. of the material are shaken for one hour in a stoppered flask with 100 c.c. of the solvent; after being allowed to settle for thirty minutes, the liquid is filtered, 50 c.c. of the filtrate are evaporated in a weighed flask, the residue of fat is dried for one hour at 100° C. and weighed. The results obtained agree well with those yielded by the ordinary extraction process with ether. W. P. S.

Method of Estimating the Quality of Wheaten Flour. L. von Liebermann and V. Andriska. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 291-293.)—The quality of wheaten flour as regards the quantity of bran substance present may be ascertained by shaking the flour with chloroform, and observing the colour of the portion which floats on the surface of the chloroform. The test may be rendered quantitative in the following manner: One grm. of the flour is shaken in a tube with 10 c.c. of chloroform, and the mixture is allowed to stand for one hour. A layer then forms on the surface of the chloroform, and its depth of colour is compared with the colours of the layers produced when mixtures of finest white flour with variable proportions of bran are subjected to similar treatment; these mixtures may conveniently contain quantities of washed bran ranging from 0 to 2 per cent. The colour of the layers should be observed from above. W. P. S.

Composition of the So-called Gallisin [Glucosin] occurring in Commercial Starch Syrup. J. Gatterbauer. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 265-290.)—That portion of commercial starch syrup which resists fermentation, and to which the name "gallisin" has been applied, consists of a small quantity of maltose together with a new carbohydrate which has the properties of a disaccharide; dextrin is not present. This carbohydrate, or "glucosin," yields only dextrose on hydrolysis, and may be regarded as an isomer of maltose. It is obtained from completely fermented starch syrup as a viscous liquid which, by treatment with absolute alcohol and ether, may be converted into a white or yellowish-white powder. "Glucosin" has $[\alpha]_D = +100°$, is fermented slowly by beer-yeast, and is converted by yeast-maltase and by emulsin into dextrose. Mineral acids and oxalic acid also convert "glucosin" into dextrose, but with high concentrations of mineral acids the reaction is reversible. In fact, the new carbohydrate is formed by the action of mineral acids on dextrose during the manufacture of starch syrup. The phenylosazone of "glucosin" is a red-brown crystalline powder melting at 97° to 100° C.; the *p*-nitrophenylosazone melts at 240° C., and yields a blue coloration when treated with sodium hydroxide. "Glucosin" also yields amorphous esters with benzoyl chloride, *p*-chlorobenzoyl chloride, *m*-nitrobenzoyl chloride, and benzene sulphochloride. W. P. S.

Estimation of Sulphurous Acid in Glucose Syrup. O. Claassen. (*Chem. Zeit.*, 1911, **35**, 1065-1066.)—The usual addition of calcium carbonate in estimating sulphurous acid by distillation with phosphoric acid and absorption in potassium iodide solution is shown to be an unnecessary complication. Thus, in comparative estimations with and without the addition of 3 grms. of calcium carbonate, the amounts of sulphur dioxide found in a glucose syrup were 0·0056 and 0·0050 per cent. respectively. No differences in the results were produced by the substitution of acetic acid for phosphoric acid. C. A. M.

Some Reactions of Gum Kino. J. L. Simonsen. (*J. Chem. Soc.*, 1911, **99**, 1530-1535.)—The author was unable to isolate the principle kinoin by the action of hydrochloric acid on kino. Catechol was, however, detected, and this is generally present in small quantity in kino. Kino is not glucosidic in character. It was found to be readily methylated by treatment with methyl sulphate and potassium hydroxide. (No methoxy-group was discovered in kino.) The methyl ether, $C_{15}H_{11}O_4(OMe)_3$, was obtained as a non-crystalline, nearly colourless powder, and the acetate, a brown powder, was of similar characters and corresponding formula. By oxidation in the cold with potassium permanganate, the methyl ether yielded veratric acid as the only product; by fusion with potassium hydroxide, protocatechuic acid and catechol were obtained, but no phloroglucinol. On oxidation with 10 per cent. nitric acid, oxalic acid and ammonium quadroxalate were formed, the latter probably by means of the strong reducing action of kino on the acid with production of ammonia.

A. R. T.

Estimation of Nicotine in Nicotine Solutions and Tobacco Extracts. R. M. Chapin. (*U.S. Dept. of Agriculture, Bureau of Animal Industry*, Bull. No. 133, 1911; through *Chem. Zentralbl.*, 1911, II., 799-800.)—The results of a critical examination of various methods used for the estimation of nicotine are recorded. Kissling's method was found to yield accurate results; as, however, all alkaline substances present in the distillate are counted as nicotine, it is probable that the correct results obtained are due to a balancing of errors. According to the directions of the American Association of Official Agricultural Chemists, the method is carried out as follows: Five grms. of tobacco extract, or 20 grms. of finely divided tobacco dried at 60° C., are mixed with 10 c.c. of alcoholic sodium hydroxide solution (6 grms. of sodium hydroxide, 40 c.c. of water, and 60 c.c. of 90 per cent. alcohol); in the case of tobacco extracts, sufficient calcium carbonate is also added, so as to convert the mixture into a moist mass. This is extracted with ether for five hours in a Soxhlet apparatus, the ethereal solution is evaporated at a low temperature, the residue is dissolved in 50 c.c. of 4 per cent. sodium hydroxide solution, transferred to a flask, and steam-distilled until 500 c.c. of distillate have been collected; at the end of the distillation the flask should contain only about 15 c.c. of liquid. The distillate is then titrated with $\frac{N}{1}$ sulphuric acid, using phenacetolin as indicator.

Toth's method (ANALYST, 1902, **27**, 12) also yields trustworthy results, although the danger that non-volatile alkaloids, if present, would be included in the nicotine result.

The silicotungstic acid process, proposed by Bertrand and Javillier (ANALYST, 1909, **34**, 219), is considered by the author to be the most convenient and accurate method for the estimation of nicotine. The procedure recommended is as follows: A quantity of the sample, corresponding with from 1 to 2 grms. of nicotine, is mixed in a flask with 1·5 grms. of paraffin, a small quantity of pumice-stone, and 10 c.c. of sodium hydroxide solution (1 : 2), and submitted to steam-distillation until a few c.c. of the distillate no longer yield a turbidity with silicotungstic acid. The distillate is received in a vessel containing 10 c.c. of hydrochloric acid (1 : 4), and at the end of the distillation is diluted to a definite volume and filtered. A quantity of the filtrate corresponding with about 0·1 grm. of nicotine is then treated with a further quantity of hydrochloric acid, 3 c.c. of the latter (1 : 4) being added for each 100 c.c. of the solution, and 10 c.c., or an excess, of 12 per cent. silicotungstic acid are added. After the lapse of eleven hours the precipitate is collected on a filter, washed with water containing 1 c.c. of hydrochloric acid per litre, and ignited in a platinum crucible. The weight of the residue multiplied by 0·114 gives the quantity of nicotine in the precipitate. The precipitate may also be collected in a Gooch crucible, dried at 125° C., and weighed as anhydrous nicotine silicotungstate ($2C_{10}H_{14}N_2.2H_2O.SiO_2.12WO_3$). W. P. S.

Analysis of Tobacco Juice and Extracts, and of Nicotine Salts, by the Method of Ulex. Essner. (*Ann. Chim. anal. appl.*, 1911, **16**, 339-341.)—The method of Ulex, the accuracy of which has been called in question by Koenig (ANALYST, 1911, 106, 348), gives closely concordant results when applied in the following manner: About 10 grms. of the juice or extract are mixed with soda-lime prepared by slaking quicklime with sodium hydroxide solution (sp. gr. 1·33), leaving a slight excess of lime, mixing one part of the mass with four parts of plaster, grinding the whole in a mortar, and sifting the powder through a sieve with 220 meshes to the sq. cm. The mixture of tobacco juice and soda-lime should also be sifted, any residue left being ground up again until the whole is reduced to a fine powder. This is exposed for about an hour in a wide vessel placed in a desiccator over sulphuric acid to facilitate the evaporation of ammonia and ammoniacal compounds prior to the distillation, after which it is transferred to a 3-litre flask containing 2½ litres of boiled water. The evaporating basin is rinsed with a few drops of hydrochloric acid, which are also added to the main liquid. About 10 grms. of sodium hydroxide and 10 to 15 grms. of paraffin wax (to prevent bumping) are now added, and the liquid distilled so as to obtain six fractions of 1,000, 500, 200, 100, 100, and 100 c.c. of distillate. Each of these fractions is separately titrated with $\frac{N}{2}$ hydrochloric acid (1 c.c. = 0·081 grm. of nicotine), with turmeric as indicator, and each result added to the preceding one. From 60 to 70 per cent. of the nicotine passes over with the first fraction, and from 85 to 90 per cent. in the first 1,500 c.c. In this way the author has estimated nicotine within 1 per cent. in concentrated tobacco extracts containing 100 to 125 grms. of the alkaloid per litre, and varying in sp. gr. from 1·060 to 1·450; whereas by Schloesing's method deviations of 10 to 15 grms. were obtained in duplicate estimations, even when the proportion of alkali was increased beyond the specified amount.

C. A. M.

Estimation of Tartaric Acid in Apples, Pears, Cider, and Perry. G. Warcollier. (*Ann. Falsific.*, 1911, 4, 485-490.)—Kling's method of estimating tartaric acid by precipitation as calcium racemate gives very accurate results. This racemate, when dissolved in hot dilute sulphuric acid, gives a quantitative reduction of potassium permanganate solution. Examined by this method, neither cider nor perry, nor the ripe or unripe fruits from which they are prepared, contained any trace of tartaric acid. C. A. M.

Detection of the Substitution of Spirit for Aged Whisky. A. B. Adams. (*J. Ind. Eng. Chem.*, 1911, **3**, 647-655.)—An account is given of the chemical and other methods employed for ascertaining whether barrels of whisky, drawn from bond and bearing Government stamps and seals indicating the quality of the whisky, had been partially emptied of their contents and refilled with other spirit by the dealers. In dealing with the cases mentioned (these were the subject of a law case, in which the findings of the analyst were upheld), samples were obtained from the distilleries, etc., as nearly as possible representing the age and quality of the suspected samples; other samples of new and old whisky were also examined for the purpose of comparison, and with the object of ascertaining the rate of change in the character and quantity of the different constituents of the whiskies during the ageing process. It was found that there is a general tendency for the alcoholic strength, colour, solids, and secondary substances, to increase with storage; this increase is uniform and comparable in barrels of proximately the same age. The barrel seems to have no other influence than to cause a slight variation in the depth of colour and amount of aldehydes. The quantity of furfural depends almost entirely on the kind of barrel and the time of storage. In all cases the composition of the colour extracted from the barrels is the same, never less than 70 per cent. insoluble in water, or the same percentage soluble in amyl alcohol. The suspected samples were not similar in composition to any of the genuine comparison samples, except as regards alcoholic strength and depth of colour. The proportions of esters, acids, and colour, yielded the most useful data in judging the quality of the samples, the content of total solids, higher alcohols, aldehydes, and furfural, affording only confirmatory evidence. W. P. S.

Analysis of Turpentine Oil. C. Blarez. (*Ann. Chim. anal. appl.*, 1911, **16**, 328-336.)—One hundred c.c. of the oil are distilled so that 80 c.c. pass over during the first twelve to fifteen minutes, and four successive fractions of 20 c.c. each of the distillate are collected, whilst the residue in the flask constitutes a fifth fraction. French turpentine oils (from *Pinus maritima*) showed the following characteristics: Sp. gr. at 15° C., 0·8660 to 0·8720; polarimeter reading, −140° to −143°; turbidity temperature with aniline, (2 c.c. + 2 c.c.), 170 to 180 (sometimes 160 in the case of old oils); refractive index at 15° C., 1·4720 to 1·4730; and acid value, 1·5. Greek, Algerian, and Provence oils (from *P. alepensis*) had a lower sp. gr., though always superior to 0·8542, and gave a polarimetric reading ranging from +177° to +190°; whilst American oils (from *P. palustris*, etc.) had sp. grs. intermediate between those of the other oils, and showed sometimes a dextro- and sometimes a lævo-rotation. The effect of the addition of 5 per cent. of various common adulterants upon a pure oil of turpentine is shown in the following table of results:

Adulterants added to Pure Turpentine Oil in the Proportion of 5 per Cent.	Pure Oil.	Leaf-bud Turpentine (*Gemme terebenthine*).	Rosin.	Crude Essential Oil (*Essence vive brute*).	Rosin Oil.	Bleached Rosin Oil.	Rectified Benzene.	Mineral Essence	White Spirit.	Petroleum Lamp Oil.

Composition of Sauerkraut. E. Feder. (*Zeitsch. Untersuch. Nahr. Genussm.* 1911, **22**, 295-296.)—Analyses of this substance yielded the following results :

	Water.	Proteins.	Fat.	Lactic Acid.	Dextrose.	Mannose.	Crude Fibre.	Ash.	Sodium Chloride.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
1	90·84	1·68	0·28	1·75	—	0·80	0·92	1·40	0·78
2	88·00	1·31	0·38	1·22	0·80	0·97	0·87	4·04	3·31
3	89·00	1·46	0·38	1·78	—	1·16	1·02	2·20	1·45
4	88·40	1·37	0·31	1·33	1·31	1·01	0·98	3·05	2·34

When an aqueous extract of sauerkraut is poured on the surface of concentrated sulphuric acid, a violet-coloured ring is formed at the junction of the two liquids; the coloration is intensified if the extract be mixed previously with a small quantity of milk, the reaction in this case being similar to that yielded by formaldehyde. Concentrated hydrochloric acid also yields a violet coloration. Mannose appears to be an important constituent of sauerkraut, its quantity amounting to about 10 per cent. of the dry solids. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Method for the Estimation of Acetone in Animal Fluids. H. Scott-Wilson. (*J. of Physiol.*, 1911, **42**, 444-470; through *Chem. Zentralbl.*, 1911, II., 903-904.)—For the estimation of acetone in urine and other animal liquids, the following modification of Marsh and Struthers' method (*J. Chem. Soc.*, 1906, **87**, 1878) has been worked out: 100 c.c. of urine (or less if the quantity of acetone be abnormally high) are placed in a boiling-flask with 25 grms. of anhydrous sodium sulphate and 1 c.c. of concentrated sulphuric acid. The flask is provided with a leading tube communicating with the outside, which is closed during the distillation, also with another tube leading into a second flask. This flask contains 10 c.c. of a 40 per cent. sodium hydroxide solution, and is connected through a reflux condenser with a flask containing the reagent. The reagent consists of a solution of 0·5 grm. of mercuric cyanide, 9 grms. of sodium hydroxide in 60 c.c. of water and 20 c.c. of a 0·7268 per cent. solution of silver nitrate; if more than 0·4 mgrm. of acetone be expected, the quantity of the reagent should be increased. On boiling the urine, the free acetone, together with that derived from any aceto-acetic acid, is driven over, through the previously heated soda solution in the second flask, which holds back phenols and volatile acids, into the reagent flask. Distillation is continued for five minutes after the first appearance of a turbidity in the mercury solution; prolonged distillation leads to a further production of acetone, owing to secondary changes. Ten minutes after the distillation has been stopped, a few drops of an emulsion of talc are added, and the liquid is filtered through a Gooch crucible. The precipitate together with the filter-paper is placed in a flask with about 10 c.c. of a mixture of 40 per cent. of nitric acid, 5 per cent. of sulphuric acid, and 55 per cent. of water;

1 c.c. of $\frac{N}{5}$ permanganate solution is added, and the liquid is boiled. The colour should disappear in one or two minutes; if it disappears in a few seconds, a further 1 c.c. of permanganate is necessary. The oxidised liquid is treated with 2 c.c. of saturated iron-alum solution and titrated with standard thiocyanate (1 c.c. = 1 mgrm. of mercury), until a brown colour is produced: 1 mgrm. of mercury corresponds to 0·058 mgrm. of acetone. If the urine has suffered decomposition by standing for twenty-four hours, the quantity of acetone may be increased by 7 to 21 per cent. in consequence of secondary reactions. The mercury reagent may also be used for the qualitative detection of an abnormal proportion of acetone in the atmosphere. The daily quantity of acetone excreted by the normal organism ranges from 2 to 4 mgrms.

J. F. B.

Absorption of Arsenic by Sugar Beets. H. Remmier. (*Chem. Zeit.*, 1911, **35**, 977-979.)—For the destruction of the horse-beetle on growing beet, the application of a spray composed of Schweinfurt green and lime to the young plants, at the end of May, has been recommended. The author has conducted experiments to ascertain whether, under these conditions, the presence of arsenic in poisonous quantities can be detected in the leaves or roots at the time of the harvest. The results showed that the beet root is indeed capable of taking up arsenic in this manner, and that the quantity of arsenic absorbed increases with the quantity of Schweinfurt green applied. Exactly by what process this absorption takes place is not yet determined, nor is the exact form of the arsenic compound in the plant known. But assuming it exists entirely in the most poisonous form, the quantity present in the plants which have been treated with the prescribed proportions of Schweinfurt green is so small that no evil results are to be feared. For instance, from 1 kilo of the roots an arsenic mirror corresponding to 0·005 mgrm. of the oxide was obtained; from 500 grms. of the leaves no mirror was produced. Beets which had been treated with an excess of the green, temporarily injurious to vegetation, showed 0·08 mgrm. of arsenious oxide per kilo, and the leaves showed 0·25 mgrm. per kilo. It is remarked that even if traces of arsenic were, by some accidental over-treatment, to appear in the juice, they would certainly be precipitated by the defecation lime; in fact, defecation lime itself may normally contain more arsenic than is likely to be present in the juice of treated beets. J. F. B.

Detection of Blood. O. von Fürth. (*Zeitsch. angew. Chem.*, 1911, **24**, 1625-1628.)—For the identification of blood when present in traces on paper, fabrics, etc., the author recommends the use of a method which is a combination of tests described by Leers (treatment with sodium hydroxide and extraction of the blood-colouring matters with pyridine) and by Adler (leucomalachite green test; *cf.* ANALYST, 1911, 284). The piece of fabric containing the stain to be tested for blood is heated for a minute or so with a few drops of 50 per cent. potassium hydroxide solution and a small quantity of alcohol. After cooling, the solution is transferred to a small separating funnel and shaken with a few c.c. of pyridine; when separation has taken place, the alkaline liquid is drawn off, and the pyridine layer is shaken with a few c.c. of 50 per cent. potassium hydroxide solution. A portion of the pyridine solution may now be examined spectroscopically, whilst another portion of about 1 c.c. is placed on a filter-paper on a glass plate and treated with a few drops of leucomalachite green solution containing 1 per cent. of hydrogen peroxide. A green coloration developes if blood is present. The leucomalachite green reagent is prepared by dissolving 1 grm. of the substance in 50 c.c. of glacial acetic acid, diluting with water to a volume of 500 c.c., and shaking the solution with chloroform to remove any green colour. When carried out in this manner the test is stated to be very sensitive, and to be free from certain objections (interference of other substances) belonging to the original methods of applying the tests. Potassium permanganate and lead peroxide are the only substances which must be removed before the test is applied; for this purpose the fabric should be treated with a small quantity of 50 per cent. hydrazine solution, and then well washed before being heated with the potassium hydroxide solution. Only when blood has been heated to temperatures above 220° C. does it fail to give a positive reaction with the test.

W. P. S.

Hæmochromogen and the Spectroscopic Differentiation between Oxyhæmoglobin and Carbon Monoxide Hæmoglobin. F. Michel. (*Chem. Zeit.*, 1911, **35**, 996.)—The best reagent for reducing the colouring matter of the blood into hæmochromogen is an alcoholic alkaline solution of sodium hydrosulphite prepared by dissolving 4 grms. of potassium hydroxide in 75 c.c. of water, adding 3 grms. of fresh sodium hydrosulphite ($Na_2S_2O_4$), diluting the solution with 40 c.c. of 98 per cent. alcohol, and filtering the liquid rapidly into a stoppered flask. On adding to the solution of blood a few drops to a few c.c. of this reagent, the characteristic spectrum of hæmochromogen is obtained even in the cold. On heating the liquid a broad absorption band appears in the case of concentrated solutions, and the spectrum gradually disappears. It may, however, be restored by the addition of 2 or 3 drops of pure pyridine, the liquid also becoming red again. On now shaking the cold solution, the red colour and hæmochromogen spectrum disappear once more, but may be restored on heating the tube. This behaviour is characteristic of blood. In the case of blood-stains upon linen, paper, etc., it is frequently sufficient to apply a few drops of the reagent and to examine the spot between two glass slips by means of transmitted light. As a confirmatory test or in case of a negative result the stains are heated in a test-tube with about 4 to 6 drops of the reagent and 1 or 2 drops of pyridine, a similar course being adopted for the examination of blood-stains on rusty iron. For the detection of minute quantities of carbon monoxide-hæmoglobin, a few drops of the blood are diluted with water, and a few c.c. of the reagent and a few drops of pyridine added. The colour of the liquid will become an intense yellowish-red, and only the oxyhæmoglobin will have been converted into hæmochromogen, until the liquid is heated, when the carbon monoxide-hæmoglobin spectrum will also give place to that of hæmochromogen.

C. A. M.

Estimation of Indophenol Oxydase of Animal Tissues. H. M. Vernon. (*J. Physiol.*, 1911, **42**, 402-407; through *Chem. Zentralbl.*, 1911, II., 796-797.)—Formation of indophenol takes place when the tissues of a rat or rabbit are mixed with α-naphthol, *p*-phenylenediamine, and sodium carbonate; with *M*/100 α-naphthol and phenylenediamine solution, the quantity of indophenol formed is proportional to the square of the amount of enzyme, with *M*/150 solution it is directly proportional to the quantity of enzyme, and with *M*/400 solution is proportional to the square root of the quantity of enzyme. The estimation may be carried out by mixing quantities of 1 grm. of the tissue in Petri dishes with 5 c.c. of *M*/100, *M*/150, and *M*/400 α-naphthol and *p*-phenylenediamine solutions containing 0·25 per cent. of sodium carbonate; at the end of a few hours the mixtures are digested for twenty-five minutes with 97 per cent. alcohol, a portion of the liquid is filtered, and the coloration is compared with that of standard solutions. The latter are prepared by mixing 1 part of the above reagent solutions with 200 parts of 50 per cent. alcohol, adding 1 part of 0·5 per cent. calcium hypochlorite solution, and allowing the mixtures to stand for twenty-four hours. The tissues of the rat are richer in oxydase than are those of the rabbit. The heart muscle contains most oxydase, then follow the tongue muscles, the diaphragm, the renal cortex, and the grey substance of the brain.

W. P. S.

Detection of Active Pepsin in the Intestines by Means of Elastin. E. Abderhalden and C. Meyer. (*Zeitsch. physiol. Chem.*, 1911, **74**, 67-100.)—Considerable quantities of active pepsin were found to be present in the intestines of animals, and this ferment seems to play an important part, in conjunction with trypsin and erepsin, in the digestion of proteins after the latter have passed the stomach. The method employed in detecting the presence of pepsin depended on the property, possessed by proteins, of being capable of absorbing pepsin; elastin was used in the experiments, quantities of it being saturated with $\frac{N}{10}$ hydrochloric acid and then immersed in the intestinal contents. After the lapse of two hours the elastin was removed, washed, and kept, together with a small quantity of water, for forty-eight hours at a temperature of 37° C. The optical activity of the solution and its behaviour towards the biuret reaction were then determined. W. P. S.

Rapid Gravimetric Method for the Estimation of Albumin in Urine. E. Simonot. (*Bull. Soc. Chim.*, 1911, [IV.], **9**, 839-842.)—Most of the methods for the gravimetric estimation of albumin are not quite satisfactory, either because of incomplete coagulation, slow filtration, or a variable coefficient; in some cases, also, the coagulum slowly disintegrates during washing. The author finds that metaphosphoric acid coagulates the albumin with results satisfactory in all respects. It is preferably liberated *in situ*, by adding a solution of sodium metaphosphate to the urine and treating with an acid. A 5 per cent. solution of sodium metaphosphate is prepared by dissolving 5·7 grms. of the finely powdered salt in 50 c.c. of hot water, boiling for five minutes, adding 50 c.c. of cold water, cooling rapidly to 15° C., and making up to 100 c.c.; the quantity of metaphosphate converted into phosphate by hydrolysis under these conditions is negligible. The urine is first tested approximately with this reagent by the diaphanometric method of Denigès (*Chimie analytique*, 3rd edition, 1907, 1011), and it should contain over 0·5 grm. of albumin per litre. A quantity of urine containing between 0·08 and 0·15 grm. of albumin is measured out, and its volume is made up to at least 100 c.c. It is placed in a capsule and heated on the boiling-water bath for ten minutes if 100 c.c. are taken, or for fifteen minutes if the volume is 200 c.c. Then are added without stirring 5 c.c. of a 5 per cent. solution of sodium metaphosphate and 1 c.c. of pure hydrochloric acid for every 100 c.c. of urine, and heating is continued for a further five or ten minutes. The coagulated albumin is deposited for the most part on the bottom of the dish. It is collected on a tared filter, dried at 110° to 120° C., care being taken to decant the liquid off first, washed with boiling water until the filtrate no longer reacts with silver nitrate, then with alcohol, and lastly with ether. The precipitate is drained by pressing between filter-paper, then dried at 110° to 120° C. and weighed. The weight multiplied by the factor 0·88, gives the weight of albumin in the urine. J. F. B.

Detection of Mercury in Urine. E. Salkowski. (*Zeitsch. physiol. Chem.*, 1911, **73**, 401-406.)—In the method described the mercury is deposited on copper, volatilised from the latter on to the sides of a glass tube, and then converted into mercuric iodide by treatment with iodine vapour. The urine is first evaporated and oxidised by means of hydrochloric acid and potassium chlorate, and filtered if necessary, in order to obtain a final solution which is about 10 c.c. in volume. Two or three strips of copper-foil, about 50 mm. long and 10 mm. wide, are immersed in this solution for an hour and a half, then removed, washed with water, alcohol, and ether. The dry strips are next heated in a dry test-tube until the mercury has sublimed on to the sides of the tube; the latter is then cooled and the strips are removed. A minute fragment of iodine is now dropped into the tube, which is placed in a boiling-water-bath until the excess of iodine has been expelled; a current of air may be blown into the tube to aid in the removal of the vapours. Should mercury be present in the urine under examination, a red mirror of mercuric iodide will be formed inside the test-tube. The test will detect as little as 0·19 mgrm. of mercury in 500 c.c. of urine. W. P. S.

Separation and Identification of Urobilin. C. Carrez. (*Ann. Chim. anal. appl.*, 1911, **16**, 337-339.)—Forty-five c.c. of the urine under examination are shaken with 30 c.c. of Denigès' mercuric sulphate reagent (ANALYST, 1898, **23**, 216) and filtered, and 50 c.c. of the filtrate (=30 c.c. of urine) shaken with about 1 grm. of talc or silica, to precipitate the urobilin. The precipitate is washed with water and tested for urobilin. Thus it may be directly treated with 5 to 6 c.c. of Oliviero's reagent (zinc chloride 10 grms. dissolved in about 30 grms. of ammonia solution, and mixed with 80 grms. of 90 per cent. alcohol, and 20 grms. of ethyl acetate), which gives an immediate green fluorescence with urobilin, the liquid showing a characteristic spectrum with an absorption-band at γ. Or the precipitate may be treated with 10 c.c. of alcohol acidified with 5 per cent. of hydrochloric acid, and the extract shaken with 5 to 6 c.c. of chloroform and 100 to 150 c.c. of water. The chloroform extract is separated and tested with a 0·1 per cent. alcoholic solution of zinc acetate, which is added drop by drop until a clear solution is obtained. In the presence of urobilin the characteristic fluorescence and spectrum will then be observed. (*Cf.* ANALYST, 1911, 223.) C. A. M.

ORGANIC ANALYSIS.

New Method of Elementary Analysis of Organic Substances containing Carbon, Hydrogen, Oxygen, and Nitrogen. J. A. A. Auzies. (*Bull. Soc. Chim.*, 1911, [IV.], 9, 814-815.)—The combustion-tube is charged with plugs of asbestos or cotton impregnated with thoria, in place of the usual copper oxide; otherwise it is fitted up in the ordinary way. The absorption vessels contain calcium chloride to absorb the water, a titrated solution of cuprous chloride in hydrochloric acid to absorb nitrogen peroxide, and potash for the carbon dioxide. The vapours of nitrogen peroxide when absorbed by the cuprous chloride produce a coloration which is proportional to the quantity absorbed. This coloration is then destroyed by the addition of a titrated solution of stannous chloride, according to reactions in which $SnCl_2$ is equivalent to $4NO_2$. The thoria cotton is prepared by steeping the cotton in a solution of a thorium salt, then in a solution of ammonia, which precipitates the hydroxide, and finally incinerating. J. F. B.

Analysis of a Substance containing Carbon, Hydrogen, Oxygen, Nitrogen, and Sulphur. J. A. A. Auzies. (*Bull. Soc. Chim.*, 1911, [IV.], 9, 815.)—In the case of a substance containing sulphur, the gases, after passing over the thoria (see preceding abstract), are conducted over lead peroxide. It is necessary to separate the lead peroxide from the thoria—for instance, by interposing a plug of asbestos, since means must be provided for removing the lead peroxide quantitatively, prior to dissolving in hydrochloric acid for the estimation of the sulphate. The best method is to pack the lead peroxide in a special cylindrical boat which slides easily into the tube, and can be withdrawn after the analysis, the lead sulphate being estimated in the ordinary way. J. F. B.

Analysis of a Substance containing Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, Chlorine, Bromine, and Iodine. J. A. A. Auzies. (*Bull. Soc. Chim.*, 1911, [IV.], 9, 815-819.)—In the case of a substance containing all the above elements, the tube is fitted up with absorption vessels containing calcium chloride, cuprous chloride, and potassium hydroxide. These account for the carbon, hydrogen, and nitrogen. The sulphur is absorbed by lead peroxide contained in the combustion-tube. In a similar manner the halogens are absorbed by means of silver chromate, also contained in a special cylindrical boat. After the combustion, the silver chromate is treated with ammonia. The ammoniacal solution contains the silver chloride and the excess of silver chromate. The filtered liquid is neutralised by acetic acid, which precipitates the silver salts, and the chloride is then re-dissolved in potassium cyanide and estimated by known methods. The residue from the ammoniacal treatment contains silver bromide and silver iodide. This is washed on the filter and treated with potassium cyanide solution, which dissolves the iodide, leaving the bromide on the filter. The complete simultaneous estimation of all these elements in a mixture of substances has been carried out with satisfactory results. The following directions are given for preparing and standardising the cuprous chloride solution used for absorbing the nitrogen peroxide: 35 to 40 grms. of copper sulphate are dissolved in a litre of water; a stannous chloride solution is also prepared by dissolving 20 grms. of the salt in 300 c.c. of water and diluting to 1 litre. Ten c.c. of the copper solution are then boiled with 25 c.c. of hydrochloric acid, and the stannous chloride is run in until decolorisation is complete. Three c.c. of a solution of pure potassium nitrate containing 0·01 grm. of N_2O_5 are then added, and the coloured liquid is again exactly decolorised by the stannous chloride, which is thereby standardised in terms of nitric acid. J. F. B.

Analysis of Beeswax, with Special Reference to East Indian and the So-called China Beeswax. G. Buchner. (*Zeitsch. öffentl. Chem.*, 1911, **17**, 225-227; through *Chem. Zentralbl.*, 1911, II, 729.)—When pure beeswax is saponified, the alcohol evaporated, and the residue treated with 250 c.c. of boiling water, a clear solution is usually obtained; certain waxes (East Indian, China, etc.) yield turbid solutions with the separation of amorphous substances, and the following tests are described for distinguishing these waxes from those adulterated with paraffin, which also yield turbid solutions. The amorphous matter is separated and boiled with acetic anhydride; a clear solution which does not yield a precipitate on cooling, indicates the presence of aliphatic alcohols, and cetyl alcohol. A crystalline precipitate on cooling denotes the presence of cholesterol, phytosterol, or myricyl alcohol, whilst a turbid solution in hot acetic anhydride indicates paraffin. The presence of a trace of alcohol retards the separation of wax alcohols from the aqueous mixture, but aids in the separation of paraffin. Estimations of glycerol in pure beeswaxes gave results which corresponded with the presence of from 0·08 to 0·1 per cent. of glycerides in the waxes. W. P. S.

Colorimetric Method for the Quantitative Estimation of Enols in Allelotropic Mixtures. L. Knorr and H. Schubert. (*Ber.*, 1911, **44**, 2772-2778). —The reaction of enolic compounds with ferric chloride plays an important part in the study of cases of desmotropy for the detection of the point at which the ketonic form begins to change into the enolic form. By the use of suitable standards and a colorimeter this reaction may be employed in a quantitative sense for the study of the equilibria at different temperatures and in different solvents. The maximum colour intensity is attained when 1 molecule of ferric chloride ($FeCl_3$) reacts with 1 molecule of the enol. A convenient standard is obtained by mixing a freshly prepared solution of the pure enolic form with an equimolecular quantity of sublimed dry ferric chloride. This solution is compared with an equally concentrated solution of the enol-ketone mixture to be examined containing the same quantity of ferric chloride as the standard solution. The above standard answers well in all cases where the enolic form can be obtained in the pure state, and is sufficiently stable in solution during the time of the experiment. In other cases standards may be made from the readily isolated ferric-enol salts of general formula FeR_3, which give maximum colorations when mixed with 2 molecules of ferric chloride and 3 molecules of hydrochloric acid. The method of preparing these salts is described in the paper. In certain other cases it is possible to use as standards stable solutions in which the equilibrium has been reached and the percentage of enol determined by one of the other standards.

The coloured solutions in organic solvents are generally very stable. The method has been used for the study of certain cases of desmotropy, that of methyl mesityloxidoxalate being described at length in the paper. About 0·2 grm. of the sample is weighed out, treated with the equivalent quantity of ferric chloride in alcoholic solution, made up to 50 c.c. with alcohol, and examined colorimetrically. J. F. B.

Specifications and Sampling of Fuel Oil and Natural Gas. I. C. Allen. (*U.S. Bureau of Mines; Technical Paper* No. 3, 1911, 1-13.)—*Specification.*—Fuel oil should be either a natural homogeneous oil or a homogeneous residue from a natural oil. If the latter, all low-flashing constituents should have been distilled off. The oil should not consist of a light oil and a heavy residue mixed in such proportions as to give the density required. The oil should not have been "burned" by distillation at too high a temperature, nor heated so as to cause separation of flecks of carbonaceous matter. The flash-point must not be below 60° C., in a closed Abel-Pensky or Pensky-Marten's tester. The limits of sp. gr. are from 0·85 to 0·96 at 15° C. The oil should be free from solid or semi-solid bodies, be mobile, and flow readily at ordinary temperatures, under a head of 1 foot of oil, through a 4-inch pipe 10 feet in length; it should not congeal nor become too sluggish to flow at 0° C. The oil should have a calorific value of not less than 10,000 calories per grm. (18,000 B. T. units per pound), 10,250 calories to be the standard. A bonus is paid, or a penalty inflicted according as the fuel is delivered above or below the standard. The oil should be rejected if it contain more than 2 per cent. of water or 1 per cent. of sulphur, and it should not contain more than a trace of sand, clay, or dirt. The oil should be described by its commercial name, and a statement made as to whether it is a crude oil, refinery residue, or a distillate.

Calculation of Weight of Oil.—The coefficient of expansion of ordinary fuel oil of asphaltic base is about 0·0006 per 1° C. This temperature correction having been made, the weight of 1 gallon in pounds is 8·3316 times the corrected sp. gr., and the weight of 1 cubic foot in pounds is 62·3425 times the corrected sp. gr. at 15° C.

Sampling.—In sampling with a dipper from a waggon, a pint of oil is taken at regular intervals from the flowing oil, twelve or more lots being taken and thoroughly mixed together, the final sample being stored in a tightly soldered can. An iron container absorbs sulphur, and must not be used. A continuous sample may be taken from a cock on the underside of the delivery-pipe during the entire time of discharge.

In sampling from a large tank, the detection of notable quantities of sediment should cause the rejection of the oil. If the oil has stood for a time sufficient to form layers of varying density, it should be sampled by means of a tinned tube of 1 inch diameter, the tube carrying a conical wooden or cork plug, with an attached wire passing up through the tube. The tube, open at both ends, is carefully lowered into the oil, and when the bottom is reached a tug on the wire will cause the plug to close the tube, and this can be repeated in various parts of the tank and the samples mixed. Bottle-sampling from varying portions and depths of the reservoir may be carried out. A single drum of oil may be sampled in the usual way by means of a glass tube.

Gas.—To obtain a sample of the gas from a well, a 1 or 2 quart bottle with glass stopper should be turned bottom upwards and the rubber connection with the pipe from which the gas is issuing passed into the bottle, which is then allowed to remain for fifteen minutes or more. The bottle is closed with a greased stopper, and finally sealed with paraffin-wax. A. R. T.

Analysis of Lactic Acid. W. Klapproth. (*Chem. Zeit.*, 1911, **35**, 1026-1027.)—The following method of titration is recommended for the estimation of lactic acid and lactic anhydride in samples of lactic acid: One grm. of the sample is diluted with 20 c.c. of distilled water, and the solution is titrated with $\frac{N}{1}$ sodium hydroxide solution, phenolphthaleïn being used as the indicator. The number of c.c. of $\frac{N}{1}$ solution required for the titration, when multiplied by 9, gives the percentage weight of the free acid in the sample—that is, the lactic acid *plus* one-half of the lactic anhydride. An excess of 1 c.c. of $\frac{N}{1}$ sodium hydroxide solution is now added to the neutral solution (in the case of samples containing more than 50 per cent. of lactic acid 3 c.c. should be added), and the mixture is heated on a boiling-water-bath for five minutes; it is then titrated with $\frac{N}{1}$ sulphuric acid, an excess of 1 c.c. of the latter is added, the mixture is again heated for two minutes, and titrated with $\frac{N}{1}$ sodium hydroxide solution. The quantity of sodium hydroxide solution used in the two titrations, less the amount of sulphuric acid added, when multiplied by 9, gives the total percentage of acid (lactic acid *plus* anhydride) in the sample, expressed in terms of lactic acid. W. P. S.

Estimation of Minute Quantities of Nitroglycerin. W. L. Scoville. (*Amer. J. Pharm.*, 1911, **83**, 359-364.)—In the author's experience the nitrometer method and saponification with alcoholic alkali are not generally reliable for this estimation, though the Kjeldahl method and the phenol-disulphonic acid method give good results. The latter may be carried out as follows: An amount of alcoholic solution of the substance, equivalent to 0·00065 grm. (or $\frac{1}{100}$ grain) of nitroglycerin, is allowed to evaporate spontaneously. If tablets are to be examined, five $\frac{1}{100}$ grain tablets are powdered, shaken with 10 c.c. of alcohol during one to two hours, and the mixture filtered. Two c.c. of this filtrate are then treated similarly. A solution of potassium nitrate containing the equivalent of 0·0001 grm. nitrogen per 1 c.c. contains, in 1·2 c.c., an amount of nitrogen equal to that present in $\frac{1}{100}$ grain pure nitroglycerin, and 1·2 c.c. of this standard solution is thus evaporated at low temperature; when the standard and sample are dry, 2 c.c. of the phenol-disulphonic acid reagent are added, the mixture stirred well, allowed to stand ten minutes, diluted with water, made slightly alkaline with potassium hydroxide, and diluted to 100 c.c., and the colours compared in the usual way. A. R. T.

Use of Miscibility Curves in the Examination of Essential Oils and Balsams. E. Louïse. (*J. Pharm. Chim.*, 1911, **4**, 193-197.)—Two c.c. of the essential oil under examination are mixed with 2 c.c. of standard petroleum spirit and increasing quantities of aniline from 5 to 30 c.c., and the miscibility curves plotted as described in previous communications (ANALYST, 1907, **32**, 365; 1910, **35**, 322). Lavender oil gives a curve far removed from that of turpentine oil or terpenyl acetate, which is sometimes used to enrich lavender oil poor in esters. The curves given by bigarade neroli oil and petit-grain oil are also distinct, the maximum difference being about 3° C. French, Japanese, and American peppermint oils gave parallel curves sufficiently far apart to enable the three kinds of oil to be distinguished. Similar differences were observed between copaiba balsams of different origin.

C. A. M.

Estimation of the Specific Gravity of Oils. E. Bellmer. (*Chem. Zeit.*, 1911, **35**, 997.)—The method of comparison with mixtures of alcohol and water affords an accurate means of determining the sp. gr. of viscous oils. A few drops of the oil under examination are introduced into 2 c.c. of absolute (98 to 99 per cent.) alcohol, and water added little by little from a burette until the drops just begin to float. The sp. gr. of the dilute alcohol is then the same as that of the oil. The value may be readily found by reference to the following table from the amount of water added:

Water c.c.	Sp. Gr. at 15° C.	Water c.c.	Sp. Gr. at 15° C.	Water. c.c.	Sp. Gr. at 15° C.	Water c.c.	Sp. Gr. at 15° C.
0·1	0·8178	1·1	0·9050	2·1	0·9376	3·1	0·9537
0·2	0·8331	1·2	0·9091	2·2	0·9397	3·2	0·9548
0·3	0·8456	1·3	0·9133	2·3	0·9417	3·3	0·9558
0·4	0·8563	1·4	0·9173	2·4	0·9436	3·4	0·9568
0·5	0·8678	1·5	0·9209	2·5	0·9453	3·5	0·9577
0·6	0·8739	1·6	0·9243	2·6	0·9469	3·6	0·9587
0·7	0·8812	1·7	0·9273	2·7	0·9485	3·7	0·9595
0·8	0·8880	1·8	0·9301	2·8	0·9499	3·8	0·9603
0·9	0·8940	1·9	0·9327	2·9	0·9512	3·9	0·9610
1·0	0·8995	2·0	0·9353	3·0	0·9525	4·0	0·9617

C. A. M.

Estimation of Rosin in Fatty Oils. W. Fahrion. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 239-242.)—About 5 grms. of the oil under examination are dissolved in a mixture of 50 c.c. of petroleum spirit and 20 c.c. of 96 per cent. alcohol, and the solution rendered faintly alkaline to phenolphthaleïn with $\frac{N}{1}$-alkali solution. After the addition of sufficient water to bring the alcoholic strength to about 60 per cent., the liquid is thoroughly shaken, an extra 1 c.c. of $\frac{N}{1}$ alkali solution added, and the alcohol evaporated on the water-bath. The residue is taken up with water, and the fatty and rosin acids liberated by shaking the liquid with several successive portions of ether and hydrochloric acid. The mixed acids left on evaporation of the ether are next esterified by treating them with 20 c.c. of absolute alcohol, adding 20 c.c. of petroleum spirit and 1 c.c. of concentrated hydrochloric acid, shaking the mixture vigorously in a separating funnel, and allowing it to stand overnight. The liquid is again rendered faintly alkaline, the alcohol once more diluted to about 60 per cent. strength, and the shaking repeated. Finally, the last traces of the ethyl esters of the fatty acids are eliminated by shaking the clear rosin soap solution with petroleum spirit, after which the alcohol is evaporated, the rosin acids liberated by treatment with ether and hydrochloric acid, the ethereal solution evaporated on the water-bath, and the residue dried for an hour at 100° C. and weighed. Results obtained in test experiments with linseed oil containing known quantities of rosin were in close agreement with theory, but an estimation in which only rosin was present gave a result 2·55 per cent. too low. From this it would appear that the relative proportion of fatty and rosin acids present had some influence upon the esterification. The proportion of unsaponifiable matter found in linseed oil containing rosin was also too low, and it is therefore recommended either that the average proportion of unsaponifiable matter in linseed oil should be taken as 1 per cent. (instead of 1·5 per cent.), or that the results should be expressed as the proportion of rosin acids found and not calculated into colophony. C. A. M.

Estimation of Fillers (Mineral Matter) in Rubber Mixtures. Brüggemann. (*Gummi Zeit.*, 1911, **25**, 1529-1530; through *Chem. Zentralbl.*, 1911, II., 801.)—The rubber material is extracted with acetone and then boiled with petroleum oil as described by Hinrichsen (Analyst, 1910, **34**, 406). After diluting with benzene, the mixture is allowed to settle, and the insoluble matter is collected on a filter prepared as follows: Two thicknesses of filter-paper are placed in a Gooch crucible, and a mixture of kieselguhr and water is poured into the crucible; before all the water has drained through, alcohol is added, and then ether. The crucible and its contents are next dried and weighed. The same filter may be used again after the surface of the kieselguhr has been removed to a depth of about 0·2 mm.

W. P. S.

The Application of Bromination Methods for the Estimation of Caoutchouc in Vulcanised Products. W. Esch. (*Chem. Zeit.*, 1911, **35**, 971-972.)—The various methods which have been proposed for the estimation of caoutchouc in vulcanised products by the action of bromine, whether in organic solvents or aqueous media, all depend on the following assumptions: (1) That 136 parts of caoutchouc hydrocarbon combine additively with 319·7 parts of bromine or 64 parts of sulphur; (2) that if 136 parts of caoutchouc have already combined with 32 parts of sulphur as the result of vulcanisation, they can only combine further with 159·85 parts of bromine; (3) that the whole of the sulphur combined with the vulcanised caoutchouc is unaffected by the bromine; (4) that the difference between the total weight and the weight of the combined sulphur and bromine represents the weight of caoutchouc; (5) that for every 64 parts of combined sulphur, or 319·7 parts of combined bromine, 136 parts of caoutchouc hydrocarbon may be calculated. The author has made a large number of analyses, from which he concludes that none of the above theoretical assumptions are actually valid. If the brominated sulphur derivative be weighed, and the weights of the combined bromine and sulphur be deducted, the results may be at one time 15 per cent. too low, and at another 23 per cent. too high. On the other hand, if the caoutchouc be calculated according to Hübener's method from the values found for combined sulphur and bromine, the results range from 7 per cent. too low to 24 per cent. too high. Further, the same kind of errors are not always found with the same samples. It is hardly to be expected that the combined sulphur of vulcanisation, which is appreciably susceptible to the oxidising action of the air, should be capable of resisting entirely the action of one of the most powerful oxidising agents known—namely, bromine, or bromine water.

J. F. B.

Estimation of Soap in Heavy Grease. W. Bockermann. (*Chem. Zeit.*, 1911, **35**, 1066.)—The following method is recommended as sufficiently accurate for most technical purposes. After estimation of the free fatty acids, 2 grms. of the grease are boiled for thirty minutes on the water-bath beneath a reflux condenser with 50 c.c. of $\frac{N}{10}$ potassium hydroxide solution and 50 c.c. of absolute alcohol. The contents of the flask are then cooled, shaken with 40 c.c. of petroleum spirit, and allowed to stand until separate layers are formed, after which 20 c.c. of the petroleum spirit layer are withdrawn and evaporated, and the residue of unsaponifiable matter dried on an oil-bath at about 140° C. until constant in weight. The difference between 100 and the percentage result gives the amount of soap in the grease. When a large quantity of free fatty acids is present, a corresponding correction must be made.

C. A. M.

Reaction of Sparteine. A. Jorissen. (*J. Pharm. Chim.*, 1911, **4**, 251-252.)—The ammonium sulphide test for sparteine described in the French *Codex* is rendered more sensitive when applied as follows: If 0·01 grm. of sparteine sulphate is placed on a strip of filter-paper and moistened with a drop of ammonium sulphide (containing polysulphides), a brownish-red coloration is produced as the liquid evaporates. This coloration is manifested in the absence of moisture, and appears to depend largely upon the presence of polysulphides. A still better modification is to add a slight excess of sodium hydroxide to a solution of a trace of sparteine sulphate in the smallest possible quantity of water, and to shake the liquid with about 10 c.c. of ether. The ethereal layer is decanted and shaken for about a minute with 0·01 to 0·02 grm. of dry sulphur, after which a current of hydrogen sulphide is introduced. This soon produces a voluminous red precipitate, which disappears on the addition of water. The reaction is clearly given by 0·01 grm. of sparteine sulphate, whereas neither other alkaloids nor pyridin behave in the same way. Coniine, however, gives an orange-yellow turbidity, whilst atropine yields a yellow precipitate.

C. A. M.

INORGANIC ANALYSIS.

Precipitation of Aluminium, Chromium, and Iron by Ammonium Nitrite. E. Schirm. (*Chem. Zeit.*, 1911, **35**, 979-980.)—In a previous communication (*Chem. Zeit.*, 1909, **33**, 877) it was shown that in presence of more than 2 per cent. of ammonium salts in the solution the precipitation of metallic hydroxide by ammonium nitrite may not take place. If the nitrous fumes be expelled by boiling, and precipitation be then effected by ammonia, the precipitate, though not possessing the granular form of the precipitate formed by the nitrite, is, nevertheless, far more readily filtered than one formed by ammonia alone, owing to the mechanical action of the nitrogen gas evolved. It has been found that the hydroxides of this group may be precipitated by sodium nitrite, regardless of the quantity of ammonium salts; but then the liquid cannot be used for the subsequent estimation of the alkalis. It is suggested that since the nitrites of the organic quaternary ammonium bases react in all respects similarly to the nitrites of alkali metals, one of these—for instance, trimethylphenylammonium nitrite—might get over both difficulties.

The author has attempted to effect the separation of aluminium, chromium, and iron from the diad metals of the ammonium sulphide group by means of the nitrite method of precipitation. Solutions of zinc, cobalt and nickel salts are not precipitated by ammonium nitrite, whilst manganese is partially precipitated in absence of ammonium salts, but not in presence of small quantities of these salts. The separation of iron from manganese is effected by precipitating the ferric hydroxide in the manner previously described, but with the addition, before precipitation, of a little ammonium sulphate. The filtrate is acidified with sulphuric acid, boiled, and the manganese estimated by the persulphate method. The manganese results come out about 2 per cent. too low owing to a slight co-precipitation with the iron, but exact results may be obtained by a double precipitation. If more than 3 grms. of ammonium sulphate be added per 250 c.c., precipitation of the iron is incomplete, and the subsequent use of ammonia is not admissible in this case, since it increases the co-precipitation of manganese. Here also better results are anticipated by the use of trimethylphenylammonium nitrite. Attempts to separate the triad metals from zinc by the nitrite method failed, since a large proportion of the zinc was always carried down in combination with the sesquioxide. J. F. B.

Analysis of Calcium Cyanamide. H. Kappen. (*Chem. Zeit.*, 1911, **35**, 950-952.)—In contradiction to Monnier (Analyst, 1911, 429), and in support of Stutzer (Analyst, *loc. cit.*), the author finds no difference in the results obtained by the ordinary Kjeldahl method and those obtained when the digestion is carried out after addition of salicylic acid and zinc dust, or of salicylic acid and thiosulphate as suggested by Monnier. Nor does moistening the material with water before addition of sulphuric acid affect the final result. He concludes that commercial calcium cyanamide yields all its nitrogen as ammonia when 0·5 grm. is digested with 30 c.c. sulphuric acid (*cf.* Dinslage, following Abstract). It is suggested that Monnier's results would probably be explained if that author had described his method in detail, and in the present paper full detail is given.

For the estimation of the cyanamide nitrogen as distinguished from total nitrogen, the author uses his modification (*Landw. Versuchsstationen*, 1909, **70**, 445) of Perotti's method (*Gaz.*, 1905, **35**, II., 228). This method, which depends on the precipitation of cyanamide by an ammoniacal solution of silver nitrate ($\frac{N}{100}$), and titration of the excess of silver by means of thiocyanate, has been criticised by Caro (Analyst, 1910, **35**, 76) on the ground that the composition of the precipitate is variable, though it contains the whole of the cyanamide. If the author's directions (*loc. cit.*) are rigidly adhered to, the precipitate has the composition indicated by theory. The experiments of Caro (*loc. cit.*), who recommended precipitation by an ammoniacal solution of silver acetate, washing the precipitate and determining its nitrogen content by Kjeldahl's method, appear to have been made exclusively with the commercial product known as "Kalkstickstoff." When the corresponding precipitate of silver cyanamide from "Stickstoffkalk," a commercial product distinguished from "Kalkstickstoff" by containing calcium chloride (and tar products, *cf.* Dinslage, following Abstract), is treated with concentrated sulphuric acid, a violent reaction attended by loss of nitrogen occurs. The nitrogen content of the precipitate may, however, be determined accurately by Kjeldahl's method, if a little water be added before the sulphuric acid.

It is pointed out that Caro's method (*loc. cit.*) for the estimation of dicyandiamide necessarily estimates as such any dicyandiamidine present. G. C. J.

[*Note by Abstractor.*—Caro showed that dicyandiamidine was not present in those brands of calcium cyanamide with which he worked.]

Analysis of Calcium Cyanamide and of Norwegian Nitre. E. Dinslage. (*Chem. Zeit.*, 1911, **35**, 1045-1046.)—*Calcium Cyanamide.*—In the author's experience the only way in which the whole of the nitrogen can be obtained as ammonia is to digest the substance with dilute sulphuric acid (1 : 1). This digestion is carried out in an ordinary 600 c.c. Jena flask (not a Kjeldahl flask) and 1 grm. of the material, 30 c.c. of dilute sulphuric acid, and a drop of mercury are taken. Decomposition is complete in one and a half to two hours. Working in this way, four different chemists found 19·19 to 19·24 per cent. nitrogen. Using concentrated acid at the start, the same sample yielded from 17·22 to 19·23 per cent. (mean of 6, 18·57 per cent.) nitrogen as ammonia. Preliminary moistening of the sample with water or alcohol appears to effect a small improvement, but the results are not concordant, and the mean values so obtained are notably lower than those obtained by the author's method. Nor does the addition of reducing agents effect any measurable improvement (*cf.* Kappen, preceding Abstract), unless at the same time the initial concentration of sulphuric acid is reduced, when the improvement is due to this diminished concentration and not to the reducing agent. The above results were obtained with the commercial product known as "Kalkstickstoff," but similar results were obtained with "Stickstoffkalk," and are given in the paper. "Stickstoffkalk" contains from 5 to 6 per cent. of calcium chloride, and the samples examined by the author yielded to ether between 6 and 7 per cent. of a yellow, unsaponifiable oil with a tarry odour, which odour and its blacker appearance distinguish "Stickstoffkalk" from "Kalkstickstoff"; the latter usually smells faintly of acetylene. The oil, which is presumably added to diminish the dust nuisance which attended the use of calcium cyanamide when first introduced, makes it very difficult to wet this product.

Norwegian Nitre.—The estimation of moisture in Norwegian nitre presents considerable difficulty. When dried alone at 100° to 105° C., the process is incomplete after as long as three weeks. In admixture with dry sand better results can be obtained in three days, but they are still below the truth (19·9 instead of 20 per cent.). The last 0·5 per cent. cannot be removed by exposure to the action of desiccating agents in an exhausted vessel. On the other hand, the determination may be made with great exactness in twenty minutes if the following directions are followed: From 3 to 5 grms. of the substance are heated in a crucible situated some

10 cm. above a small flame. At the end of the process the contents of the crucible should have an irregular form and opaque appearance. If heated too strongly, the mass melts a second time and forms at its edges a compact, transparent cake; this change is attended with loss of matter other than water. The estimation of nitrate and nitrite present no difficulty, and that of iron, aluminium, manganese and magnesium is simplified by the fact that, with the exception of a trace of magnesium, these remain wholly with the insoluble residue. G. C. J.

Practical Value of Calorimetry in Testing Anthracite. S. F. Peckham. (*Chem. Engineer*, 1911, **14**, 351-355.) As the result of experimental work carried out in controlling the coal supplies of the Corporation of New York, the author arrives at the conclusion that, so far as anthracite is concerned, the use of a calorimeter is not justified, since it gives results which are directly proportional to the fixed carbon, and the latter can be determined more expeditiously and more cheaply than the calorific power. He also protests against the false assumption, made in the specifications of the City of New York, that the practical value of coal bears a simple direct ratio to its calorific power. The practical value falls far more rapidly than the calorific power, and may reach zero when the calorific power is still 50 per cent. of that of the best coal (*Cf.* Pope, ANALYST, 1911, 229). G. C. J.

Analysis of Graphite. F. Mayer. (*Chem. Zeit.*, 1911, **35**, 1024-1025.)—The amount of graphitic carbon in graphite may be accurately and conveniently estimated by taking the calorific value of the sample. For this purpose 0·6 grm. of the graphite is mixed with 0·4 grm. of pure benzoic acid, the mixture is pressed into the form of a tablet, and its calorific value is estimated in a Berthelot bomb apparatus. The benzoic acid is added in order to insure complete combustion of the graphite; 1 kilo. of benzoic produces 6,322 calories, and 1 kilo. of graphitic carbon 7,900 calories. A simple calculation gives the quantity of graphitic carbon from the calorific value found. Should the graphite contain sulphur, the result obtained must be corrected for its quantity; the sulphuric acid resulting from the combustion of the sulphur dissolves in the water contained in the bomb, and the solution is titrated. For each c.c. of $\frac{N}{10}$ solution required for the titration 7·06 calories are deducted from the calorific value of the sample. W. P. S.

Estimation of Carbon in Steel by Means of a Calorimetric Bomb. P. Mahler and E. Goutal. (*Compt. Rend.*, 1911, **153**, 549-551.)—The bomb used is a large one of 1,000 c.c. content, and it is neither lined with platinum nor with enamel, but contains a removable porcelain beaker so as to make it possible to conduct the estimation of sulphur simultaneously. The sample (2 to 5 grms.) is contained in a capsule of fire-clay, free from carbonates, and ignition is effected by means of a piece of fine iron wire, through which an electric current is passed when all is ready. Copper is used in place of platinum for the electrodes and support for the capsule. There are two cocks, to one of which a copper tube is attached, reaching nearly to the bottom of the bomb, the whole arrangement being very similar to that of bombs used for determining the calorific power of gases and oils. It is advisable, as a matter of routine, to mix the sample with litharge, to insure complete combustion, but this is only necessary with very hard steels. Combustion takes place under a pressure of no more than 5 to 8 atmospheres, and at its conclusion the gases are passed through a measured quantity of baryta solution of known strength, which is then titrated with oxalic acid. The results obtained with a number of steels of very different character agreed closely with those supplied by the works (Creusot and Imphy) with each sample, except in two cases. In one of these cases the steel was highly silicious (1·3 per cent.), the other contained 5·1 per cent. of chromium, and the makers' numbers for carbon appear to have been wrong, since the authors confirmed their own higher numbers by liberation of the carbon, followed by its dry combustion. G. C.

Rapid Estimation of Ferric Oxide in Cement. A. Golubinzeff. (*Chem Zeit.*, 1911, **35**, 961-962.)—A weighed quantity (2 grms.) of the cement is brought into an Erlenmeyer flask and moistened with 10 c.c. of water. After ten minutes, a further 75 c.c. of water are added, and then gradually, with shaking, 100 c.c. of $\frac{N}{1}$ hydrochloric acid. Shaking is continued until the greater part of the cement is dissolved, and solution (except of any sandy particles) is completed by warming. The solution is reduced by means of sulphur dioxide or hydrogen sulphide, the reducing agent expelled by passing a current of carbon dioxide through the boiling solution, and the solution cooled in an atmosphere of carbon dioxide and titrated with permanganate in presence of 10 c.c. of Reinhardt's solution (manganese sulphate and phosphoric acid). The whole operation occupies only forty-five to sixty minutes, and the method, which allows of the use of larger quantities of material than are usually taken, gives results which are substantially identical with those yielded by the most exact gravimetric methods, and which agree better among themselves than do duplicate gravimetric determinations. For example, the precipitate of ferric oxide and alumina obtained in the ordinary course of analysis, after separation of silica, was fused with bisulphate, and the melt taken up in dilute hydrochloric acid. After addition of tartaric acid and ammonia to this solution, iron was precipitated by means of ammonium sulphide, the iron sulphide dissolved in hydrochloric acid, with the addition of a little nitric acid, and the iron finally precipitated by means of ammonia, the precipitate tested for the presence of silica, and its weight corrected for the amount found. Duplicate determinations gave 2·82 and 2·89 per cent. Ten determinations by the author's method gave results which lay between 2·82 and 2·88 per cent. G. C. J.

Simultaneous Estimation of Ferrocyanides and Thiocyanates. L. Ronnet. (*Ann. Chim. anal. appl.*, 1911, **16**, 336-337.)—An aliquot portion of the solution is strongly acidified with hydrochloric acid, and treated with a slight excess of a hot solution of ferric chloride. The precipitate of Prussian blue and ferric thiocyanate is digested for thirty minutes on the boiling-water-bath, and then separated and washed with boiling water until the washings are neutral and colourless. The filter containing the Prussian blue is transferred to a graduated flask, into which is also introduced a definite volume of 10 per cent. potassium hydroxide solution (sufficient to dissolve the Prussian blue). The flask is now thoroughly shaken and allowed to stand for twelve to sixteen hours, after which its contents are made up to the mark, shaken, and filtered. Finally, an aliquot portion of the filtrate is slightly acidified with 10 per cent. sulphuric acid and titrated with $\frac{N}{10}$ potassium permanganate, 1 c.c. of which is equivalent to 0·0422 grm. of crystalline potassium ferrocyanide, or to 0·02866 grm. of anhydrous Prussian blue. The filtrate from the Prussian blue is made up to definite volume, and an aliquot part decolorised with sodium bisulphite solution (added in slight excess), heated for a few moments on the water-bath, and treated with a slight excess of 10 per cent. copper sulphate solution. After standing for thirty minutes on the water-bath the liquid is filtered, and the precipitate of cuprous thiocyanate washed with boiling water until the washings are free from copper, after which it is dissolved in ammonia solution (1 : 3), and the solution heated and titrated with $\frac{N}{10}$ potassium permanganate solution. One c.c. is equivalent to 0·0016 grm. of potassium thiocyanate. C. A. M.

Preparation of Pure Potassium Ferrocyanide and its Analytical Control. K. Schroeder. (*Zeitsch. anorg. Chem.*, 1911, **72**, 89-99.)—Crystals of potassium ferrocyanide obtained by cooling, with shaking, a hot concentrated solution of the commercial salt, have the composition represented by the formula $K_4Fe(CN)_6 3H_2O$. Statements to the contrary—*e.g.*, that of Müller and Diefenthäler (*Zeitsch. anorg. Chem.*, 1910, **67**, 421)—are based on indirect determinations of the water of crystallisation, which indicated a somewhat lower percentage of water than corresponds to the above formula. Though it is possible, with suitable precautions, to determine the water of crystallisation by loss in weight on drying, anhydrous ferrocyanide is somewhat hygroscopic, and tends to become oxidised when maintained for long periods at temperatures in the neighbourhood of 100° C.

A convenient means of controlling the purity of potassium ferrocyanide is to decompose it by boiling with concentrated sulphuric acid, and then to precipitate the iron by means of nitrosophenylhydroxylamine (ANALYST, 1910, **35**, 327). The decomposition is conveniently effected in a large (500 to 600 c.c.) Erlenmeyer flask, supported on asbestos in an air-bath of such depth that only the upper third of the flask remains outside it. When the evolution of carbon monoxide is ended, the temperature is raised until the acid begins to fume and is maintained for half an hour. For the decomposition of 2 grms. of ferrocyanide, 15 c.c. of sulphuric acid is a suitable quantity. To the cooled solution, water and 15 c.c. of concentrated hydrochloric acid are added; the mixture is warmed to effect complete solution of the ferric sulphate, and then cooled, and the ferric iron is finally precipitated as stated.

The following new volumetric method is described: It depends on the destruction of the ferrocyanogen complex in such a manner that the whole of the iron is obtained as ferrous salt, which is then titrated with permanganate. When a solution of a ferrocyanide is added to a cold saturated solution of mercuric chloride, mercuric ferrocyanide separates as a yellow precipitate. If the ferrocyanide be added in small quantities to a hot solution of mercuric chloride, the ferrocyanogen complex is completely broken down, and the solution gives the reactions of ferrous iron.

If the addition of ferrocyanide be continued, the speed of its decomposition slackens and ferrous ferrocyanide has a more than momentary existence, and this compound readily undergoes oxidation. The method, therefore, is as follows: The solution of ferrocyanide (2 grms. in 50 to 100 c.c. cold water) is added to 100 c.c. of a cold saturated solution of mercuric chloride. This mixture is added in small portions at a time to 200 c.c. of a boiling solution of mercuric chloride to which 2 or 3 drops of hydrochloric acid (1 : 1) have been added, making fresh additions as fast as the precipitate of mercuric ferrocyanide disappears. Finally, the first flask is rinsed with water, and the washings transferred to the second flask, which should be a large one (1,000 c.c.). The operation takes about fifteen minutes. The cooled mixture is then titrated with permanganate after addition of 30 c.c. of Reinhardt's solution (manganese sulphate and phosphoric acid). The results are strictly concordant, and, on 2 grms. of pure ferrocyanide, are 0·1 per cent. higher than theory, which corresponds to a consumption of 0·05 c.c. more permanganate than is required by theory. G. C. J.

Electro Analysis. (*Report of the Committee British Association,* 1911.)—Attention has been directed during the past year particularly to the application of the electrometric method to the titration of weak acids in such liquids as tan liquors. It was found that the potentiometer-box and auxiliary electrode constructed for the separation of metals by graded potential may be conveniently employed for this purpose in conjunction with a form of hydrogen electrode specially designed to combine ease of manipulation and rapidity of saturation. The question regarding the "end-point" of the titration has been examined. It is known that if the object of the titration be to determine the number of equivalents of acid present, then not only the nature of the acid or acids must be considered, but also the concentration of the salts resulting from the titration. It has been pointed out, however, that in most practical cases it will be possible to fix end-points of special importance for the particular purpose in question. Frequently the liquid may be titrated until the hydrion-concentration of pure water is reached. This corresponds to a potential difference between the hydrogen-electrode and the normal calomel electrode recommended for these titrations of 0·69 volt (ANALYST, 1911, 121).

It has been found possible by Hildebrand and E. F. Smith and his co-workers (ANALYST, 1907, **32**, 268) to electrolyse the alkali metals with a mercury cathode and to analyse both the anion and cation. For this purpose a double cell is employed, the inner and outer portions being sealed by means of mercury. The alkali salt to be analysed, say potassium sulphate, is placed in solution in the central cell, where an anode of platinum gauze is rapidly rotated. The outer cell contains water, with a small quantity of sodium chloride solution to make it conductive. On electrolysing the SO_4 anions are discharged at the anode, and a solution of sulphuric acid obtained. The K cations are discharged on the mercury, which is made the cathode. Owing to the rotation of the anode, the amalgam, which is specifically lighter than the pure mercury, is swept into the outer compartment, where it is decomposed by means of an auxiliary nickel cathode placed above the mercury in the solution. When the electrolysis is complete, the SO_4 in the inner cell is titrated by means of standard alkali, and the K in the outer cell by means of standard acid.

There are disadvantages in the apparatus of Hildebrand, the outer cell of which is a glass crystallising basin, the inner consisting of a beaker with the bottom cut off. The inner cell is kept in a central position by having corks wedged at the sides. F. M. Perkin has now had a vessel made of fused quartz. The centre cell is kept concentric by having quartz rods fused to it and to the inside wall of the outer basin. Being of quartz, the vessel can, for cleaning purposes, be heated to redness, is absolutely unattacked by alkali, and there are no corks which, if they get accidentally splashed, absorb some of the alkali and vitiate the results.

Experiments on the analysis of the anions and cations are being carried out with this apparatus, and the results so far have been encouraging.

Estimation of Manganese as Oxide. P. N. Raikow and P. Tischkow. (*Chem. Zeit.*, 1911, **35**, 1013-1015.)—Having regard to the doubt which has been cast on methods which depend on the weighing of manganese as one of its oxides, a doubt which found its strongest expression in a paper by Gooch and Austin (*Zeitsch. anal. Chem.*, 1899, **38**, 690), the authors have made a study of the conditions which determine the conversion of one oxide into another. Mn_3O_4 or Mn_2O_3 can be reduced quantitatively to MnO by a few minutes' heating over a Teclu burner in a Rose crucible, through which a brisk current of hydrogen is passed. If the current of hydrogen is insufficient, the reduction may take an hour or more.

Mn_2O_3 is reduced quantitatively to Mn_3O_4 by five minutes' heating over the blowpipe flame in a Rose crucible, through which a current of carbon dioxide is passed. As the carbon dioxide takes no part in the reaction, but serves merely by reducing the partial pressure of the oxygen, the current need not be a brisk one, and should not be, for fear of mechanical loss. MnO can be oxidised to Mn_3O_4 by prolonged heating over the blowpipe flame in an uncovered crucible, but the most convenient means of converting MnO into Mn_3O_4 is to heat the former in an open crucible over a Teclu burner, and then to reduce the resulting mixture of Mn_2O_3 and Mn_3O_4 by five minutes' heating over the blowpipe flame in an atmosphere of carbon dioxide.

Lower oxides can be oxidised quantitatively to Mn_2O_3 by heating to a low red heat over an ordinary Bunsen burner in a Rose crucible through which a current of oxygen is passed.

If the manganese is obtained as carbonate, this can be oxidised to Mn_2O_3 in fifteen minutes in an atmosphere of oxygen, using at first the full heat of an ordinary Bunsen burner, and subsequently reducing the temperature to a low red heat. The Mn_2O_3 may then be reduced to MnO, and a check obtained on the first result.

If it be desired to convert manganese sulphate into an oxide for weighing, the most convenient method is to heat it several times alternately in an atmosphere of hydrogen and in an uncovered crucible. The sulphate is reduced by the hydrogen to sulphite and partially to sulphide, which, on heating in air, give rise to sulphur dioxide and oxides of manganese. When sulphur dioxide is no longer evolved, the mixed oxides are raised to a low red heat in a current of oxygen, and converted wholly into Mn_2O_3. In this way the sulphate may be converted into Mn_2O_3 in twenty minutes.

G. C. J.

Action of Salicylic Acid on Metallic Acids. J. H. Müller. (*J. Amer. Chem. Soc.*, 1911, **33**, 1506-1510.)—Titanium dioxide may be separated from the oxides of columbium, tantalum, zirconium, and thorium as follows: The mixed oxides (0·5 grm. or more) are fused with sodium carbonate, the melt is taken up in 350 to 400 c.c. water, salicylic acid (14 to 15 grms.) is added, and the solution kept at the boiling-point for three or four hours. The titanium remains in solution, the other metals are precipitated as salicylates, which are filtered rapidly, washed with hot water, ignited and weighed as oxides. The precipitate tends to be contaminated with alkali salicylate, and it is recommended that the ignited precipitate be fused with bisulphate, and then treated in the usual manner. Extreme error for columbium, ±0·5 mgrm. on 0·3 grm. taken; for tantalum, +0·8 mgrm. (never negative) on 0·5 grm.; for thorium, +0·5 grm. (never negative) on 1 grm.; and for zirconium, −0·5 mgrm. (never positive) on 0·5 grm. Titanium is precipitated in the concentrated filtrate by means of ammonium hydroxide. A bisulphate fusion is even more necessary in this case. Error for titanium, ±1·3 mgrm. Alkali fluorides prevent the precipitation of columbium and tantalum by salicylic acid.

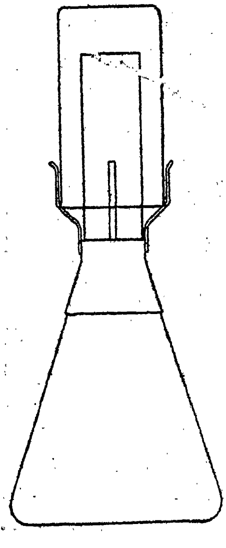
The intense colour produced by the addition of salicylic acid to alkaline titanates in absence of fluorides is recommended as the basis of a colorimetric method for the very accurate determination of very pure titanic oxide, and for the detection of this oxide in acid earths. The sensitiveness of the reaction is great, so little as 0·05 mgrm. in 100 c.c. showing a distinct yellow colour; but its applicability is strictly limited. Not only iron, but zirconium, columbium, and molybdenum, interfere with its quantitative application. As a qualitative test it is scarcely interfered with by zirconium and columbium, as the brown coloration yielded by these elements with salicylic acid is negligible, except when they are present in large quantity, and is distinguished from the yellow colour of titanium solutions by not being discharged by ammonia.
G. C. J.

Use of Sulphur Monochloride in the Determination and Analysis of Rare Earth Minerals. W. B. Hicks. (*J. Amer. Chem. Soc.*, 1911, **33**, 1492-1496.)—Columbium, tantalum, titanium, and tungsten may be readily and completely separated from the rare earth metals by subjecting the finely ground mineral, contained in a boat in a heated combustion-tube, to the vapours of sulphur monochloride. At the end of the operation dry hydrogen chloride is passed through the tube, and the volatile chlorides are finally driven out of this by the use of a Bunsen burner held in the hand. The acid earth metals and most of the iron are volatilised as chlorides, and, together with the excess of sulphur monochloride, pass into the receiver, which is charged with dilute nitric acid. The lumps of sulphur which separate in the receiver are broken up, and the sulphur is dissolved by addition of ammonia and ammonium sulphide. The solution which contains all the tungsten is filtered from the oxides of titanium, columbium, tantalum, and iron, and the tungsten sulphide in the filtrate is precipitated by addition of acid, is washed with water, alcohol, and carbon disulphide, oxidised by means of nitric acid, ignited, and weighed as WO_3. The mixture of acid earths with ferric hydroxide, as well as the non-volatile residue in the boat, are then further examined in any convenient manner.

The above method has been used in opening up large quantities (50-100 grms.) of rare earth minerals which were specially examined for the presence of scandium, which would remain with the non-volatile portion. Neither fergusonite, eschynite, euxenite, nor samarskite yielded even spectroscopic traces of scandium. On the other hand, it is shown that fergusonite may contain 2 or 3 per cent. of thorium, a metal not generally mentioned as a constituent of this mineral. G. C. J.

Rapid Qualitative Detection of Elements, the Sulphides of which are Precipitated by Hydrogen Sulphide in Acid Solution. E. Pozzi-Escot. (*Bull. Soc. Chim.*, 1911, [iv.], 9, 812-814.)—A rapid method for separating the sulphides of the metals of the hydrogen sulphide group, where a quantitative separation is not required, has been worked out by the author. The precipitated sulphides are treated with hydrochloric acid (1 : 4); the sulphides of lead, antimony, tin, cadmium and zinc go into solution, whilst the sulphides of copper, molybdenum, arsenic, bismuth, mercury, gold, and platinum remain insoluble. The solution of sulphides is treated with ammonia, which gives a precipitate with lead, antimony, and tin, whilst cadmium and zinc are not precipitated. The metals are then identified by known tests. The sulphides which resist treatment with hydrochloric acid are treated with nitric acid. Those of copper, molybdenum, arsenic, and bismuth go into solution, and the solution is employed for the identification tests. The sulphides unattacked by nitric acid are dissolved in aqua regia, and the nitric acid is expelled by treatment with hydrochloric acid; the solution is then tested for the presence of mercury, gold, and platinum. J. F. B.

APPARATUS, ETC.



Flask for Quantitative Fermentation Experiments. H. Franzen. (*Chem. Zeit.*, 1911, 35, 987.)—In quantitative fermentation experiments it is necessary, among other things, to provide for a uniform exchange of air. According to the supply of air to the culture, the conditions under which the bacteria develop are modified. In comparative experiments it is particularly necessary that the bacteria should always have the same available supplies of oxygen. The ordinary cotton-wool plugs in no way provide for this uniform circulation of air, but the flask illustrated here has been specially designed for this purpose. It consists of an Erlenmeyer flask with a long neck, the edges of which are not turned over in the usual way. The flask carries a metal collar with wire clips, on which an inverted glass cap is supported. Nutrient solutions kept in these flasks, protected from unnecessary draughts, may be relied on to remain free from germs for at least ten days; an infection by bacteria has not been observed in any case. J. F. B.

Apparatus for the Estimation of the Melting-Point of Fats. L. von Liebermann. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 294-295.)—A U-tube is partially filled with mercury, and into one of the limbs a quantity of the molten fat is poured so as to form a layer above the mercury. A thermometer and a platinum wire are fitted into the tube so that their ends are immersed in the layer of fat. When the latter has solidified, a quantity of mercury is poured on its surface, a second platinum wire is placed in the other limb of the U-tube, and the two wires are then connected with an electric bell and battery. The U-tube is now placed in a water-bath, and the temperature is raised gradually; when the fat begins to melt, the mercury above it passes downwards, making connection between the two platinum wires through the main volume of mercury, and the bell rings.

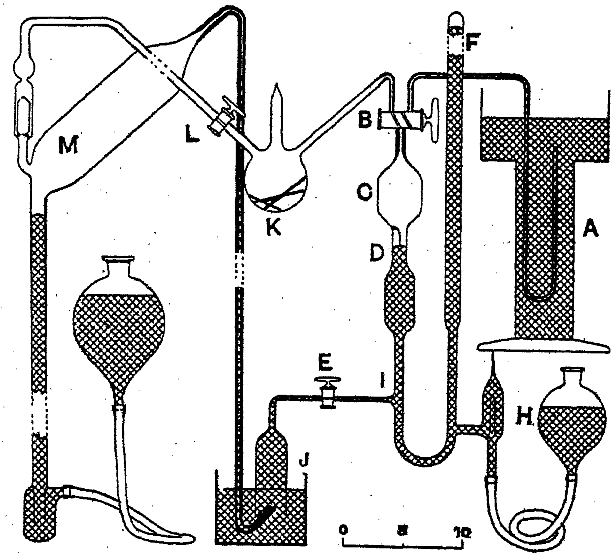
W. P. S.

Use of Indicators for determining Affinity Values. V. H. Veley. (*British Association*, 1911.)—A brief account was given of the use of indicators, especially methyl orange, for determining the affinity value of acids, as also of bases by the hydrolysis values of their hydrochlorides. The advantages, limitations, and defects of the method proposed were discussed in detail, and especial stress was laid upon the fact that the method, though simple in its execution, is not intended to supersede other methods of greater accuracy, available under like conditions. The data of the hydrolysis, and affinity values deduced therefrom, are independent of the more or less conflicting theories—namely, the ionic and chromophoric—of indicators. Exception was more particularly taken to any correction of the experimental results for the hydrogen ion concentration of the solutions, such correction being based upon theoretical speculations based upon the former theory, which has not met with universal acceptance.

Combined Fixing and Staining Processes for Microscopical Preparations. F. Strecker. (*Zeitsch. wiss. Mikroscop.*, 1911, **28**, 17-21; through *Chem. Zentralbl.*, 1911, II., 986-987.)—For fixing and staining sections of kidneys and other organs the author recommends a mixture of 10 or 20 per cent. formaldehyde solution with an equal volume of Ehrlich-Blondi's triacid reagent. A mixture consisting of 3 parts of toluidine blue dissolved in 100 parts of 10 per cent. formaldehyde solution may also be used, followed by treatment with ammonium molybdate.

W. P. S.

Volumetric Estimation of Oxygen in Air. H. E. Watson. (*J. Chem. Soc.*, 1911, **99**, 1460-1466.)—The apparatus used by the author is shown in the accompanying figure. The air to be tested is collected in test-tubes of just over 50 c.c. capacity, on the top of which some potassium hydroxide has previously been fused. The tubes are inverted over mercury, and the gas allowed to remain for two hours to remove carbon dioxide and water-vapour. The gas is admitted into the burette C through the inverted syphon A and the two-way tap B, but some small volume of gas is left in the syphon to avoid filling the tube between B and C with mercury. By means of the reservoir H the height of the mercury is adjusted so that it just reaches a point, D, which is set in the middle of a piece of tubing 1 cm. in diameter, and exactly similar to the manometer-tubing F. F may be either evacuated, boiled out, and sealed off, or preferably connected with a small pump maintaining a good vacuum. The difference in mercury level in F and at D is read off by cathetometer, and the meniscus heights noted. A water-jacket (not shown in figure) completely surrounds the burette and manometer-tube, the water being at room temperature, and kept uniform to $\frac{1}{50}$° C. previous to and during the measurements. The thin glass bulb K, of 60 c.c. capacity, contains 5 grms. of yellow phosphorus, introduced through the tube at the top of the bulb, this tube being afterwards sealed off, and K evacuated by means of the Antropoff pump M, with a delivery-tube of not more than 0·75 mm. diameter. The air passes into K after measurement (L being closed), the mercury in C being passed well beyond the tap B, which is then turned off. K is now heated with a smoky flame for about five minutes, during which time the oxygen is completely absorbed.



After twenty minutes' standing, when the vapours have settled, B is opened and H lowered till the mercury falls just below the connection I, and half the gas passes into the burette. B is closed, and the remaining gas pumped into J, which has a capacity of 20 c.c., and is completely filled. The delivery-tube of the pump must be tapped after the pumping in of the gas, to disengage the final bubble remaining on the end of the tube. E is opened, and the gas from J passes into the burette C. The pressure in C is sufficiently low to cause the mercury to rise in J and pass to I. The tube between these points is of 0·5 mm. bore, and carefully blown on at each end, so that no bubbles of air can be caught in it. The tap E should be turned completely round once or twice to insure that no bubble remains. H is raised carefully while the mercury is running from I, and if any air remains at I, it is displaced by again lowering H. The mercury is now raised to point D, the temperature and pressure measured after a short interval, and the gas expelled through A, the complete analysis being made in one and a half hours, allowing fifteen minutes between each pressure reading and for the complete evacuation with the pump. The phosphorus may be used many times over. It is essential before starting work for the first time that the dry nitrogen formed in the first combustion be circulated through all parts of the apparatus several times. If p be the pressure of the air, T its absolute temperature, and $p'T'$ the corresponding quantities of gases remaining after absorption, the percentage of these gases is given by $\frac{100\,p'T}{pT'}$. The total maximum error of the method does not exceed 6 parts in 15,000.

GOVERNMENT REPORTS.

Report of the Principal Chemist upon the Work of the Government Laboratory for the Year ending March 31, 1911, with Appendices. (*Issued as a Parliamentary Paper*, Pp. 1-27.)

Work in connection with the Board of Customs and Excise, Government Departments, the Food and Drugs Acts, and the Fertilisers and Feeding-Stuffs Acts, entailed the analysis and examination of 186,044 samples during the year, against 170,033 for the preceding year.

Five hundred and fifteen samples of beer, out of a total of 7,217 samples taken from retailers, were found to be adulterated with water, and small quantities of saccharin were detected in some cases. Of 638 samples of beer, wort, and materials used by brewers, 41 samples were found to contain arsenic in excess of the limits laid down by the Royal Commission on Arsenical Poisoning; 6 samples of malt, out of a total of 83, contained arsenic in quantities varying from $\frac{1}{90}$ to $\frac{1}{15}$ of a grain per pound. Of 171 samples of glucose, invert sugar, and caramel, none contained arsenic in excess of the limit. One hundred and seven samples of mineral acids, chemicals, drugs, vinegar, etc., were also examined as to the presence of arsenic.

Of 1,398 samples of imported butter examined in accordance with the provisions of the Sale of Food and Drugs Act, 1899, and the Butter and Margarine Act, 1907, 482 samples were found to contain boron preservative, 93 added colouring matter, and 4 an excess of water. One sample of milk-blended butter was imported in packages not marked as required by statute, and proceedings were taken against the importer. Four hundred and eighty-one samples of imported margarine were free from excess of butter-fat, but 7 of these samples contained water in excess of the legal limit. One sample of sweetened condensed milk, out of a total of 83 samples, was found to be prepared from milk which had been deprived of more than half its fat; all the samples of imported milk examined were free from preservatives and from added colouring matters. The amount of fat present in imported creams varied from 11·2 to 56·2 per cent.; 40 out of 58 samples of French cream contained boron preservatives, and calcium sucrate was present in 4 of the samples. Two hundred and thirteen samples of sheep-dips were submitted to the Board of Agriculture and Fisheries; 34 of these samples were deficient in active ingredients at the dilution recommended by the manufacturers, and in 92 other cases the formulæ required modification. The miscellaneous samples examined for this Board numbered 261, and comprised butter, milk, milk-powder, cheese, cider, rice, meals, seeds, feeding-stuffs, soils, fertilisers, poisoned fish, and river water.

The number of samples referred by magistrates under the provisions of the Food and Drugs Act was 83; one sample of milk was not examined on account of leakage from the bottle during transit. In the case of 9 of the samples, the reports of the public analysts could not be confirmed; two of these reports related to milk. Five samples of butter were reported by the public analyst to contain excess of water, 3 to contain foreign fat, and 1 to contain boric acid; the reports could not be confirmed in two cases of alleged excess of water and in two cases where foreign fat was stated to be present. One sample of lard was alleged to contain cocoanut oil, and another "animal membrane" foreign to lard, but these allegations could not be supported. Apple pulp was found to be present in a sample of black currant jam, as reported by the public analyst. The Government laboratory was unable to agree with the analyst in a case in which malt vinegar was alleged to contain artificial vinegar.

The number of samples examined under the Fertilisers and Feeding-Stuffs Act was 20. The samples comprised among fertilisers, superphosphates, dissolved bones, kainit, and various compound fertilisers; among feeding-stuffs, cotton and linseed cakes, sharps, fish-meal, and special feeding meals. The allegation made against the manures was that they were deficient in the guaranteed proportions of phosphate, nitrogen, or potash, and with regard to the feeding-stuffs that they were deficient in albuminoids, and that they contained some worthless or deleterious ingredient.

W. P. S.

Report to the Local Government Board on an Inquiry as to Condensed Milks; with Special Reference to their Use as Infants' Foods. [*Food Reports*, No. 15.] **F. J. H. Coutts.**—Emanating from the Medical Department of the Local Government Board, this report treats of condensed milk chiefly from the point of view of the medical officer, but contains a good deal of information that may prove useful to the analyst. Unfortunately, the chemical portions of the report are neither so full nor so up-to-date as would doubtless have been the case had the report been more, comprehensive; thus, quite a number of papers giving the composition of condensed milks published in the ANALYST have been overlooked, a considerable number of the analyses quoted are incomplete, and, of the detailed analyses, but few have been made within the last fifteen years. The composition of condensed milks is thus stated in terms more general than precise, and the author of the report has been led to overestimate the general degree of condensation, which, although he does not state it in very precise terms, he takes as one-third (pp. 17 and 40), while the analytical figures, as well as a general experience, show a proportion approximating more nearly to 1 to 2¾ in the case of full-cream sweetened milks, and rather less in the case of unsweetened milks.

A point, which may escape observation, though it is not ignored in the report, is the magnitude of the condensed milk industry in the United Kingdom; no analyses are given of British condensed milks, though in the case of three brands it is stated that their origin is Great Britain or a foreign country; the statistics given refer entirely to imports from abroad, and the wording of the paragraph devoted to the manufacture in the United Kingdom is so framed, doubtless unintentionally, as to give the impression that the industry is but a small one.

It is pointed out in the report that no samples of condensed milk examined are free from bacteria, though it appears to be proved that tubercle bacilli, and probably other pathogenic organisms do not survive the process of condensation; as to the origin of the bacteria present, the statements in the report are somewhat conflicting; while it is stated in the report that it is probable that the larger portion of the bacteria found in condensed milk have gained admission during the process of cooling and of filling the tins, in an Appendix, Drs. Gordon and Elmslie appear to come to an opposite conclusion in the case of sweetened milks. It is difficult, however, to agree with the conclusions of the authors of the Appendix, that, in the process of condensing unsweetened milk, sterility is secured, and that the organisms found in these milks are subsequently introduced from the air; as the process of preparing condensed unsweetened milks differs chiefly from that of condensing sweetened milks in that the tins of unsweetened milk are sterilised by heat after condensation and closure, it is not easy to see how the aerial contamination can occur, and this fact casts doubt upon the train of reasoning pursued.

The remarks on labelling will be of interest to Public Analysts, who are doubtless aware of the misleading character of many of the labels, which, though they comply with the regulations of the Sale of Food and Drugs Acts, do not disclose to the casual purchaser the nature of the contents; the unwisdom of coining, by Act of Parliament, a special name, which was previously unknown is brought out by the evidence adduced in the report that "Machine-Skimmed" is taken by many purchasers to indicate a specially high quality, instead of an extreme degree of impoverishment.

The conclusions of the Report are excellent, and, if carried into law, would doubtless tend to prevent many of the evils admittedly connected with the indiscriminate use of condensed milks for infant feeding; these are, briefly:

1. That condensed skim milk should be labelled in a prominent place, and entirely separate, "SKIMMED MILK—UNFIT FOR INFANTS."

2. That the use of any preservative, except sugar, should be prohibited in condensed milk.

3. That a control over false or misleading statements on labels and show-cards should be exercised.

4. That the minimum content of milk-fat, and the maximum of added sugar, should be stated on the label.

5. That the name of the responsible manufacturer or dealer should appear on the tin.

H. DROOP RICHMOND.

REVIEWS.

THE SOIL SOLUTION: THE NUTRIENT MEDIUM FOR PLANT-GROWTH. By FRANK K. CAMERON. *Bureau of Soils: U.S. Department of Agriculture.* The Chemical Publishing Co., Easton-Penna, 1911. Pp. 136. Price $1·25.

In this work are summarised the views held by Whitney and his colleague, the author, on the nutrition of plants through the medium of the soil. These are in direct contradiction to the views so long held in this country and elsewhere, as the outcome of field experiments such as those of Rothamsted and elsewhere, and which point to the importance of the mineral ingredients in soil and the influence of fertilisers containing them. The author criticises the present methods of soil analysis, and the importance to be attached to this, maintaining that neither the contents of a soil with respect to potash, phosphoric acid, and other mineral plant-food, nor the determination of "available" food by the use of different solvents bear any necessary relation to the crop-producing power of the soil. Ash analyses, he points out, have failed to act as a guide to the fertiliser requirements of a crop.

In place of attaching importance to the mineral constituents, Cameron puts forward two contentions: (1) That the soil problem is one of "dynamic" nature and depends upon the "soil solution," by which is meant the solution formed by the action of the soil-water on the soil particles themselves; (2) that "toxic" substances are formed in the soil as the result of crop-growing, and that the action of fertilisers is to destroy these toxic substances.

The solid components of the soil are always in motion, and it is the movement of the "film water" over the surface of the soil grains which requires to be studied in order to follow a rational practice of soil-control. The statement is made that practically every soil contains all the rock-forming minerals, and hence, but for certain disturbing factors, the concentration of the soil solution is practically the same in all cases, and does not need to be influenced by the presence of further mineral constituents in the soil or the additional supply of them in fertilisers. A description is given of the attempts made to extract the solution naturally existing in the soil and to analyse it. Small quantities were obtained by using powerful centrifuges on saturated soils, and the results seemed to indicate that the concentration of the soil solutions thus obtained differed little with soils of very different textures, and the variations could in no way be correlated with the respective crop-producing powers of the soils. A more ready, if less satisfactory, way of pursuing the inquiry, was found by making an aqueous extract of the soil and passing it through a Pasteur-Chamberland filter, subsequently using the solution in water-culture experiments. As the result, it is stated that there were no recognisable differences in the soluble mineral constituents of good and bad soils respectively, but that the processes going on in the soil tend to form and maintain a normal concentration of the mineral constituents in the soil solution. It is further pointed out that the rise of the capillary water is, in itself, capable of maintaining a sufficient supply of mineral nutrients for crop requirements.

Undoubtedly, it is the case that sufficient attention has not been given in the past to the movements that go on in the soil, and that there is much to learn in this respect, so that the author has done good service in drawing attention to the dynamical considerations that affect crop-growing. But, on the other hand, until some more satisfactory way of getting to know what the "soil solution" really is, one would hardly feel disposed to accept the author's conclusions unreservedly. Moreover, the experimental data on which the conclusions are based are very meagre, and the whole takes the form rather of statements than of proofs. Further, the fact that the conclusions have been based entirely on results obtained in water-culture must tell much against their ready acceptance, for it by no means follows that what takes place under conditions of water-culture would hold equally well in the case of a plant growing in a soil under natural conditions. In face of the long-continued field-work carried on at Rothamsted and elsewhere, as well as of practical experience of the influence of such mineral constitents as potash, phosphoric acid, lime, etc., one may well hesitate to accept, without further proof than can be obtained from soil extracts used in water-culture experiments, the conclusions arrived at as to the practical unimportance of the mineral ingredients in soils.

In the second part of the work the organic constituents of the soil-solution are dealt with, and, once again, soil-extracts have been used, and the results from water-culture have been relied on. Confined as these have been to periods varying from seven to at most thirteen days, the application to actual soil-cultivation conditions must remain very doubtful. The author, however, shows that the soil-solution contains "toxic" substances, several of which have been isolated, and that when a fertiliser has been found to benefit a particular crop growing in a soil, it has also been found to benefit the soil-extract, and to destroy the influence of a "toxic" substance which had proved inimical to a plant growing in water-culture. The differences between extracts from soils known as "good" and those classed as "bad," are stated to be due, not to any differences in their mineral constituents (for these were found to be practically identical) but to the presence of something "toxic" to plant growth. To this, and not to any lack of mineral ingredients, is, in the author's opinion, due the apparent lack of fertility of certain soils. In conclusion, the author comments on the enormous annual waste that has been going on in the misapplication of fertilisers, and urges that the practical problem for the future is, not the seeking of new fertilisers, but the rational use of those at hand. J. A. VOELCKER.

HUILES MINERALES (PÉTROLES, BENZOLS, BRAIS, PARAFFINES, VASELINES, OZOKÉRITE). BY HENRI DELEHAYE. Librarie Polytechnique Ch., Béranger, Paris, 15, Rue des Saintes Pères. 1911. Pp. 215. Price 4 francs.

This useful volume, which forms a part of the Collection des Manuels Pratiques D'Analyses Chimiques, published under the direction of Messrs. F. Bordas and Eugène Roux, may be particularly recommended to those who are interested in petroleum and its products, but are not fully conversant with commercial usage or with the general technical methods of testing. The work deals also, though somewhat more briefly, with the distillates from shale and lignite, in addition to the matters covered by its title. It contains excellent descriptions both of the physical and analytical methods commonly employed for commercial testing work, and includes definitions and technical descriptions of the principal original and finished products, together with tabulated information regarding the most typical, and their constants. A valuable feature is an appendix covering the laws and regulations relating to the petroleum industry in France. The work will be found extremely useful as an adjunct to the possibly more complete, but less technical, works which form the recognised authorities on this subject. Written by one who is especially interested in the practical application of the materials dealt with, the tests recommended for application prior to the distillation and other more elaborate analyses, and the sections dealing with the interpretation of results, and the possibility of determining the source of an oil, are of especial value and interest. Owing to the Customs duties prevailing in France, it is scarcely profitable to import other than the crude oil or partially refined products, and the author considers the subject largely from this point of view, and has thereby broken ground left almost untouched by many other works on petroleum. Unfortunately, although there is a well-arranged table of contents, no index has been supplied with the work.

G. T. Holloway.

Collective Index of the Journal of the Institute of Brewing, 1887-1910. Compiled by W. H. Bird. London: Harrison and Sons, 1911. Price 10s. 6d.

Since 1895 the *Journal of the Institute of Brewing* has formed a comprehensive record of scientific and practical work carried out in connection with brewing, malting, distilling, and the allied industries in all parts of the world. The Collective Index, which is an exhaustive book of reference to the *Journal*, and thus to the entire literature of the fermentation industries, covers 550 pages. Divided into four parts—(1) Authors, (2) Subjects, (3) General Matter, and (4) List of Journals from which Papers have been abstracted—it has been made, by this means and by a system of cross-indexing, almost impossible to miss any reference having a bearing upon the subject to be traced. Part (4) probably represents the most complete list of journals of interest to the fermentation industries extant. Not only will the Collective Index be welcomed by all who have the *Journal* of the Institute and are actually engaged in the industries with which it deals, but the publication itself will be found most useful by everyone who indirectly has an interest in the technology of those industries. Instead of the double columns adopted in many other indexes, the matter is printed exceptionally clearly across the page, and the whole arrangement both of matter and printing greatly facilitates the work of reference.

DECEMBER, 1911. Vol. XXXVI., No. 429.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

NOTE ON THE EXAMINATION OF FINNISH TURPENTINE.

By L. MYDDELTON NASH, F.I.C.

(Read at the Meeting, November 1, 1911.)

The examination of some Finnish turpentine, recently imported, showed that it was normal in all respects except that the close flash was 67° F. instead of from 90° to 100° F. Finnish turpentine gives the Conradsen reaction (a yellow colour on shaking with sulphurous acid, sometimes erroneously referred to as the Hertzfeld reaction), showing that it is distilled from the wood. It was at first thought that the low flash might be due to the presence of a small amount of acetone produced during the distillation of the wood, and, consequently, the three following methods of separation were carried out:

(1) Distillation, using a Young's disc and rod stillhead; (2) shaking out with a strong solution of sodium bisulphite, distilling the bisulphite with carbonate of soda solution, fractionating the distillate by further distillation, and dehydrating with calcium chloride; (3) shaking out with water, fractionating and dehydrating as in (2).

By all three methods a small quantity of "spirit" was obtained, which inflamed at ordinary temperature, and in each case it was found that the turpentine, after separation of the spirit, flashed between 90° and 100° F.

To ascertain whether such a small quantity as seemed to be present was capable of lowering the flash to so great an extent, a mixture of 1 part by volume of acetone and 99 parts by volume of turpentine was made. At 73° F. it flashed with explosive violence. One half per cent. of acetone in turpentine was then tried, and the flash-point found to be 71° F.

A large quantity of the turpentine was then shaken out in successive portions with 100 c.c. of water, the aqueous extract distilled, and the first 25 c.c. collected. This was dehydrated, first with calcium chloride, and then with anhydrous copper sulphate, until, finally, about 2 c.c. of spirit was obtained, which inflamed at the ordinary temperature, burning with a non-luminous flame. On oxidation with bichromate of potassium and sulphuric acid, the pungent odour of formic acid was noticed, and the distillate reduced ammoniacal silver nitrate. The presence of methyl alcohol was thus suspected.

A larger quantity of the turpentine was then shaken out with water which was afterwards fractionally distilled. The distillate was distilled three times over quicklime, and four times over anhydrous copper sulphate, when the sp. gr. at 15·5° C. of the resulting spirit was found to be 0·810. It may be mentioned here that the spirit dissolved some of the copper sulphate, giving a blue solution; methyl alcohol behaves similarly. The spirit obtained was then fractionated in a Wurtz flask and collected in three portions—viz., from 65° to 70° C., from 70° to 75° C., and from 75° to 80° C. Some commercial methyl alcohol of sp. gr. 0·821 was also fractionated, the range of temperature being the same as that of the spirit under examination.

The refractive indices of the two lighter fractions of the spirit were found to be almost identical with those of the two lighter fractions of the commercial methyl alcohol. The portion boiling between 65° and 75° C was further fractionated, using a Young's disc and rod stillhead, and the fraction distilling between 65° and 67° C. was separated for the determination of its vapour density. The molecular weight was thus found to be 31, methyl alcohol being 32. The crystalline oxalate was prepared, and found to have the same appearance and melting-point as that prepared from methyl alcohol. The behaviour of the spirit with barium oxide and with calcium chloride was also characteristic of methyl alcohol. It was therefore evident that the spirit washed out of the turpentine was crude wood alcohol, the methyl alcohol itself being identified.

It may be objected that methyl alcohol is insoluble in turpentine, but, curiously enough, thes pirit obtained was also found to be insoluble in turpentine, consequently, it was impossible to determine the flash-point of a mixture of the two.

In all probability several other substances are present in minute quantities which hold the methyl alcohol in solution in the turpentine.

This note is recorded chiefly to warn those inexperienced in the examination of turpentine against the danger of reporting as necessarily adulterated with light petroleum spirit or benzene, turpentine flashing at ordinary temperature, and yielding by Armstrong's process about 10 per cent. of unpolymerisable residue. This quantity seems to be normal for Finnish turpentine, and is chiefly cymene, as might be expected from the method of preparation.

My thanks are due to Mr. J. H. Coste for confirming the identification of methyl alcohol.

DISCUSSION.

Mr. F. W. RICHARDSON said he was not sure whether the lowering of the flash-point was entirely due to the methyl alcohol. It seemed remarkable that as little as 0·5 per cent. of such a substance should have the effect of lowering the flash-point to the extent of over 20°, and he should be inclined to think that there must have been some other impurity as well. Personally, however, he did not often determine the flash-point in the case of turpentine.

Mr. A. CHASTON CHAPMAN stated that in his opinion the determination of the flash-point was a very important item in the analytical examination of turpentine.
